YDB Quick Start

In this guide, you will install a single-node local YDB cluster and execute simple queries against your database.

Normally, YDB stores data on multiple SSD/NVMe or HDD raw disk devices without any filesystem. However, for simplicity, this guide emulates disks in RAM or using a file in a regular filesystem. Thus, this setup is unsuitable for any production usage or even benchmarks. See the documentation for DevOps Engineers to learn how to run YDB in a production environment.

Install and start YDB

Linux x86_64

> **Note**
>
> The recommended environment to run YDB is x86_64 Linux. If you don't have access to one, feel free to switch to the instructions on the "Docker" tab.

1. Create a directory for YDB and use it as the current working directory:

   ```
   mkdir ~/ydbd && cd ~/ydbd
   ```

2. Download and run the installation script:

   ```
   curl https://install.ydb.tech | bash
   ```

   This will download and unpack the archive containing the `ydbd` executable, libraries, configuration files, and scripts needed to start and stop the local cluster.

   The script is executed entirely with the current user privileges (notice the lack of `sudo`). Therefore, it can't do much on the system. You can check which exactly commands it runs by opening the same URL in your browser.

3. Start the cluster in one of the following storage modes:
   - In-memory data:

     ```
     ./start.sh ram
     ```

     In this case, all data is stored only in RAM, it will be lost when the cluster is stopped.
   - Data on disk:

     ```
     ./start.sh disk
     ```

     When you run this command an 80GB `ydb.data` file will be created in the working directory if it weren't there before. Make sure there's enough disk space available to create it. This file will be used to emulate a raw disk device, which would have been used in production environments.
   - Data on a real disk drive:

     ```
     ./start.sh drive "/dev/$DRIVE_NAME"
     ```

     Replace `/dev/$DRIVE_NAME` with an actual device name that is not used for anything else, for example `/dev/sdb`. The first time you run this command, the specified disk drive will be fully wiped and then used for YDB data storage. It is recommended to use a NVMe or SSD drive with at least 800Gb data volume. Such setup can be used for single-node performance testing or other environments that do not have any fault-tolerance requirements.

   Result:

   ```
   Starting storage process...
   Initializing storage ...
   Registering database ...
   Starting database process...

   Database started. Connection options for YDB CLI:

   -e grpc://localhost:2136 -d /Root/test
   ```

Docker x86_64

> **Note**
>
> If you are using a Mac with an Apple Silicon processor, emulate the x86_64 CPU instruction set with Rosetta:
>
> - colima with the `colima start --arch aarch64 --vm-type=vz --vz-rosetta` options.
> - Docker Desktop with installed and enabled Rosetta 2.
>
> If Rosetta 2 is not enabled, add the `-e YDB_USE_IN_MEMORY_PDISKS=true` parameter to the command for running the Docker container. For more information, see Configuring the YDB Docker container.

1. Create a directory for YDB and use it as the current working directory:

```
mkdir ~/ydbd && cd ~/ydbd
mkdir ydb_data
mkdir ydb_certs
```

2. Run the Docker container:

```
docker run -d --rm --name ydb-local -h localhost \
  --platform linux/amd64 \
  -p 2135:2135 -p 2136:2136 -p 8765:8765 -p 9092:9092 \
  -v $(pwd)/ydb_certs:/ydb_certs -v $(pwd)/ydb_data:/ydb_data \
  -e GRPC_TLS_PORT=2135 -e GRPC_PORT=2136 -e MON_PORT=8765 \
  -e YDB_KAFKA_PROXY_PORT=9092 \
  ydbplatform/local-ydb:latest
```

If the container starts successfully, you'll see the container ID. The container might take a few seconds to initialize. The database will not be available until container initialization is complete.

Minikube

1. Install the Kubernetes CLI kubectl and Helm 3 package manager.
2. Install and run Minikube.
3. Clone the repository with YDB Kubernetes Operator:

```
git clone https://github.com/ydb-platform/ydb-kubernetes-operator && cd ydb-kubernetes-operator
```

4. Install the YDB controller in the cluster:

```
helm upgrade --install ydb-operator deploy/ydb-operator --set metrics.enabled=false
kubectl rollout status deployment/ydb-operator --timeout=5m
```

5. Apply the manifest for creating a YDB cluster:

   First, check that the API server can call the controller's admission webhook and accept the manifest without creating the resource:

```
kubectl apply --dry-run=server -f samples/minikube/storage.yaml
```

   The webhook may still be unavailable after `rollout status` completes. If the check reports `connection refused` or `no endpoints available` when calling the webhook, wait a few seconds and retry the check. Resolve the cause of any other errors before proceeding. Apply the manifest only after the check succeeds:

```
kubectl apply -f samples/minikube/storage.yaml
```

6. Wait for `kubectl get storages.ydb.tech` to become `Ready`.
7. Apply the manifest for creating a database:

```
kubectl apply -f samples/minikube/database.yaml
```

8. Wait for `kubectl get databases.ydb.tech` to become `Ready`.
9. After processing the manifest, a StatefulSet object that describes a set of dynamic nodes is created. Use the following separate services to connect from the same Kubernetes namespace:
   - `database-minikube-sample-grpc:2135` (gRPC);
   - `database-minikube-sample-status:8765` (YDB UI).

   Database path: `/Root/database-minikube-sample`.
10. To continue, get access to port 8765 from outside Kubernetes using `kubectl port-forward database-minikube-sample-0 8765`.

Kind

1. Install the Kubernetes CLI kubectl and Helm 3 package manager.
2. Install Kind.
3. Clone the repository with YDB Kubernetes Operator:

```
git clone https://github.com/ydb-platform/ydb-kubernetes-operator && cd ydb-kubernetes-operator
```

4. Create a Kind cluster and wait until it is ready:

```
kind create cluster --config=samples/kind/kind-config.yaml  --wait 5m
```

5. Install the YDB controller in the cluster:

```
helm upgrade --install ydb-operator deploy/ydb-operator --set metrics.enabled=false
kubectl rollout status deployment/ydb-operator --timeout=5m
```

6. Apply the manifest for creating a storage:

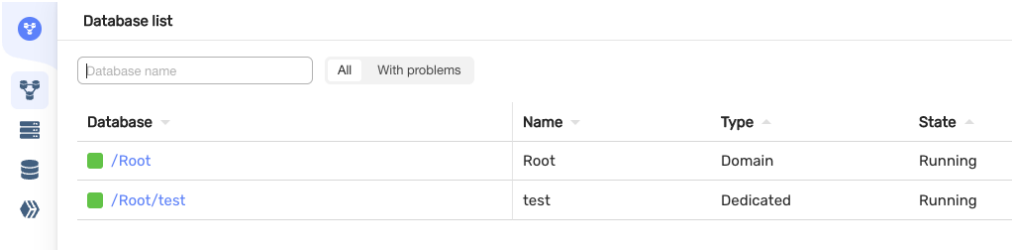
   First, check that the API server can call the controller's admission webhook and accept the manifest without creating the resource:

```
kubectl apply --dry-run=server -f samples/kind/storage.yaml
```

The webhook may still be unavailable after `rollout status` completes. If the check reports `connection refused` or `no endpoints available` when calling the webhook, wait a few seconds and retry the check. Resolve the cause of any other errors before proceeding. Apply the manifest only after the check succeeds:

```
kubectl apply -f samples/kind/storage.yaml
```

7. Wait for `kubectl get storages.ydb.tech` to become `Ready`.
8. Apply the manifest for creating a database:



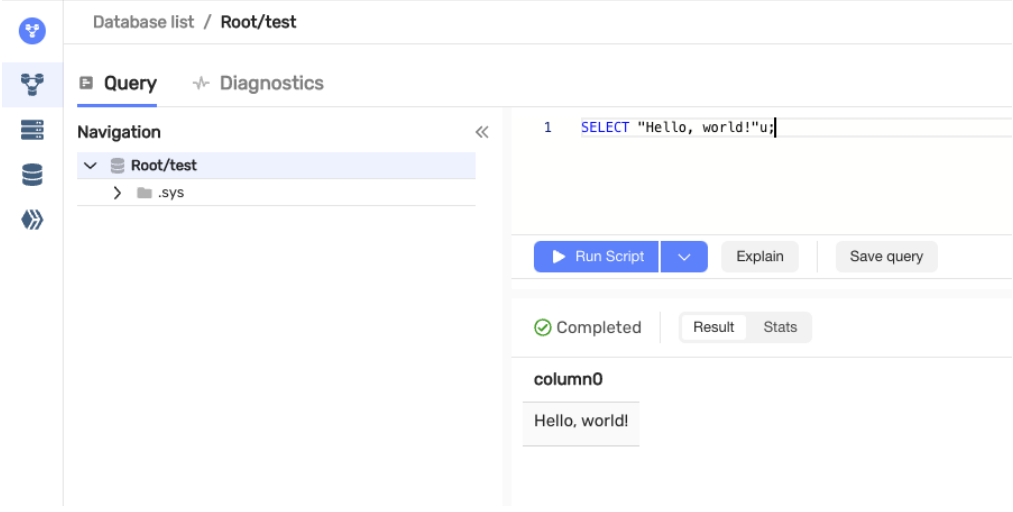
```
kubectl apply -f samples/kind/database.yaml
```

9. Wait for `kubectl get databases.ydb.tech` to become `Ready`.
10. After processing the manifest, a StatefulSet object that describes a set of dynamic nodes is created. Use the following separate services to connect from the same Kubernetes namespace:
    - `database-kind-sample-grpc:2135` (gRPC);
    - `database-kind-sample-status:8765` (YDB UI).

    Database path: `/Root/database-kind-sample`.
11. To continue, get access to port 8765 from outside Kubernetes using `kubectl port-forward database-kind-sample-0 8765`.

Run your first "Hello, world!" query

The simplest way to launch your first YDB query is via YDB UI. It is launched by default on port 8765 of the YDB server. If you have launched it locally, open localhost:8765 in your web browser. If not, replace `localhost` with your server's hostname in this URL or use `ssh -L 8765:localhost:8765 my-server-hostname-or-ip.example.com` to set up port forwarding and still open localhost:8765. You'll see a page like this:



YDB is designed to be a multi-tenant system, with potentially thousands of users working with the same cluster simultaneously. Hence, most logical entities inside a YDB cluster reside in a flexible hierarchical structure more akin to Unix's virtual filesystem rather than a fixed-depth schema you might be familiar with from other database management systems. As you can see, the first level of hierarchy consists of databases running inside a single YDB process that might belong to different tenants. `/Root` is for system purposes. To run queries, select the database created in the previous step:

Installation method	Database
Linux x86_64	`/Root/test`
Docker x86_64	`/local`
Minikube	`/Root/database-minikube-sample`
Kind	`/Root/database-kind-sample`

Click on the corresponding database, enter your first query, and hit the "Run" button:

```
SELECT "Hello, world!"u;
```

The query returns the greeting, as it is supposed to:

Note

Did you notice the odd `u` suffix? YDB and its query language, YQL, are strongly typed. Regular strings in YDB can contain any binary data, while this suffix indicates that this string literal is of the `Utf8` data type, which can only contain valid UTF-8 sequences. Learn more about YDB's type system.

The second simplest way to run a SQL query with YDB is the command line interface (CLI), while most real-world applications will likely communicate with YDB via one of the available software development kits (SDK). Feel free to follow the rest of the guide using either the CLI or one of the SDKs instead of the web UI if you feel comfortable doing so.

Create your first table

The main purpose of database management systems is to store data for later retrieval. As an SQL-based system, YDB's primary abstraction for data storage is a table. To create our first one, run the following query:

```
CREATE TABLE example
(
    key UInt64,
    value String,
    PRIMARY KEY (key)
);
```

As you can see, it is a simple key-value table. Let's walk through the query step-by-step:

- Each SQL statement kind like `CREATE TABLE` has more detailed explanation in YQL reference.
- `example` is the table name identifier, while `key` and `value` are column name identifiers. It is recommended to use simple names for identifiers like these, but if you need one that contains non-trivial symbols, wrap the name in backticks.
- `UInt64` and `String` are data type names. `String` represents a binary string, and `UInt64` is a 64-bit unsigned integer. Thus, our example table stores string values identified by unsigned integer keys. More details about data types.
- `PRIMARY KEY` is one of the fundamental concepts of SQL that has a significant impact on both application logic and performance. Following the SQL standard, the primary key also implies an unique constraint, meaning the table cannot have multiple rows with equal primary keys. In this example table, it's quite straightforward which column should be chosen as the primary key, which we specify as `(key)` in round brackets after the respective keyword. In real-world scenarios, tables often have dozens of columns, and primary keys can be compound (consisting of multiple columns in a specified order), making choosing the right primary key more of an art. If you are interested in this topic, there's a guide on choosing the primary key for maximizing performance. YDB tables are required to have a primary key.

Add sample data

Now let's fill our table with some data. The simplest way is to just use literals:

```
INSERT INTO example (key, value)
VALUES (123, "hello"),
       (321, "world");
```

Step-by-step walkthrough:

- `INSERT INTO` is the classic SQL statement for adding new rows to a table. However, it is not the most performant, as according to the SQL standard, it has to check whether the table already has rows with the given primary key values, and raise an error if they exist. Thus, if you run this query multiple times, all attempts except the first will return an error. If your application logic doesn't require this behavior, it is better to use `UPSERT INTO` instead of `INSERT INTO`. Upsert (which stands for "update or insert") will blindly write the provided values, overwriting existing rows if there were any. The rest of the syntax will be the same.
- `(key, value)` specifies the names of the columns we're inserting and their order. The values provided next need to match this specification, both in the number of columns and their data types.
- After the `VALUES` keyword, there's a list of tuples, each representing a table row. In this example, we have two rows identified by 123 and 321 in the `key` column, and "hello" and "world" values in the `value` column, respectively.

To double-check that the rows were indeed added to the table, there's a common query that should return `2` in this case:

```
SELECT COUNT(*) FROM example;
```

A few notable details in this one:

- The `FROM` clause specifies a table to retrieve data from.
- `COUNT` is an aggregate function that counts the number of values. By default, when there are no other special clauses around, the presence of any aggregate function collapses the result to one row containing aggregates over the whole input data (the `example` table in this case).
- Asterisk `*` is a placeholder that normally means "all columns"; thus, `COUNT` will return the overall row count.

Another common way to fill a table with data is by combining `INSERT INTO` (or `UPSERT INTO`) and `SELECT`. In this case, values to be stored are calculated inside the database instead of being provided by the client as literals. We'll use a slightly more realistic query to demonstrate this:

```
$subquery = SELECT ListFromRange(1000, 10000) AS keys;

UPSERT INTO example
SELECT
    key,
    CAST(RandomUuid(key) AS String) AS value
FROM $subquery
FLATTEN LIST BY keys AS key
```

There's quite a lot going on in this query; let's dig into it:

- `$subquery` is a named expression. This syntax is YQL's extension to the SQL standard that allows making complex queries more readable. It behaves the same as if you wrote that first `SELECT` inline where `$subquery` is later used on the last row, but it allows comprehending what's going on piece by piece, like variables in regular programming languages.
- `ListFromRange` is a function that produces a list of consecutive integers, starting from the value provided in the first argument and ending with the value provided in the second argument. There's also a third optional argument that can allow skipping integers with a specified step, but we omit it in our example, which defaults to returning all integers in the given range. `List` is one of the most common container data types.
- `AS` is a keyword used to give a name to the value we're returning from `SELECT`; in this example, `keys`.
- `FROM ... FLATTEN LIST BY ... AS ...` has a few notable things happening:
  - Another `SELECT` used in the `FROM` clause is called a subquery. That's why we chose this name for our `$subquery` named expression, but we could have chosen something more meaningful to explain what it is. Subqueries normally aren't materialized; they just pass the output of one `SELECT` to the input of another on the fly. They can be used as a means to produce arbitrarily complex execution graphs, especially if used in conjunction with other YQL features.
  - `FLATTEN LIST BY` clause modifies input passed via `FROM` in the following way: for each row in the input data, it takes a column of list data type and produces multiple rows according to the number of elements in that list. Normally, that list column is replaced by the column with the current single element, but the `AS` keyword in this context allows access to both the whole list (under the original name) and the current element (under the name specified after `AS`), or just to make it more clear what is what, like in this example.
- `RandomUuid` is a function that returns a pseudorandom UUID version 4. Unlike most other functions, it doesn't actually use what is passed as an argument (the `key` column); instead, it indicates that we need to call the function on each row. See the reference for more examples of how this works.
- `CAST(... AS ...)` is a common function for converting values to a specified data type. In this context, the type specification is expected after `AS` (in this case, `String`), not an arbitrary name.
- `UPSERT INTO` will blindly write the values to the specified tables, as we discussed previously. Note that it didn't require `(key, value)` column names specification when used in conjunction with `SELECT`, as now columns can just be matched by names returned from `SELECT`.

Quick question!

What will the `SELECT COUNT(*) FROM example;` query return now?

Stop the cluster

Stop the local YDB cluster after you have finished experimenting:

Linux x86_64

To stop the local cluster, run the following command:

```
~/ydbd/stop.sh
```

Optionally, you can then clean up your filesystem by removing your working directory with the `rm -rf ~/ydbd` command. All data inside the local YDB cluster will be lost.

Docker

To stop the Docker container with the local cluster, run the following command:

```
docker kill ydb-local
```

Optionally, you can then clean up your filesystem by removing your working directory with the `rm -rf ~/ydbd` command. All data inside the local YDB cluster will be lost.

Minikube

To delete the YDB database, it is enough to delete the Database resource associated with it:

```
kubectl delete database.ydb.tech database-minikube-sample
```

To delete the YDB cluster, execute the following commands (all data will be lost):

```
kubectl delete storage.ydb.tech storage-minikube-sample
```

To remove the YDB controller from the Kubernetes cluster, delete the release created by Helm:

```
helm delete ydb-operator
```

Kind

To delete the YDB database, it is enough to delete the Database resource associated with it:

```
kubectl delete database.ydb.tech database-kind-sample
```

To delete the YDB cluster, execute the following commands (all data will be lost):

```
kubectl delete storage.ydb.tech storage-kind-sample
```

To remove the YDB controller from the Kubernetes cluster, delete the release created by Helm:

```
helm delete ydb-operator
```

To delete `kind` cluster, run the following command:

```
kind delete cluster
```

Done! What's next?

After getting a hold of some basics demonstrated in this guide, you should be ready to jump into more advanced topics. Choose what looks the most relevant depending on your use case and role:

- Walk through a more detailed YQL tutorial that focuses on writing queries.
- Try to build your first app storing data in YDB using one of the SDKs.
- Learn how to set up a production-ready deployment of YDB.
- Read about YDB concepts.

Concepts YDB

This documentation section covers the fundamental concepts and architectural principles of YDB. This information will help you better understand what happens when you study more practical content that can be found in other sections designed for specific roles.

The following topics provide comprehensive coverage of the core functionality of YDB, from high-level architecture and data model to advanced capabilities such as transactions, indexing, and federated queries.

- Glossary
- Analytical capabilities
- Stream processing
- Architecture
- Database connection
- Schema objects
- Cluster topology
- Query execution
- Transactions
- Change Data Capture (CDC)
- Time to Live (TTL) and data eviction to external storage
- Database limitations
- Asynchronous replication
- Bridge mode
- Data transfer

YDB glossary

This article is an overview of terms and definitions used in YDB and its documentation. It starts with key terms that will be useful to get acquainted with early when you start working with YDB, while the rest of it is more advanced and might be helpful later on.

Key terminology

This section describes terms that are useful to anyone working with YDB, regardless of their role or use case.

Cluster

A **cluster** YDB is a set of interconnected nodes YDB that exchange data to execute user queries and ensure reliable data storage. These nodes form one of the supported cluster topologies, which directly affects its reliability and performance characteristics.

Clusters YDB are multi-tenant and can contain several isolated databases.

Database

Like in most database management systems, a **database** in YDB is a logical container for other entities like tables. However, in YDB, the namespace inside databases is hierarchical like in virtual file systems, and thus folders allow for further organization of entities.

Another essential characteristic of YDB databases is that they typically have dedicated compute resources allocated to them. Hence, creating a database requires additional operations from DevOps engineers.

Node

YDB A **node** is a server process that runs an executable called `ydbd`. Multiple nodes YDB can run on a single physical server or virtual machine, which is common practice. Thus, in the context of YDB, nodes are **not** synonymous with hosts.

Since YDB uses an approach with separate storage and compute layers (storage and compute separation), `ydbd` has several operation modes that define the node type. The available node types are described below.

Database node

Database nodes (also known as **tenant nodes** or **compute nodes**) process user queries addressed to a specific logical database. Their state is stored only in RAM and can be restored from distributed storage. The set of database nodes of a given cluster YDB can be considered the compute layer of that cluster. Thus, adding database nodes and allocating additional resources (CPU and RAM) to them are the main ways to increase the compute resources of a database.

The main role of database nodes is to run various tablets and actors, as well as accept incoming requests via various endpoints.

Storage node

Storage nodes are stateful nodes responsible for long-term storage of data fragments. The set of storage nodes in a given cluster YDB is called distributed storage and can be considered as the storage layer of that cluster. Thus, adding additional storage nodes and their disks is the primary way to increase the storage capacity and I/O throughput of the cluster.

Hybrid node

A **Hybrid node** is a process that simultaneously performs both the roles of a database node and a storage node. Hybrid nodes are often used for development purposes. For example, you can run a container with a full-featured YDB containing only one `ydbd` process in hybrid mode. They are rarely used in production environments.

Static node

Static nodes are configured manually during initial cluster initialization or reconfiguration. Typically, they serve as storage nodes, but they can technically be configured as database nodes.

Dynamic node

Dynamic nodes are added and removed from the cluster on the fly. They can only act as database nodes.

Distributed storage

Distributed storage, **Blob storage**, or **BlobStorage** is a distributed fault-tolerant data persistence layer of YDB. It has a specialized API designed for storing immutable pieces of tablet's data.

Multiple terms related to the distributed storage implementation are covered below.

Storage group

Storage group, **distributed storage group**, or **Blob storage group** is a place for reliable data storage, similar to RAID, but using disks from multiple servers. Depending on the selected cluster topology, storage groups use different algorithms to ensure high availability, similar to standard RAID levels.

Distributed storage typically manages a large number of relatively small storage groups. Each group can be assigned to a specific database to increase disk capacity and input/output throughput available to this database.

Static and dynamic storage groups are physical, meaning their data is placed directly on VDisks.

Static group

A **static group** is a special storage group created during the initial deployment of the cluster. Its main role is to store data of system tablets, which can be considered as cluster-level metadata.

A static group might require special attention during major maintenance, such as decommissioning an availability zone.

Dynamic group

Ordinary storage groups that are not static are called **dynamic groups**. They are called dynamic because they can be created and removed on the fly while the cluster is running.

Virtual storage group

A **virtual storage group** is an entity that is not actually a storage group but appears as one from the outside (provides a similar external interface). It can store its data in other storage groups or in S3.

Storage pool

A **storage pool** is a set of data storage devices with similar characteristics. Each storage pool is assigned a unique name within the YDB cluster. Technically, each storage pool consists of multiple physical disks (PDisk). Each storage group is created in a specific storage pool, which determines the performance characteristics of the storage group through the selection of appropriate storage devices. Typically, separate storage pools are created for devices of different types (e.g., NVMe, SSD, and HDD) or for specific models of these devices with different capacity and access speed.

Actor

The Actor model is one of the main approaches to execution parallelism used in YDB. In this model, **actors** are lightweight user-space processes that can have and modify their private state, but can only influence each other indirectly through message passing. YDB has its own implementation of this model, which is described below.

In YDB, actors with the reliably persisted state are called tablets.

Tablet

A **tablet** is one of the main building blocks and abstractions of YDB. It represents an entity responsible for a relatively small segment of user or system data. Typically, a tablet manages up to several gigabytes of data, although some types of tablets can handle larger volumes.

For example, a row-oriented user table is managed by one or more DataShard tablets, with each tablet responsible for a continuous range of primary keys and the corresponding data.

End users sending queries to a YDB cluster aren't expected to know much about tablets, their kinds, or how they work, but it might still be helpful, for example, for performance optimizations.

Technically, tablets are actors with state reliably stored in distributed storage. This state allows a tablet to continue operating on a different database node if the previous one fails or becomes overloaded.

Tablet implementation details and related terms, as well as main tablet types, are covered below in the advanced section.

Transactions

YDB implements **transactions** on two main levels:

- Local database and the rest of the tablet infrastructure allow tablets to manipulate their state using **local transactions** with serializable isolation level. Technically, they are not local to a single node, since this state is stored remotely in distributed storage.
- In the context of YDB, the term **distributed transactions** usually refers to transactions that span multiple tablets. For example, transactions between tables or even rows of the same table are often distributed.
- **Single-shard** transactions cover one tablet and execute faster. For example, transactions between rows of the same table partition are often single-shard.

Together, these mechanisms allow YDB to provide strict consistency.

The implementation of distributed transactions is covered in a separate article DataShard: distributed transactions, while below there's a list of several related terms.

Sessions

Logical connections to the database that store the context needed for executing queries and managing transactions. Sessions are described in more detail in the section Sessions.

Client-side timeout

Client-side timeout — a time limit that an application or YDB SDK waits for a database operation to complete (for example, executing a query or receiving a response via a gRPC call). After this time expires, the client usually aborts the wait: closes the connection or data stream, receives a transport or SDK error — even before the server has returned an explicit response (see YDB server response codes).

If the client-side timeout is shorter than the query execution time on the YDB side, then due to the specifics of query processing in the cluster, a query interrupted on the client side may continue to execute on the server for some time. If this situation occurs on a large scale, the server becomes overloaded with queries for which the client is not waiting for a response. Therefore, frequent retries of the same query immediately after a timeout can exacerbate the overload. For more details, see the articles Retry cascade effect and Overloaded errors; retry policies in the SDK are described in the section Handling errors.

Implicit transactions

Implicit transaction is a query execution mode in which the transaction mode is not specified. In this case, YDB independently determines whether to wrap them in a transaction. This mode is described in more detail in Implicit transactions.

Interactive transactions

An **interactive transaction** is a transaction in which multiple queries are executed, with application logic potentially running between them. It allows the program to send multiple queries and make decisions about the further course of the transaction based on the data received. Such a transaction can explicitly begin with a separate step (or open together with the first query) and complete separately. Unlike a single query that is executed and committed atomically, an interactive transaction enables building complex workflows in which multiple related operations are treated as a single atomic unit. At the same time, it incurs overhead on the system, as it requires holding optimistic locks and uncommitted changes for longer, and also increases the complexity of the application-side code.

Multi-version concurrency control

Multi-version concurrency control, **multi-version concurrency control** or **MVCC** is a method used by YDB for concurrent access of multiple parallel transactions to the database without interfering with each other. It is described in more detail in a separate article Multi-Version Concurrency Control (MVCC).

Streaming queries

A type of query designed for stream processing of an unbounded data stream. Unlike regular queries, streaming queries have no restrictions on execution duration, automatically restart on errors, and periodically save their state as checkpoints to ensure fault tolerance.

Streaming queries are described in more detail in Streaming queries.

Streaming query checkpoints

A periodically saved state of a streaming query, necessary for automatically restoring its operation after failures in a distributed system. For more details about checkpoints, see the article Checkpoints.

Topology

YDB supports several **topologies** of a cluster (or **topology**), described in more detail in a separate article YDB Cluster Topology. Below, several related terms are explained.

Availability zones and regions

An **availability zone** is a data center or an isolated segment thereof with minimal physical distance between nodes and minimal risk of failure at the same time as other availability zones. Thus, availability zones are expected not to share any infrastructure like power, cooling, or external network connections.

A **region** is a large geographic area containing several availability zones. The distance between availability zones in one region should be about 500 km or less. YDB performs data writes to each availability zone in the region synchronously, ensuring reasonable latency and uninterrupted operation in case of failure of one of the availability zones.

Rack

A **rack** or **server rack** is equipment used to organize the placement of multiple servers. Servers in the same rack are more likely to become unavailable simultaneously due to rack-level issues related to power supply, cooling, etc. YDB can take into account information about which server is in which rack when placing each data fragment in environments based on physical servers.

Pile

A **Pile** is a set of nodes that can fail or be shut down simultaneously while maintaining the operability of other parts of the cluster (pile). A Pile can remain operational when other cluster nodes are shut down. Piles are used in bridge mode to split the cluster into several parts between which synchronous replication is performed. A Pile can consist of nodes from one or more regions.

Bridge mode

Bridge mode is a special cluster topology in which data is stored with synchronous replication between several piles. The features of this mode are described in Bridge mode and also in Bridge cluster operation mode.

Table

A **table** is a structured piece of information arranged in rows and columns. Each row represents a single record or entry, while each column represents a specific attribute or field with a particular data type.

There are two main approaches to representing tabular data in memory or on disks: row-based (row by row) and column-based (column by column). The chosen approach greatly affects the performance characteristics of operations on this data: the former is more suitable for transactional workloads (OLTP), and the latter for analytical workloads (OLAP). YDB supports both approaches.

Row-oriented table

Row-oriented tables store data for all or most columns of a given row physically close to each other. They are explained in more detail in Row-Oriented Tables.

Column-oriented table

Column-oriented tables or **columnar tables** store data for each column separately. They are optimized for building aggregates over a small number of columns, but are less suitable for accessing specific rows, as rows need to be reconstructed from their cells on the fly. They are described in more detail in Column-Oriented Tables.

Primary key

A **primary key** is an ordered list of columns, the values of which uniquely identify rows. It is used to build the table's primary index. It is provided by the YDB user during table creation and dramatically impacts the performance of workloads interacting with that table.

Guidance on choosing primary keys is provided in Choosing a primary key.

Primary index

Primary index or **primary key index** is the main data structure used to find rows in a table. It is created based on the selected primary key and determines the physical order of rows in the table; thus, each table can have only one primary index. The primary index is unique.

Secondary index

A **secondary index** is an additional data structure used to find rows in a table, typically when this cannot be done efficiently using the primary index. Unlike a primary index, secondary indexes are managed independently of the table's main data. Thus, a table can have multiple secondary indexes for different scenarios. The capabilities of YDB regarding secondary indexes are described in a separate article Secondary indexes. A secondary index can be either unique or non-unique.

Special types of secondary indexes include vector index, full-text index, and JSON index.

Vector Index

Vector index is an additional data structure used to speed up the solution of the vector search problem when there is a lot of data and exact vector search without an index does not work satisfactorily.
The capabilities of YDB for approximate nearest neighbor search (ANN search) using vector indexes are described in a separate article Vector Indexes.

A **vector index** is a specialized type of secondary index designed for similarity search, as opposed to traditional secondary indexes optimized for equality or range search.

Fulltext index

Full-text index is an additional data structure used to speed up text search on a table column (by words and phrases, and when using N-grams, also by substrings).

The features of full-text search and index parameters are described in the articles Fulltext Indexes and Fulltext search.

JSON-index

JSON index is an additional data structure used to speed up predicates with the JSON_EXISTS and JSON_VALUE functions on a column of type `Json` or `JsonDocument`. Unlike traditional secondary indexes, which are optimized for equality or range searches on individual table columns, the JSON index works with arbitrary JsonPath paths within a JSON document.

A JSON index, like a full-text index, is built on top of an inverted index, but uses its own JSON document tokenizer. JSON search capabilities are described in the articles JSON indexes and Searching JSON document contents.

Local index

A local index is an auxiliary structure stored together with table data (unlike a global secondary index, which materializes a separate index table). It is applied while reading the main table in storage. See local indexes.

Bloom filter

A Bloom filter is a probabilistic data structure that allows you to quickly check whether an element belongs to a set. False positives are possible, but false negatives are not.

Local bloom index

A local Bloom index is a special case of a local index: a probabilistic filter on column values based on a Bloom filter that speeds up selective queries by skipping data fragments where the searched value is guaranteed to be absent. For more information, see Bloom indexes and local indexes.

Column family

Column family or **column group** is a feature that allows storing subsets of columns of a row table separately in a family or group. The main use case is storing some columns on other disk types (moving less important columns to HDD) or with different compression settings. If the workload requires many column families, consider using column tables.

Column encoding

Column encoding is a data storage optimization mechanism for table columns that reduces disk space usage and speeds up some operations.

Time to live

Time to live or **TTL** is a mechanism for automatically removing old rows from a table asynchronously in the background. It is explained in a separate article Time to Live (TTL) and Eviction to External Storage.

View

View is a way to save a query and access its results as if they were a real table. The view itself does not store any data except the query text. The query stored in the view is executed each time a SELECT is performed on it, generating the returned result. Any changes to the tables referenced by the view are immediately reflected in the read results.

Views can be user-defined or system.

User-defined views

User-defined views are created by the user using the CREATE VIEW command. They are described in more detail in View.

System view

System views are special views automatically created by the system for monitoring the state of the database and cluster. They are located in a special directory `.sys` in the root folder of each database. System views for databases are described in System database views; system views for the cluster and access management issues are described in Cluster System Views.

Topic

Message queue is used for reliable asynchronous communication between different systems by passing messages. YDB provides infrastructure that ensures exactly-once semantics in such communications. Using it, you can guarantee no lost messages or accidental duplicates.

Topic is a named entity in a message queue for interaction between writers and readers.

Several terms related to topics are listed below. How topics work in YDB is explained in more detail in a separate article Topic.

Partition

For horizontal scaling, topics are divided into separate elements called **partitions**. Thus, partitions are the unit of parallelism within a topic. Messages within each partition are ordered.

However, subsets of data managed by a single data shard or column shards can also be called partitions.

Offset

Offset is a sequence number that identifies a message within a partition.

Producer

Writer or **producer** is an entity that writes new messages to a topic.

Consumer

Reader or **consumer** is an entity that reads messages from a topic.

Change data capture

Change data capture or **CDC** is a mechanism that allows subscribing to a **change feed** for a specific table. Technically, it is implemented on top of topics. It is described in more detail in a separate article Change Data Capture (CDC).

Change feed

Change feed is an ordered list of changes to a table placed in a topic.

Backup collection

Backup collection is a schema object that organizes full and incremental backups for selected row tables. Collections provide point-in-time recovery by maintaining backup chains and ensuring consistent recovery of multiple tables. A table can belong to only one backup collection at a time.

For more information, see Backup collection.

Backup

Backup is a copy of data at a specific point in time that can be used for data recovery. In the context of backup collections, there are two types:

- **Full backup**: A complete snapshot of all data in the collection. It serves as the basis for backup chains and can be restored independently.
- **Incremental backup**: Captures only changes (inserts, updates, deletes) since the previous backup. Requires the entire backup chain for restoration.

Backup chain

Backup chain is an ordered sequence of backups starting with a full backup followed by zero or more incremental backups. Each incremental backup depends on all previous backups in the chain. Deleting any backup in the chain makes subsequent incremental backups unrecoverable.

Asynchronous replication instance

Async replication instance is a named entity that stores async replication settings (connection settings, list of replicated objects, etc.). It can also be used to obtain information about the async replication status: initial scan progress, lag, errors, etc.

Replicated object

Replicated object is an object (for example, a table) for which async replication is configured.

Replica object

Replica object is a mirror copy of the replicated object, automatically created by the async replication instance. Typically, it is read-only.

Transfer instance

Transfer instance is a named entity that stores transfer settings, including connection settings and data transformation rules. It can also be used to obtain information about the transfer status, for example errors.

Coordination node

Coordination node is a schema object that allows client applications to create semaphores for coordinating their actions. Coordination nodes are used to implement distributed locks, service discovery, leader election, and other scenarios. For more information about coordination nodes.

Semaphore

Semaphore is an object inside a coordination node that provides a synchronization mechanism for distributed applications. Semaphores can be persistent or temporary and support create, acquire, release, and monitor operations. For more information about semaphores in YDB.

Resource pool

Resource pool is a schema object that describes the limits imposed on resources (CPU, RAM, etc.) available for executing queries in this resource pool. A query is always executed in some resource pool. By default, all queries are executed in a resource pool named `default`, which does not impose any limits. For more information about using resource pools, see Workload Manager — resource consumption management.

Resource pool classifier

Resource pool classifier is an object designed to manage the distribution of queries among resource pools. It describes the rules by which a resource pool is selected for each query. These classifiers are global for the entire database and apply to all queries that come into it. For more information about their usage, see Workload Manager — resource consumption management.

YQL

YQL (YDB Query Language) is a high-level language for working with the system. It is a dialect of ANSI SQL. There's a lot of content covering YQL, including a tutorial, reference, and recipes.

Federated queries

Federated queries is a feature that allows executing queries to data stored in systems external to the YDB cluster.

A few terms related to federated queries are listed below. How YDB federated queries work is explained in more detail in a separate article Federated query.

External data source

External data source or **external connection** is metadata describing how to connect to a supported external system to execute federated queries.

External table

External table is metadata describing a specific dataset that can be retrieved from an external data source.

Secret

Secret is confidential metadata that requires special handling. For example, secrets can be used in definitions of external data sources and represent entities such as passwords and tokens.

Auth token

Auth token is a token used for authentication in YDB.

YDB supports various authentication modes and token types.

Cluster scheme

A **YDB cluster scheme** is a hierarchical namespace of a YDB cluster. The top-level element of the namespace is the cluster scheme root that contains databases as its children. Scheme objects inside databases can use nested directories to form a hierarchy.

Database scheme

A **database scheme** is a subset of the hierarchical namespace of a YDB cluster that belongs to a database.

Database root

A **database root** is a path to a database in a YDB cluster scheme.

Scheme root

Cluster schema root is the root element of the YDB namespace, whose child elements are databases.

Scheme object

A database schema consists of **scheme objects**, which can be databases, tables (including external tables), topics, folders, and so on.

For organizational convenience, scheme objects form a hierarchy using folders.

Folder

As in file systems, a **folder** or **directory** is a container for scheme objects.

Folders can contain subfolders, and this nesting can have arbitrary depth.

Access object

An **access object** during authorization is an entity for which access rights and restrictions are configured. In YDB, access objects are schema objects.

Each schema object has an owner and an access control list on that object, granted to users and groups (access subjects).

Access subject

An **access subject** is an entity that can access access objects and perform certain actions in the system.

Gaining access during these requests and actions depends on the configured access control lists and the access level of the subject.

An access subject can be a user or a group.

Access right

An **access right** is an entity that represents permission for an access subject to perform a specific set of operations in a cluster or database on a specific access object.

Access right inheritance

Access rights inheritance is a mechanism where access rights granted on parent access objects are inherited by child objects in the hierarchical database structure. This ensures that permissions granted at a higher level of the hierarchy apply to all lower levels unless they are explicitly overridden.

Permissions list

access control list or **ACL** — a list of all rights granted to access subjects (users and groups) on a specific access object.

Access level

An **access level** determines additional privileges of an access subject for scheme objects as well as privileges that are not related to scheme objects.

- Database
- Viewer
- Monitoring
- Administration.

The access level for a subject is configured using access control lists.

Access level list

Access Control List or **Permission List** — a list of SIDs of access subjects that are allowed a certain access level.

YDB provides several access level lists that collectively determine access levels in the system.

Detailed information about access control lists, their hierarchy, and operating principles is provided in the Access control lists section of the authorization documentation.

Owner

Owner — an access subject (user or group) that has full rights to a specific access object.

User

User — a person who uses YDB to perform a specific function.

YDB has the following types of users depending on their source:

- Local users in databases YDB.
- external users from third-party directories.

A user is identified by SID.

Local user

A **local user** is an individual whose YDB account is created directly in YDB using the `CREATE USER` command or during the initial security configuration.

External user

A user YDB whose account is created in an external directory, for example, an LDAP directory or IAM system.

Group

Group or **access group** - a named set of users and other groups with equal permissions for their members.

A group is identified by SID.

Role

A **role** is a named collection of access rights that can be granted to users or groups.

Roles in YDB are implemented using groups, which are created during the initial deployment of the cluster and are assigned a specific access rights list at the cluster schema root. For more information about roles, see the Initial cluster security configuration article.

SID

SID or **security identifier** — a string of the form `<name>` or `<name>@<auth-domain>` that identifies an access subject. It is used in authentication, authorization, access control lists, and access level lists.

SID identifies an individual user or group of users.

The optional suffix `@<auth-domain>` identifies the source of the access subject, i.e., the external directory or system from which it was obtained. For example, users or groups from an LDAP directory may have the suffix `@ldap`. The absence of a suffix means that the user or group was created and exists directly in YDB.

Query optimizer

Query optimizer is a set of YDB components responsible for converting the logical representation of a query into a specific physically executable plan for obtaining the requested result. The main goal of the optimizer is to select, among all possible query execution plans, one that is sufficiently efficient in terms of predicted execution time and cluster resource consumption. It is described in more detail in a separate article Query Optimization in YDB.

Compilation cache

compile cache is a cache of compiled queries on each node of the cluster. It is used to avoid recompilation: if the query text is already in the node's cache, no additional compilation is performed. For more details, see the Query Compilation Cache section.

Advanced Terminology

This section explains terms that are useful for YDB contributors and users who want to understand what happens inside the system more deeply.

Actor Implementation

Actor System

actor system is a C++ library with an implementation of the actor model for the needs of YDB.

Actor Service

actor service is an actor that has a well-known name and usually runs as a single instance on a node.

ActorId

ActorId is a unique identifier of an actor or a tablet in a cluster.

Actor System Interconnect

actor system interconnect or **interconnect** is the internal network layer of the cluster. All actors communicate with each other in the system via the interconnect.

Local

local is an actor service running on each node. It directly manages tablets on its node and interacts with Hive. It registers with Hive and receives commands to start tablets.

Tablet Implementation

tablet is an actor with persistent state. It includes a set of data that this tablet is responsible for and a state machine through which the tablet's data (or state) is modified. The tablet is a fault-tolerant entity because the tablet's data is stored in distributed storage, which survives disk and node failures. The tablet is automatically restarted on another node in case of failure or overload of the previous one. Data in the tablet is modified sequentially, as the system infrastructure guarantees that there is no more than one tablet leader through which tablet data changes are performed.

A tablet solves the same problem as the Paxos and Raft algorithms in other systems, namely the problem of distributed consensus. From a technical point of view, the tablet implementation can be described as a replicated state machine (RSM) on top of a shared log, since the tablet state is fully described by an ordered log of commands stored in a distributed and fault-tolerant storage.

At runtime, the tablet state machine is managed by three components:

1. The common tablet part ensures log consistency and recovery in case of failures.
2. **executor** is an abstraction of a local database, namely data structures and code that organize work with data stored by the tablet.
3. An actor with user code that implements the specific logic of a particular tablet type.

In YDB, there are multiple kinds of specialized tablets storing all kinds of data for all sorts of tasks. Many YDB features like tables and topics are implemented as specific tablets. Thus, reusing tablet infrastructure is one of the key means of YDB extensibility as a platform.

Typically, a YDB cluster runs orders of magnitude more tablets compared to the processes or threads that other systems would use for a cluster of similar size. In a YDB cluster, hundreds of thousands or millions of tablets can easily run simultaneously.

Since a tablet stores its state in distributed storage, it can be (re)started on any node of the cluster. Tablets are identified by TabletID, a 64-bit number assigned when the tablet is created.

Tablet Leader

Tablet leader is the current active leader of a given tablet. The tablet leader accepts commands, assigns them an order, and confirms them to the outside world. It is guaranteed that at any given time there is at most one leader for each tablet.

Tablet candidate

Tablet candidate is one of the election participants that wants to become the leader of a given tablet. If the candidate wins the election, it becomes the tablet leader.

Tablet follower

Tablet follower or **hot standby** is a copy of the tablet leader that applies the command log accepted by the leader (with some delay). A tablet can have zero or more replicas. Replicas perform two main functions:

- In case of termination or failure of the leader, replicas are preferred candidates for the new leader role, as they can become the leader much faster than other candidates because they have applied most of the log.
- Replicas can answer read-only requests if the client explicitly chooses an optional relaxed transaction mode that allows stale reads.

Tablet generation

Tablet generation is a number that identifies the reincarnation of the tablet leader. It changes only when a new leader is elected and always increases.

Tablet local database

Tablet local database or **local database** is a set of data structures and associated code that manage the state of the tablet and the data it stores. Logically, the state of the local database is represented by a set of tables, very similar to relational tables. Modification of the local database state is performed by local tablet transactions created by the user tablet actor.

Each local database table is stored using the LSM tree data structure.

Log-structured merge-tree

Log-structured merge-tree is a data structure designed to optimize write and read performance in storage systems. It is used in YDB to store tables of the local database and data of VDisks.

MemTable

All data written to the tables of the local database is initially stored in an in-memory data structure called **MemTable**. When the MemTable reaches a specified size, it is flushed to disk as an immutable data structure SST.

Sorted string table

Sorted string table is an immutable data structure that stores table rows sorted by key, facilitating efficient key lookup and range scans. Each SST consists of a continuous series of small data pages, typically about 7 KiB each, which further optimizes reading data from disk. An SST is usually part of an LSM tree.

Tablet pipe

Tablet pipe or **TabletPipe** is a virtual connection that can be established with a tablet. It involves finding the tablet leader by TabletID. This is the recommended way to work with a tablet. The term **open a pipe to a tablet** describes the process of resolving (finding) a tablet in the cluster and establishing a virtual communication channel with it.

TabletID

A **TabletID** is a cluster-wide unique tablet identifier.

Bootstrapper

Bootstrapper is the main mechanism for starting tablets, used for system tablets (e.g., Hive, DS controller, root SchemeShard). Hive initializes the other tablets.

Shared cache

Shared cache is an actor that stores data pages recently read from distributed storage. Caching these pages reduces the number of disk I/O operations and speeds up data retrieval, improving overall system performance.

Memory controller

A **memory controller** is an actor that manages YDB memory limits.

Spilling

Spilling is a memory management mechanism in YDB that temporarily offloads intermediate query data to external storage when such data exceeds the available RAM of the node. In YDB, disk is currently used for spilling.

For more details on spilling, see Spilling.

Tablet types

Tablets can be considered as a framework for building reliable components operating in a distributed system. Many components of YDB — both system and those working with user data — are implemented using this framework; the main ones are listed below.

Scheme shard

A **Scheme shard** or **SchemeShard** is a tablet that stores a database schema, including metadata of user tables, topics, etc.

In addition, there is a **root SchemeShard** that stores information about databases created in the cluster.

Data shard

DataShard or **Data shard** is a tablet that manages a segment of a row-based user table. A logical user table is divided into segments by continuous ranges of the table's primary key. Each such range is managed by a separate DataShard tablet. The range itself is also called a partition. The DataShard tablet stores data row by row, which is efficient for OLTP workloads.

Column shard

A **column shard** or **ColumnShard** is a tablet that stores a data segment of a column-oriented user table.

KV Tablet

KeyValue, **KV Tablet** is a tablet that implements a simple key → value mapping, where keys and values are strings. It also has several specific features, such as locks.

PQ Tablet

A **PQ Tablet** or **persistent queue tablet** is a tablet that implements the concept of a topic. Each topic consists of one or more partitions, and each partition is managed by a separate PQ tablet instance.

TxAllocator

A **TxAllocator** or **transaction allocator** is a system tablet that allocates unique transaction identifiers (TxID) within the cluster. Typically, a cluster has several such tablets, from which transaction proxy pre-allocates and caches ranges for local issuance within a single process.

Coordinator

Coordinator is a system tablet that ensures global ordering of transactions. The coordinator's task is to assign a logical time PlanStep to each transaction planned through this coordinator. Each transaction is assigned exactly one coordinator, selected by hashing its TxId.

Mediator

The **Mediator** is a system tablet that distributes the transactions planned by coordinators to the transaction participants (usually, DataShards). Mediators ensure the advancement of global time. Each transaction participant is associated with exactly one mediator. Mediators allow to avoid the need for a full mesh of connections between all coordinators and all participants in all transactions.

Hive

Hive is a system tablet responsible for launching and managing other tablets. Its responsibilities include moving tablets between nodes in case of failure or overload of a node. For more details about Hive, see the dedicated article.

CMS

CMS or **cluster management system** is a system tablet responsible for managing information about the current state of the YDB cluster. This information is used for performing rolling restarts of the cluster without affecting user workloads, maintenance, cluster reconfiguration, etc. CMS includes Sentinel, a component that implements SelfHeal.

SelfHeal

SelfHeal is a set of mechanisms that automatically maintain and restore cluster fault tolerance. Storage SelfHeal relocates VDisks of storage groups after prolonged node or disk failures. Metadata Distribution SelfHeal relocates State Storage, Board, and SchemeBoard replicas after failures and can add replicas when new nodes appear.

NodeBroker

NodeBroker is a system tablet responsible for registering dynamic nodes in the cluster.

BSController

BSController (also known as **blob storage controller**) manages the dynamic configuration of the distributed storage, including information about PDisk, VDisk, and storage groups. It interacts with node warden to start various distributed storage components. It interacts with Hive to allocate channels to tablets.

Console

Console is a system tablet responsible for storing the dynamic configuration and delivering it to cluster nodes.

Kesus

Kesus is a tablet that implements a coordination node.

SysViewProcessor

SysViewProcessor is a tablet that stores data for some of the system views.

SequenceShard

SequenceShard is a tablet that serves Sequence objects used to implement serial data types.

ReplicationController

ReplicationController is a tablet responsible for the asynchronous replication process.

StatisticsAggregator

StatisticsAggregator is a tablet responsible for collecting statistics used in cost optimization.

Slot

A **slot** in YDB can be used in two contexts:

- **Slot** is a portion of server resources allocated to run one node of YDB. A typical slot size is 10 CPU cores and 50 GB of RAM. Slots are used when the YDB cluster is deployed on servers or virtual machines with sufficient resources to host multiple slots.
- **VDisk slot** or **VSlot** is a portion of a PDisk that can be allocated to one of the VDisk instances.

State storage

State storage (also known as **StateStorage**) is a distributed service that stores information about tablets, namely:

- The current leader of the tablet or its absence.
- Tablet followers.
- Generation and step of the tablet `(generation:step)`.

State storage is used as a service for resolving tablet names, i.e., to obtain an ActorId from a TabletID. StateStorage is also used in the tablet leader election process.

The information in the state storage is volatile. Thus, it is lost on power failure or process restart. Despite its name, this service is not a permanent long-term storage. It only contains information that is easy to recover and that does not need to be durable. However, the state storage stores information on multiple nodes to minimize the impact of node failures. This service can also be used to gather a quorum, which is used for tablet leader election.

Due to its nature, the state storage service operates on a best-effort basis. For example, the absence of multiple tablet leaders is guaranteed through the leader election protocol on the distributed storage, not on the state storage.

Board

Board is a distributed service designed to store metadata as key-value pairs. It is used, among other things, to store information about endpoints.

SchemeBoard

SchemeBoard is a distributed service designed to store metadata as key-value pairs. It is used, among other things, to store information about schemas.

Compaction

Compaction is the internal background process of rebuilding LSM tree data. The data in VDisks and local databases are organized in the form of an LSM tree. Therefore, there is a distinction between **VDisk compaction** and **Tablet compaction**. The compaction process is usually quite resource-intensive, so efforts are made to minimize the overhead associated with it, for example, by limiting the number of concurrent compactions.

gRPC proxy

gRPC proxy — a proxy system for external user requests. Client requests enter the system via the gRPC protocol, then the proxy component translates them into internal calls to execute these requests, transmitted via interconnect. This proxy provides an interface for both request-response and bidirectional streaming data.

Distributed configuration

Distributed configuration or **DistConf** — an internal mechanism of cluster configuration that ensures the startup and configuration of static nodes, automatic management of the static storage group and State Storage. Distributed configuration starts before any tablets, storage groups, or State Storage.

For more on how distributed configuration works, see Internals of the V2 configuration mechanism.

Distributed storage implementation

Distributed storage — a distributed fault-tolerant data storage layer that stores binary records called LogoBlob, addressed by a specific type of identifier called LogoBlobID. Thus, Distributed storage is a key-value store that maps a LogoBlobID to a string of up to 10 MB. Distributed storage consists of many storage groups, each of which is an independent data repository.

Distributed storage stores immutable data, with each immutable data block identified by a specific LogoBlobID key. The Distributed storage API is very specific, intended only for use by tablets to store their data and change logs. Thus, it is not intended for general-purpose data storage. Data in Distributed storage is deleted using special barrier commands. Due to the absence of mutations in its interface, Distributed storage can be implemented without implementing distributed consensus. Distributed storage is just one of the components that tablets use to implement distributed consensus.

LogoBlob

LogoBlob — a set of binary immutable data, identified by LogoBlobID and stored in Distributed storage. The data block size is limited at the VDisk level and above in the stack. Currently, the maximum data block size that a VDisk can handle is 10 MB.

LogoBlobID

LogoBlobID — an identifier of a LogoBlob in Distributed storage. It has a structure of the form `[TabletID, Generation, Step, Channel, Cookie, BlobSize, PartID]`. The main elements of LogoBlobID:

- `TabletID` — the ID of the tablet that owns the LogoBlob.
- `Generation` — the generation of the tablet in which the data block was written.
- `Channel` — the channel of the tablet on which the LogoBlob is written.
- `Step` — an incremental counter, usually within the tablet generation.
- `Cookie` — a unique identifier of a data block within a single `Step`. Cookie is typically used when writing multiple data blocks into one `Step`.
- `BlobSize` — the size of the LogoBlob.
- `PartID` — the identifier of a data block part. It is important when the original LogoBlob is split into parts using erasure coding, and the parts are written to the corresponding VDisk and storage groups.

Replication

Replication — a process that ensures a sufficient number of copies (replicas) of data to maintain the desired availability characteristics of the cluster YDB. Typically used in geo-distributed clusters YDB.

Erasure Coding

Erasure coding is a data encoding method where the original data is supplemented with redundancy and split into multiple fragments, enabling recovery of the original data if one or more fragments are lost. It is widely used in clusters YDB with a single availability zone, as opposed to replication with 3 replicas. For example, the most popular erasure coding scheme 4+2 provides the same reliability as three replicas, with a space overhead of 1.5 versus 3.

PDisk

PDisk, **physical disk** is a component that controls a physical disk drive (block device). In other words, PDisk is a subsystem that implements an abstraction similar to a specialized file system on top of block devices (or files emulating a block device for testing purposes). PDisk provides data integrity control (including erasure coding of sector groups to recover data on individual damaged

sectors, integrity checking using checksums), transparent encryption of all data on the disk, and transactional guarantees for disk operations (write confirmation strictly after `fsync`).

PDisk contains a scheduler that ensures shared use of the device's bandwidth among multiple clients (VDisk). PDisk divides the block device into blocks called slots (about 128 megabytes in size; smaller blocks are also allowed). At any given time, no more than one VDisk can own each slot. PDisk also maintains a recovery log shared by PDisk service records and all VDisks.

VDisk

VDisk, **virtual disk** is a component that implements data storage of distributed storage LogoBlob on PDisk. VDisk stores all its data on PDisk. One VDisk corresponds to one PDisk, but typically several VDisks are associated with one PDisk. Unlike PDisk, which hides blocks and logs behind it, VDisk provides an interface at the LogoBlob and LogoBlobID level, for example writing a LogoBlob, reading LogoBlobID data, and deleting a set of LogoBlobs using a special command. VDisk is a member of a storage group. VDisk itself is local, but many VDisks in a given group provide reliable data storage. VDisks in a group synchronize data with each other and replicate data in case of losses. The set of VDisks in a storage group forms a distributed RAID.

Yard

Yard is the name of the PDisk API. It allows VDisk to read and write data to blocks and logs, reserve blocks, delete blocks, and transactionally acquire and release ownership of blocks. In some contexts, Yard can be considered a synonym for PDisk.

Skeleton

A **Skeleton** is an actor that provides an interface to a VDisk.

SkeletonFront

SkeletonFront is a proxy actor for Skeleton that controls the flow of messages coming to Skeleton.

Distributed storage controller

The **distributed storage controller** or **DS controller** manages the dynamic configuration of distributed storage, including information about PDisks, VDisks, and storage groups. It interacts with node wardens to launch various distributed storage components. It interacts with Hive to allocate channels to tablets.

Proxy

Distributed storage proxy, **DS-proxy**, or **BS-proxy** acts as a client library for performing operations with distributed storage. The users of DS-proxy are tablets that write to and read from distributed storage. DS-proxy hides the distributed nature of distributed storage from the user. The task of DS-proxy is to write to a quorum of VDisk, perform retries when necessary, and control the write/read flow to prevent VDisk overload.

Technically, the DS proxy is implemented as an actor service launched by node warden on each node for each storage group, handling all requests to the group (writing, reading, and deleting LogoBlob, and group locking). When writing data, the DS proxy performs erasure coding of the data, splitting the LogoBlob into parts that are then sent to the corresponding VDisks. The DS proxy performs the reverse process when reading, receiving parts from VDisks and reconstructing the LogoBlob from them.

Node warden

Node warden or `BS_NODE` is an actor service on each cluster node that launches PDisks, VDisks, and DS proxies of static storage groups when the node starts. It also interacts with the DS controller to launch PDisk, VDisk, and DS proxies of dynamic groups. The DS proxy of dynamic groups is launched on demand: node warden processes undelivered messages to DS proxies, launches the corresponding DS proxies, and receives group configuration from the DS controller.

Failure realm

A **fail realm** is a set of failure domains that can fail simultaneously due to a common cause. A correlated failure of two VDisks in the same fail realm is more likely than a failure of two VDisks from different fail realms.

An example of a fail realm is a set of equipment located in a single data center, or availability zone, which can fail entirely due to a natural disaster, large-scale power outage, or other similar event.

Failure domain

A **fail domain** is a set of hardware that may fail simultaneously. The correlated failure of two VDisks within the same fail domain is more probable than the failure of two VDisks from different fail domains. In the case of different fail domains, this probability is also affected by whether these domains belong to the same fail realm or not.

An example of a fail domain is a set of disks connected to a single server, since all disks of a particular server may become unavailable if the server's power supply or network controller fails. Typically, all servers located in a single server rack are considered a common fail domain, because power or network issues at the rack level cause all equipment in it to become unavailable. Thus, a typical fail domain corresponds to a server rack (if the cluster is configured with rack-aware topology) or an individual server.

Failures at the fail domain level are automatically handled by YDB without stopping the cluster.

Distributed storage channel

A **distributed storage channel**, **DS channel**, or **channel** is a logical connection between a tablet and a storage group. A tablet can write data to different channels, and each channel maps to a specific storage group. Having multiple channels allows a tablet to:

- Write more data than a single storage group can hold.
- Store different LogoBlobs in different storage groups, with different properties, such as erasure coding or on different media (HDD, SSD, NVMe).

Distributed transactions implementation

Below are the terms related to the implementation of distributed transactions. The implementation itself is described in a separate article DataShard: distributed transactions.

Deterministic transactions

Distributed transactions in YDB are inspired by the research paper Building Deterministic Transaction Processing Systems without Deterministic Thread Scheduling by Alexander Thomson and Daniel J. Abadi from Yale University. The paper introduced the concept of **deterministic transaction processing**, which allows efficient processing of distributed transactions. The original paper imposed restrictions on the types of operations that could be performed this way. Since these restrictions hindered real-world user scenarios, YDB evolved its algorithms to handle them, using deterministic transactions as stages for executing user transactions with additional orchestration and locking.

Optimistic locking

As in many other database management systems, queries in YDB can place locks on certain data fragments, such as table rows, to ensure that concurrent changes do not lead to an inconsistent state. However, YDB checks these locks not at the start of transactions, but when attempting to commit them. The first approach is called **pessimistic locking** (for example, used in PostgreSQL), and the second is called **optimistic locking** (used in YDB).

Transaction lock invalidation

Transaction Lock Invalidation (**TLI**) is the normal behavior of YDB when parallel transactions conflict under optimistic locks. If one transaction (the violator) writes data and thereby breaks the locks of another transaction (the victim), YDB detects this when the victim commits and aborts it with error `transaction locks invalidated`. For more details on TLI diagnostics, see Transaction lock invalidation.

Prepare stage

Preparation phase is the transaction phase during which the transaction body is registered on all participating shards.

Execute stage

Execution phase is the transaction phase during which the scheduled transaction is executed and a response is generated.

In some cases, instead of prepare and execute, the transaction is immediately executed, and a response is generated. For example, this happens for transactions involving only one shard or consistent reads from a snapshot.

Dirty operations

In the case of read-only transactions, similar to "read uncommitted" in other database management systems, it might be necessary to read data that has not yet been committed to disk. This is called **dirty operations**.

Read-write set

Read-write set or **RW-set** is a data set that will participate in the execution of a distributed transaction. It combines the read set data that will be read and the write set for which modifications will be performed.

Read set

Read set or **ReadSet data** is what participating shards send during transaction execution. In the case of data transactions, it may contain information about the state of optimistic locks, the shard's readiness to commit, or a decision to abort the transaction.

Transaction proxy

Transaction proxy or `TX_PROXY` is a service that orchestrates the execution of many distributed transactions: sequential phases, phase execution, scheduling, and result aggregation. In the case of direct orchestration by other actors (for example, QP data transactions), it is used for caching and allocating unique TxIDs.

Transaction flags

Transaction flags or **TxFlags** is a bitmask of flags that somehow modify the execution of a transaction.

Transaction ID

TxID is a unique identifier assigned to each transaction when it is accepted by YDB.

Transaction order ID

Transaction order id is a unique identifier assigned to each transaction during scheduling. It consists of PlanStep and Transaction ID.

PlanStep

PlanStep or **Step** is the logical time at which the execution of a set of transactions is scheduled.

Mediator time

During the distributed query execution, **mediator time** is the logical time before which (inclusive) the shard participant must know the entire execution plan. It is used to advance the time in the absence of transactions on a particular shard, to determine whether it can read from a snapshot.

MiniKQL

MiniKQL is a language that allows expressing a single deterministic transaction in the system. It is a functional, strongly typed language. Conceptually, the language describes a graph of reading from the database, performing computations on the read data, and writing results to the database and/or to a special document representing the query result (for display to the user). A MiniKQL transaction must explicitly specify its read set (data to be read) and assume deterministic selection of execution branches (for example, no randomness).

MiniKQL is a low-level language. The system's end users only see queries in the YQL language, which relies on MiniKQL in its implementation.

Query Processor

Query Processor or **QP** (formerly **KQP**) is a YDB component responsible for orchestrating the execution of user queries and generating the final response.

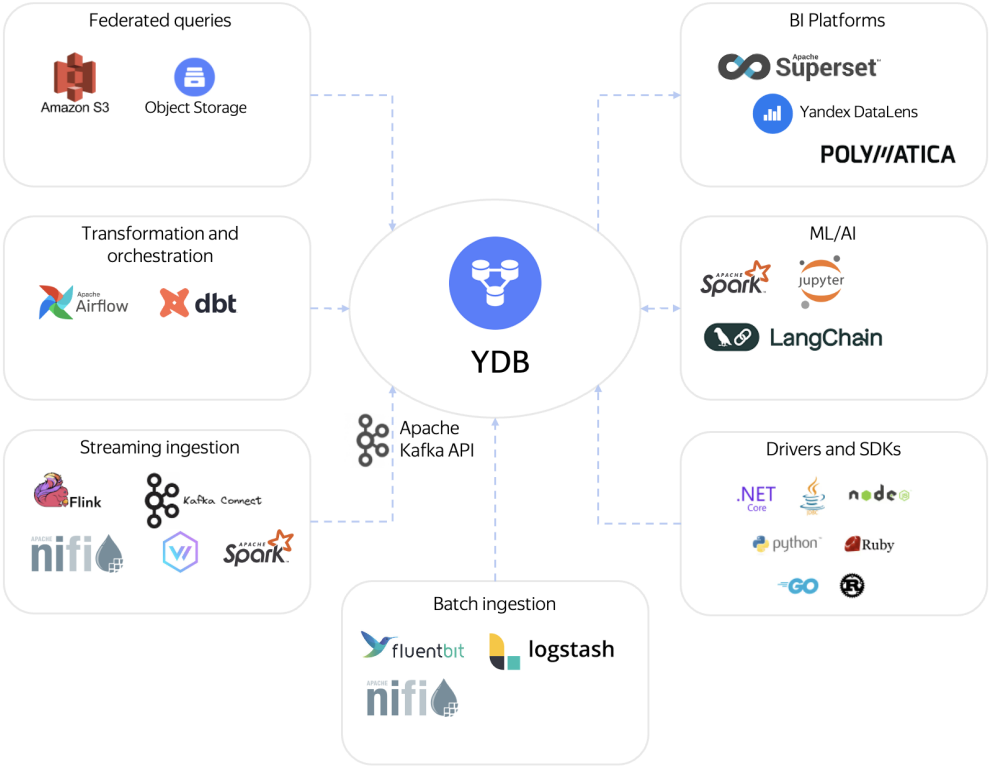
Global schema

Global scheme, **global schema**, or **database schema** is the schema of all data stored in a database. It consists of tables and other entities such as topics. The metadata about these entities is called the global schema. The term is used in contrast to **local schema**, which refers to the data schema inside a tablet. YDB users never see the local schema and work only with the global schema.

KiKiMR

KiKiMR is the former name of YDB, used before it became an open source product. It can still be found in source code, old articles, videos, etc.

Tablet Recovery Mode



Recovery mode is a mode in which a tablet is started and accessible via the YDB UI, but **does not respond to requests**, **does not perform any background activities**, and **does not read data from the distributed storage**, allowing recovery operations to be performed. Other tablets continue to operate normally, allowing the cluster to keep functioning, but operations and UI related to the

tablet placed in Recovery mode will be unavailable.

Overview

YDB is a distributed, fault-tolerant database that provides components for building a data warehouse (DWH) on a unified platform.

Using YDB allows you to consolidate the functionality of several technologies (for example, separate systems for streaming, storage, and analytics) into a single solution. You can use familiar tools and approaches while gaining the benefits of a distributed system.

Data Ingestion

The platform is designed to handle streaming and batch data ingestion at large scale.

- Streaming processing: Built-in topic system with Kafka API support for integration with existing systems. Plugins for Fluent Bit and Logstash are available for log collection.
- Batch loading: BulkUpsert API for efficiently loading large data sets and a connector for Apache Spark to integrate with data processing platforms.
- Connection via standard interfaces: JDBC-driver and native SDK.

Data Storage

The core of the storage system is — column-oriented tables with built-in compression, optimized for analytical workloads.

- Separation of storage and compute: A key feature of YDB, enabling independent scaling of disk space and computing resources.
- Minimized administration: Background processes for (compaction) and TTL-based data removal reduce the need for manual operations.

Query Execution

YDB is an Massively Parallel Processing (MPP) DBMS with no dedicated master node. All nodes perform the same roles, and the system scales horizontally by dynamically adding or removing compute resources.

- Cost-Based Optimizer (CBO): Selects the optimal query execution plan by analyzing data statistics.
- Spilling mechanism: Enables execution of queries whose intermediate results do not fit in RAM by offloading them to disk.
- Workload Manager: Manages resource allocation among queries, isolating different types of workloads.

Data Transformation

Data transformation is supported using standard approaches and tools.

- ELT with SQL: Use `INSERT INTO ... SELECT` to build data marts. For managing complex SQL pipelines, integration with dbt is available.
- ETL with Apache Spark: Run ETL jobs on Apache Spark using the parallel connector.
- Orchestration: Automate pipelines with Apache Airflow.

Federated Queries

YDB allows you to run queries on data stored in S3-compatible storage without preloading it. This simplifies working with data stored in a data lake.

Data Analysis and Visualization (BI and ML)

You can use industry-standard tools for data analysis:

- BI tools: Yandex DataLens, Apache Superset, Grafana.
- ML tools: Use Jupyter Notebook and Apache Spark for data preparation and machine learning model training.

Data Ingestion

YDB is designed to ingest both streaming and batch data. The absence of dedicated master nodes allows for parallel writes to all database nodes, enabling write throughput to scale linearly as the cluster grows. The choice of tool depends on the requirements for latency, delivery guarantees, and data volume.

Streaming Ingestion (Real-time)

For scenarios requiring minimal latency, such as logs, metrics, and CDC streams.

- Topics with Kafka API: the primary and recommended method for streaming ingestion. Topics are the YDB built-in equivalent of Apache Kafka. Thanks to Kafka API support, you can use existing clients and systems (Apache Flink, Spark Streaming, Kafka Connect) without any changes. The key advantage is the ability to perform transactional writes from a topic to a table, which guarantees `exactly-once` semantics at the database level.
- Plugins for Fluent Bit / Logstash: if you use Fluent Bit or Logstash for log collection, specialized plugins allow you to write data directly to YDB, bypassing intermediate message brokers.
- Built-in data transfer (Transfer): the Transfer service allows you to transform and move data from topics to tables in streaming mode.

Batch Ingestion (Batch)

For loading large volumes of historical data, exports from other systems, or the results of batch jobs.

- BulkUpsert - the most performant method for batch inserts. BulkUpsert is a specialized API optimized for maximum throughput. It requires fewer resources compared to transactional operations, allowing you to load large datasets at maximum speed.
- Federated queries to data in S3 / Data Lakes - YDB allows you to execute SQL queries directly against data stored in S3-compatible object storage or other external systems. This is a convenient way to load data without using separate ETL tools.
- Apache Spark connector saves data directly to YDB tables in multi-threaded mode for the most performant writes.
- JDBC driver and native SDKs- with these, you can connect any applications or pipelines, including Apache Spark, Apache NiFi, and other solutions.

Data Storage

Efficient data storage is the foundation of any analytical warehouse. YDB uses a columnar format, a storage and compute disaggregation architecture, and automatic maintenance processes to ensure high performance and a low total cost of ownership.

Columnar tables

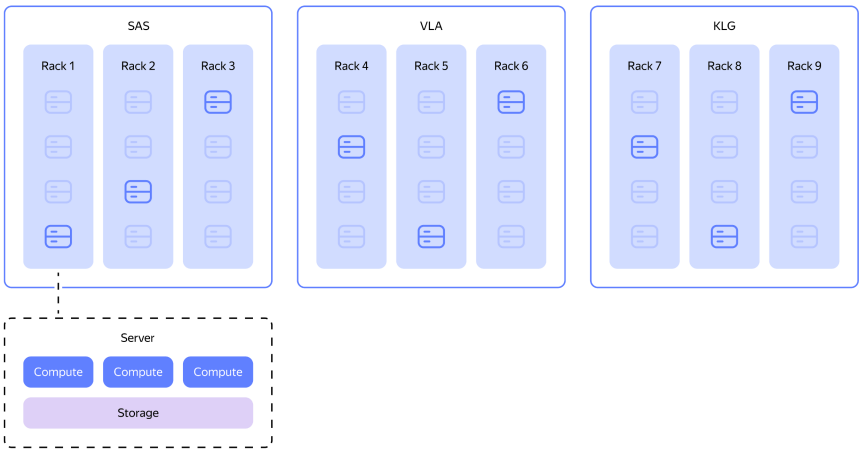
Data in columnar tables is stored by columns instead of rows. This approach is the standard for OLAP systems and offers two key advantages:

1. Reduced read volume: when a query (e.g., `SELECT column_a, column_b FROM...`) is executed, only the data from the columns involved in the query is read from the disk.
2. Data compression: columnar storage lets you apply compression and encoding per column, which compresses data better than heterogeneous row data. By default, the `LZ4` compression algorithm is used without special encoding; both settings can be configured per column. For details, see CREATE TABLE request parameters.

Architecture with storage and compute disaggregation

Storage and compute disaggregation is an architectural principle of YDB. The nodes responsible for data storage (storage nodes) and the nodes that execute queries (dynamic nodes) are separate. This allows you to:

- scale resources independently: if you run out of disk space, you add storage nodes. If you lack CPU for queries, you add compute nodes. This differs from systems where storage and compute resources are tightly coupled;
- redistribute load quickly: redistributing compute load between nodes does not require physical data movement; only metadata is transferred.



Automatic storage optimization

YDB is designed to minimize manual maintenance operations.

- Automatic data compaction: Data is stored in LSM-like structures; data merging and optimization processes run continuously in the background. You do not need to run VACUUM or similar commands.
- Automatic data deletion: To manage the data lifecycle, use the TTL-based deletion mechanism.

Built-in fault tolerance

YDB was designed from the ground up as a fault-tolerant system and supports various data placement modes to protect against hardware, rack, or even entire data center failures.

Query Execution

YDB is a distributed Massively Parallel Processing (MPP) database designed for executing complex analytical queries on large volumes of data. Each query is automatically parallelized across all available compute nodes in the cluster, enabling efficient use of compute resources.

YDB supports several key technologies that ensure high performance and stability:

- Decentralized MPP architecture
- Cost-Based Query Optimizer
- Handling data that exceeds RAM
- Workload Isolation and Resource Management

Decentralized MPP architecture

Unlike MPP systems with a dedicated master node, YDB's architecture is completely decentralized. This provides two main advantages:

- High fault tolerance: any node in the cluster can accept and coordinate query execution. There is no single point of failure (SPOF). The failure of some nodes does not halt the cluster—the load is automatically redistributed among the remaining nodes.
- Compute scalability: you can add or remove compute nodes without downtime, and the system automatically adapts, distributing the load to account for the new cluster composition.

Cost-Based Query Optimizer

Before executing a query, YDB uses a Cost-Based Optimizer (CBO). It analyzes the query text, metadata, and statistics on data distribution in tables to build a physical execution plan with the lowest estimated cost.

The optimizer can:

- choose the join order for queries with dozens of `JOIN`s;
- select distributed `JOIN` algorithms (e.g., Grace Join, Broadcast Join) depending on table sizes;
- push down filters (`WHERE` clauses) as close as possible to the data sources to reduce the amount of data processed in subsequent stages.

Handling data that exceeds RAM

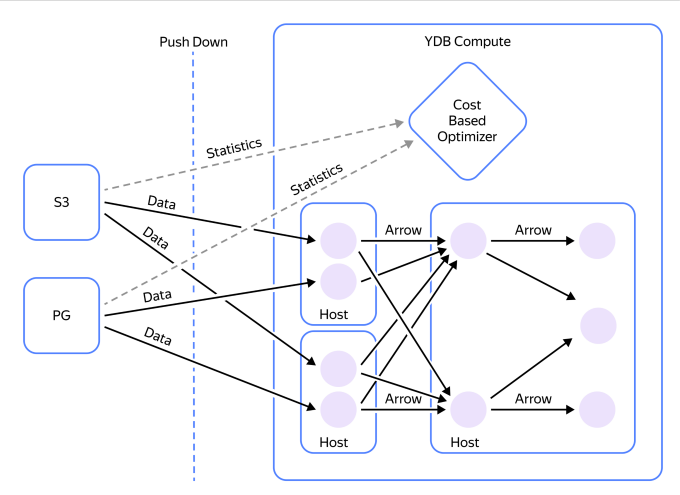
Analytical queries can require large amounts of RAM, especially for `JOIN` and `GROUP BY` operations. YDB is designed to work with data that may not fit into RAM.

- Spilling: if the intermediate results of a query exceed the memory limit, YDB automatically spills them to the node's local disk. This prevents the query from failing with an "Out of Memory" error and allows queries to be executed on large volumes of data.
- Distributed JOIN algorithms: for joining tables that exceed the memory of a single node, distributed algorithms are used that process data in chunks across different nodes.

Workload Isolation and Resource Management

In a corporate DWH, different teams often run different types of workloads. To prevent these workloads from interfering with each other, YDB has a built-in resource manager.

- Workload Manager: the built-in `workload manager` allows you to create resource pools and, using classifiers, assign queries from different user groups to different pools. This mechanism solves the "noisy neighbor" problem, where a single resource-intensive query can slow down the system for all other users.



Federated queries

Federated queries allow you to query data stored in external systems without first loading it (ETL) into YDB. The most popular use case is working with data in S3-compatible object storage.

How it works

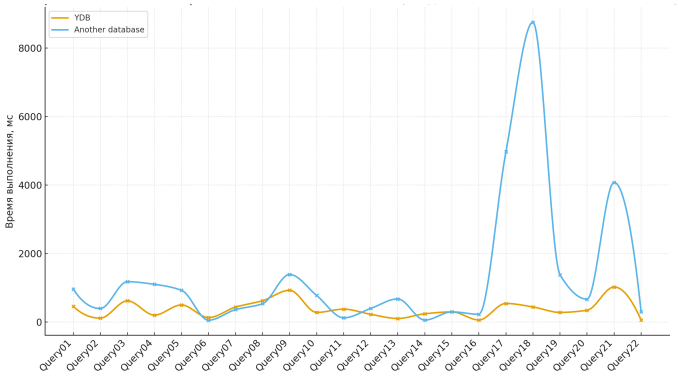
You can create an external table in YDB that references data in S3. When you execute a SELECT query against such a table, YDB initiates a parallel read from all compute nodes. Each node reads and processes only the portion of data it needs.

- Supported formats: Parquet, CSV, JSON with various compression algorithms.
- Read optimization: YDB uses S3 data read optimization mechanisms (partition pruning) for Hive-style partitioning and for more complex partitioning schemes.

Data transformation and preparation (ETL/ELT)

Data preparation for analysis is a key stage in building a data warehouse. YDB supports all standard data transformation approaches, allowing you to choose the most suitable tool for a specific task: from pure SQL to complex pipelines on Apache Spark.

ELT



Data transformations using SQL are often the most performant, since all processing occurs directly within the YDB engine without moving data to and from external systems. The logic is described in SQL and executed by the distributed MPP engine, which is optimized for analytical operations.

Performance in the TPC-H benchmark

The performance of ELT operations directly depends on the execution speed of complex analytical queries. The industry-standard benchmark for evaluating such queries is TPC-H.

A comparison with another distributed analytical DBMS on the TPC-H query set shows that YDB demonstrates more stable performance, especially when executing queries that contain:

- connections (`JOIN`) of a large number of tables (five or more);
- nested subqueries used for filtering;
- aggregations (`GROUP BY`) followed by complex filtering of the results.

This stability indicates the high efficiency of the YDB cost-based query optimizer in building execution plans for complex SQL patterns typical of real-world ELT processes. For a data warehouse (DWH) platform, this means predictable data update times and a reduced risk of uncontrolled performance degradation in the production environment.

Key use cases

- Building data marts: use the familiar `INSERT INTO ... SELECT FROM ...` syntax to create aggregated tables (data marts) from raw data;
- joining OLTP and OLAP data: YDB allows you to join data from both transactional (row-based) and analytical (column-based) tables in a single query. This enables you to enrich "cold" analytical data with up-to-date information from the OLTP system without the need for duplication;
- bulk updates: for "blind" writes of large volumes of data without existence checks, you can use the `UPSERT INTO` operator.

Managing SQL pipelines with dbt

To manage complex SQL pipelines, use the dbt plugin. This plugin allows data engineers to describe data models as `SELECT` queries, and dbt automatically builds a dependency graph between models and executes them in the correct order. This approach helps implement software engineering principles (testing, documentation, versioning) when working with SQL code.

ETL

Complex transformations using external frameworks

For tasks that require complex logic in programming languages (Python, Scala, Java), integration with ML pipelines, or processing large volumes of data, it is convenient to use external frameworks for distributed processing.

Apache Spark is one of the most popular tools for such tasks, and a dedicated connector to YDB has been developed for it. If your company uses other similar solutions (e.g., Apache Flink), they can also be used to build ETL processes using the JDBC driver.

A key advantage of YDB when working with such systems is its architecture, which allows for parallel data reading. YDB has no dedicated master node for exports, so external tools can read information directly from all storage nodes. This ensures high-speed reads and linear scalability.

Pipeline orchestration

Orchestrators are used to run pipelines on a schedule and manage dependencies.

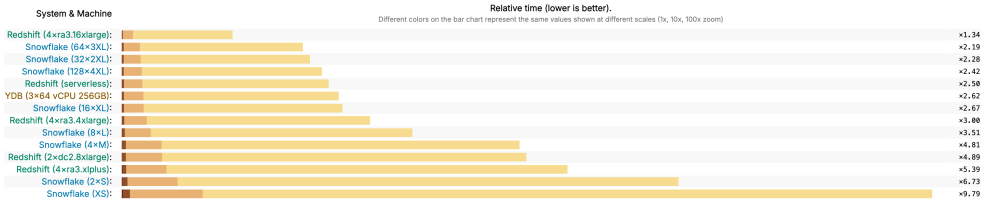
- Apache Airflow: an Apache Airflow provider is supported for orchestrating data in YDB. It can be used to create DAGs that run `dbt run` , execute YQL scripts, or initiate Spark jobs.
- built-in mechanisms: For some tasks, an external orchestrator is not required. YDB can perform some operations automatically:
  - TTL-based data expiration: automatically cleans up partitions after a specified time;
  - automatic compaction: data merging and optimization processes for the LSM tree run in the background, eliminating the need to regularly run commands like `VACUUM` ;
- other orchestrators: if your company uses a different tool (e.g., Dagster, Prefect) or a custom scheduler, you can use it to run the same commands. Most orchestrators can execute shell scripts, allowing you to call the YDB CLI, dbt run, and other utilities.

Integration with other ETL tools via JDBC

YDB provides a JDBC driver, enabling the use of a wide range of existing ETL tools, such as Apache NiFi and other JDBC-compliant systems.

BI analytics and data visualization

The interactivity of BI dashboards directly depends on the performance of the underlying database. YDB was designed as a high-performance analytical platform that executes queries in sub-second time, enabling analysts to work with data interactively.



This is achieved through key architectural features:

- columnar storage: queries read only the columns specified in the request from disk, which reduces the volume of I/O operations;
- MPP architecture: each query is parallelized across all available compute nodes of the cluster, harnessing all available resources for its execution;
- decentralized architecture: the absence of a single master node enables efficient processing of multiple concurrent queries from BI systems.

Performance in independent benchmarks

Although synthetic tests do not always reflect real-world workloads, they serve as a good starting point for performance comparison. ClickBench is an independent benchmark for analytical DBMSs, developed by the creators of ClickHouse.

On a set of 43 analytical queries, YDB shows competitive results, outperforming many popular open-source and cloud analytical databases. This confirms the engine's high performance on typical OLAP queries.

Integrations with BI platforms

YDB supports the following BI platforms:

- Yandex DataLens;
- Apache Superset;
- Grafana;
- Polymatica.

Machine Learning

YDB serves as an effective platform for storing and processing data in ML pipelines. You can use familiar tools, such as Jupyter Notebook and Apache Spark, throughout all stages of the ML model lifecycle.

Feature Engineering

Use YDB as an engine for feature engineering:

- SQL and dbt: execute complex analytical queries to aggregate raw data and create new features. Materialize feature sets into row-based tables for fast access;
- Apache Spark: for more complex transformations that require Python or Scala logic, use the Apache Spark connector to read data, process it, and save the results back to YDB.

Model Training

YDB can serve as a fast and scalable data source for model training:

- Jupyter Integration: connect to YDB from Jupyter Notebook for ad-hoc analysis and model prototyping;
- distributed training: the Apache Spark connector enables parallel reading of data from all cluster nodes directly into a Spark DataFrame. This allows you to load training sets for models in PySpark MLlib, CatBoost, Scikit-learn, and other libraries.

Online Feature Store

The combination of row-based (OLTP) and columnar (OLAP) tables in YDB allows you to implement not only an analytical warehouse but also an Online Feature Store on a single platform.

- Use row-based (OLTP) tables to store features that require low-latency point reads; this allows ML models to retrieve features in real time for inference.
- Use columnar (OLAP) tables to store historical data and for the batch calculation of these features.

Key Analytics Capabilities: Quick Reference

This page is a map of the documentation for the analytical features of YDB. The content is organized by the stages of the data lifecycle to help you quickly find the information you need for designing, developing, and operating analytical solutions.

Data Warehouse Design (Concepts & Design)

Core concepts for organizing, scaling, and managing data.

Main Concepts and Data Types

- Column-Oriented Tables: Storage architecture optimized for OLAP workloads.
- Data Types: Comprehensive reference for supported types.

Scalability and Performance

- Primary Key Design for Maximum Performance: How to choose `PRIMARY KEY` and `PARTITION BY`.
- Table Partitioning: Mechanism for distributing data across nodes.

Data Lifecycle Management

- TTL (Time-to-Live): Automatic deletion of outdated data after expiration.

Streaming Ingestion

- Topics (Kafka API): Native streaming using the Kafka protocol.
- Connector Fluent Bit: Direct log ingestion.

Batch Ingestion

- Apache Spark Connector: Read and write data for ETL/ELT tasks.
- BulkUpsert API: High-performance bulk inserts via SDK.

Integration with External Systems

- Federated Queries: Run queries on data in external systems (S3, ClickHouse, Postgres).
- Working with S3 via External Tables: Read and write Parquet/CSV data in Object Storage.

Data Processing and Transformation (ETL/ELT)

Query language and integration with orchestration tools.

YQL Query Language

- Full Reference for YQL: Syntax, functions, and operators.
- Date and Time Functions: Complete list and typical use cases.
- JSON Functions: Extracting data from JSON documents.

Pipeline Building Tools

- dbt (Data Build Tool) Integration: Managing ELT pipelines with SQL.
- Apache Airflow Integration: Orchestrating complex ETL/ELT processes.

Application Development & Integration (Development & SDKs)

Tools for application developers.

- YDB SDK Overview: Native SDKs for Go, Python, Java, C++, JavaScript.
- JDBC driver: Standard connectivity for the Java ecosystem.
- YDB CLI: Command-line tool for administration and query execution.

Data Analysis and Visualization

Integration with end-user tools.

BI Tools

- Apache Superset
- Grafana
- Yandex DataLens

Data Science Tools

- Jupyter Notebooks: Running YQL queries and interactive data analysis.

Operations & Performance Management

Administration, monitoring, security, and optimization.

Performance Management

- Query Plan Analysis (EXPLAIN): How to understand query execution plans and identify bottlenecks.
- Cost-Based Optimizer: Overview of how the query planner works.

Monitoring and Diagnostics

- YDB UI: Web interface for cluster monitoring and diagnostics.
- Metrics Reference: Full list of metrics for monitoring systems.
- Ready-to-use Grafana Dashboards: Templates for quick monitoring setup.

Security and Fault Tolerance

- Authentication and Authorization: User access configuration, including LDAP support.

Streaming data processing

This section describes the key concepts of stream processing (stream processing) in YDB:

- Streaming queries — a type of query for continuous processing of incoming events. Sources and sinks of data, delivery guarantees, limitations, and query management are described.
- Watermarks — a mechanism for tracking the progress of event processing over time.

Streaming queries

A streaming query is a type of query designed for continuous processing of an unbounded data stream (stream processing). Unlike regular queries, a streaming query does not terminate after returning a result but runs continuously, processing data as it arrives.

Stream data processing is a widely used approach implemented in systems such as Apache Flink, Apache Kafka Streams, Amazon Kinesis Data Analytics. Typical use cases include monitoring and alerting, metric aggregation over time windows, real-time event transformation and filtering, enriching events with reference data, and pattern detection in event sequences.

YDB implements stream processing as part of a unified data platform. In addition to typical streaming query use cases, integration into the YDB common platform allows you to read data from topics YDB, process change streams from row tables via CDC, and write processing results to output topics or directly to tables. This enables building data processing pipelines within YDB with minimal latency.

Differences from regular queries

Regular queries work with data already stored in tables. A query executes, returns a result, and terminates. A streaming query is created and runs indefinitely until explicitly canceled by the user. Data continuously arrives in a topic, flows through the query, and is written to a sink — another topic or table.

Characteristic	Regular queries	Streaming queries
Data	Finite set in tables	Infinite stream of events
Lifetime	Terminates after processing	Runs continuously
Result	Available after completion	Updated as data arrives
Recovery on failures	Manual restart	Automatic recovery from checkpoint

Data sources and sinks

Streaming queries read data from topics YDB and write results to topics or tables YDB. Data can arrive in a topic from external systems (for example, an application writes events via the SDK), but the streaming query itself only works with YDB entities. Direct reading from external systems, such as Apache Kafka, or writing to tables in other databases, such as PostgreSQL, is not supported.

Sources

Topics are the main source of streaming data. The query reads messages from one or more topics and processes them as they arrive. Data can be written to a topic by:

- **External applications** — via the YDB SDK or Kafka API. For example, a service sends telemetry events or logs to a YDB topic, and the streaming query processes them.
- **CDC (Change Data Capture)** — change streams from tables, implemented via built-in topics. They allow reacting to inserts, updates, and deletes of records in real time. For more information, see Change Data Capture (CDC).

Sinks

Topics — for passing results to other systems or subsequent processing stages.

Tables — for materializing results. Data is saved via UPSERT and is available for regular SQL queries.

Guarantees

Under normal operation, streaming queries provide an at-least-once data delivery guarantee — on failures, the query automatically recovers from a checkpoint and resumes reading from saved offsets.

However, it is important to consider the limitations of the current implementation:

- **Offset reset on query recreation:** changing the query text via DROP + CREATE deletes the checkpoint. The new query starts reading from the end of the topic, skipping events that arrived between the deletion of the old version and the start of the new one.
- **Incomplete aggregates due to lack of watermarks:** due to the absence of a watermarks mechanism, time windows are closed based on system time (wall-clock). Events that arrive late (e.g., due to slow partitions or network lag) are not included in the aggregates of already closed windows.

Detailed description of guarantees, anomalies, and ways to minimize them — in the Data delivery guarantees section.

> **Note**
>
> We are constantly working on developing streaming processing mechanisms. In future versions, the guarantees provided will be improved.

Limitations

> **Warning**
>
> - The query must contain at least one read from a topic, as streaming processing requires a continuous input data stream.
> - `JOIN` of two streams is not supported (temporary architectural limitation).

The following are also not supported in the current version:

- The important reader flag for consumers used by streaming queries.
- Autopartitioning (split/merge of partitions) of topics used by streaming queries. When the number of partitions in a topic from which a running streaming query reads increases, new partitions will not be processed.
- Changing the text of a running query. To change a query, you need to recreate it — delete it using DROP STREAMING QUERY and create it again using CREATE STREAMING QUERY.

Management

Streaming queries are created, modified, and deleted using YQL commands:

- CREATE STREAMING QUERY — creation.
- ALTER STREAMING QUERY — modification and state management.
- DROP STREAMING QUERY — deletion.

Query state is available in the system table `.sys/streaming_queries`.

Query language

Streaming queries are written in YQL and support familiar SQL constructs: SELECT, WHERE, GROUP BY, JOIN. For working with time windows, GROUP BY HOP is used.

A single streaming query can read multiple input topics, use the UNION ALL construct to combine data streams, and write the result to multiple output topics and/or tables (see more details in the articles Formats for writing data and Writing to tables).

Watermarks

A watermark in stream processing (stream processing) is a monotonically increasing lower bound on the event times that may still arrive in the stream. When the watermark reaches a value X, the system declares that all events with time less than X have most likely been received.

YDB implements the watermark mechanism in streaming queries: they are used to correctly close time-based aggregation windows (HoppingWindow) and ensure that the window result is emitted only when the system has confirmed the completeness of input data for that period.

In stream processing, each event has two timestamps: **event time** — the moment when the event occurred in the real world, and **processing time** — the moment when the system received the event. Due to network delays, failures, and uneven load, these two values can differ significantly. This is precisely why the system needs a watermark mechanism: without it, the system does not know when a past time range can be considered sufficiently complete to emit a result.

Accuracy vs. Latency Trade-off

In YDB, this trade-off is explicitly controlled: the `WATERMARK` parameter in the `GROUP BY` clause specifies the expression for computing the watermark, including the amount of lag behind the last event time. This allows you to balance between result freshness and completeness of accounting for late events.

A watermark cannot simultaneously account for arbitrarily large event delays and advance quickly: the longer the system waits for late events, the later it emits results. This is a fundamental trade-off in stream processing.

Events that arrive after the watermark has passed the corresponding time range are considered late and are discarded. For more details on handling late events and configuring watermarks, see Watermarks.

YDB Architecture Overview

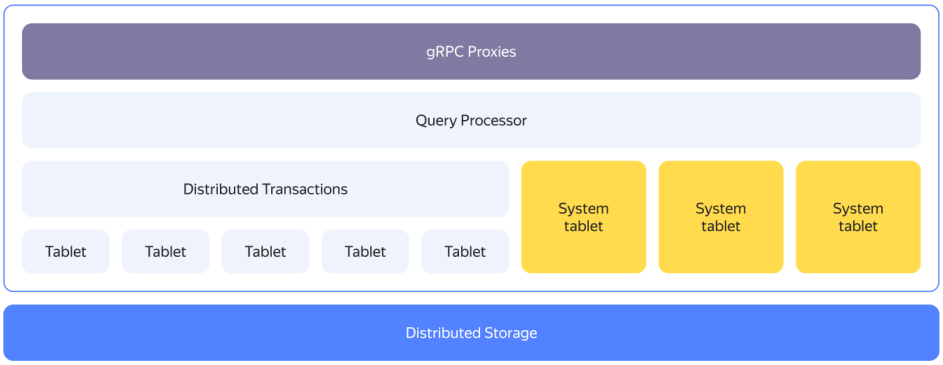
Introduction

YDB is a horizontally scalable, distributed, and fault-tolerant database system designed as a versatile platform for high performance — for example, a typical cluster node can process tens of thousands of queries per second. The system supports geographically distributed (cross-datacenter) configurations, ranging from small clusters with a few nodes to large-scale deployments of thousands of servers capable of efficiently handling hundreds of petabytes of data.

Key Features and Capabilities of YDB

- **Horizontal scaling and automatic sharding**: data and workload are dynamically distributed across available hardware resources as data volume or query intensity grows.
- **Fault tolerance**: automatic recovery from failures of nodes, racks, or availability zones.
- **Data high availability and durability**: ensured through automatic synchronous data replication within the cluster.
- **Strong consistency and ACID transactions**: the system provides distributed transactions with *serializable* isolation. Consistency and isolation levels can be relaxed when higher performance is required.
- **YQL**: a SQL dialect optimized for large-scale data and complex processing scenarios.
- **Relational data model**: supports both row-oriented and column-oriented tables, enabling efficient handling of both transactional (OLTP) and analytical (OLAP) workloads within a single system.
- **Hierarchical namespace**: tables, topics, and other objects are organized in a hierarchical namespace, similar to a filesystem.
- **Asynchronous replication**: near real-time data synchronization between YDB databases — both within a single cluster and across different clusters.
- **Streaming data processing and distribution**:
  - **Topics**: storage and streaming delivery of unstructured messages to multiple subscribers. Supports the Kafka protocol.
  - **Change Data Capture (CDC)**: built-in stream of table data changes published as a topic.
  - **Transfers**: automated data delivery from topics to tables.
- **Federated queries**: execute queries against external data sources (e.g., S3) as part of YQL queries, without prior data import to YDB storage.
- **Vector indexes**: support for storing and searching vector embeddings — ideal for semantic search, similarity matching, and ML use cases.
- **Observability**: built-in metrics, logs, and dashboards.
- **Security and audit**: data encryption (at-rest and in-transit), operation auditing, and support for authentication and authorization — see Security.
- **Tools, integrations, and APIs**: YDB CLI for running queries, administration, and debugging. SDKs for C++, C#, Go, Java, JavaScript, PHP, Python, and Rust. Integrations with various third-party systems. Learn more in Integrations YDB and Languages and APIs.
- **Open architecture**: source code is available under the Apache License 2.0. The system uses the open gRPC protocol, enabling client implementations in any programming language.

Key Use Cases



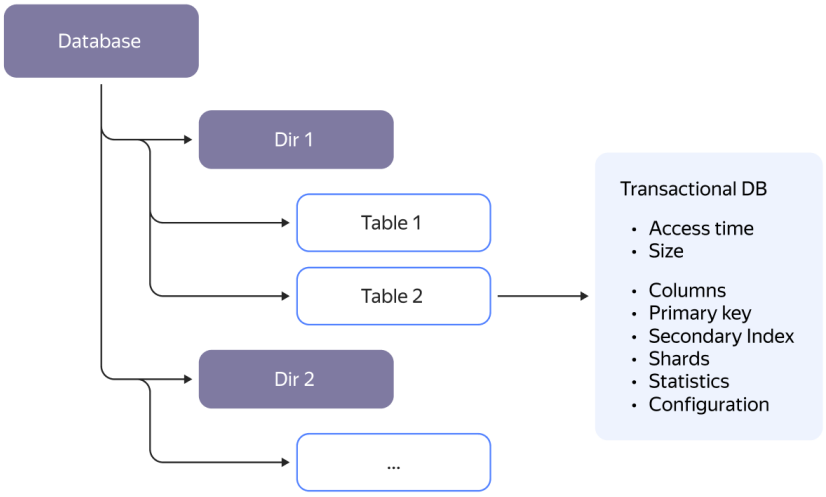
YDB is a versatile platform suitable for a wide range of scenarios requiring scalability, reliability, and flexibility. Typical use cases include:

- In distributed systems requiring **strong consistency or support for multi-row and multi-table transactions**. YDB combines NoSQL-like scalability with the consistency and integrity guarantees of relational databases.
- Systems that store and process **very large datasets** and require nearly unlimited horizontal scaling (production clusters with thousands of nodes, handling millions of RPS and petabytes of data).
- High-load systems relying on **manual sharding** of relational databases. YDB simplifies architecture by automatically handling the sharding logic, re-sharding, query routing, and cross-shard transactions out of the box.
- New product development with **uncertain load patterns** or expected scale beyond the limits of traditional relational database management systems (RDBMS).
- Projects requiring a **flexible platform** capable of handling diverse workloads and use cases — including transactional, streaming, and analytical.

How It Works?

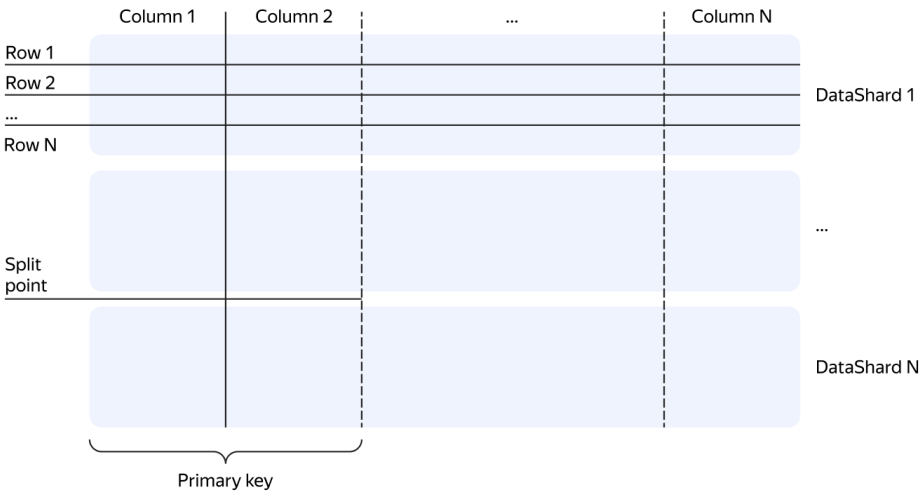
Fully explaining how YDB works in detail takes quite a while. Below you can review several key highlights and then continue exploring the documentation to learn more.

YDB Architecture



YDB clusters typically run on commodity hardware with a shared-nothing architecture. From a bird's eye view, YDB exhibits a layered architecture. The compute and storage layers are disaggregated; they can either run on separate sets of nodes or be co-located.

One of the key building blocks of YDB's compute layer is called a *tablet*. Tablets are stateful logical components implementing various aspects of YDB.



The next level of detail of the overall YDB architecture is explained in the General YDB schema article.

Hierarchy

From the user's perspective, everything inside YDB is organized in a hierarchical structure using directories. It can have arbitrary depth depending on how you choose to organize your data and projects. Even though YDB does not have a fixed hierarchy depth like in other SQL implementations, it will still feel familiar as this is exactly how any virtual filesystem looks.

Table

YDB provides users with a well-known abstraction — tables. In YDB, there are two main types of tables:

- Row-oriented tables are designed for OLTP workloads.
- Column-oriented tables are designed for OLAP workloads.

Logically, from the user's perspective, both types of tables look the same. The main difference between row-oriented and column-oriented tables lies in how the data is physically stored. In row-oriented tables, the values of all columns in each row are stored together. In contrast, in column-oriented tables, each column is stored separately, meaning that cells from different rows are stored next to each other within the same column.

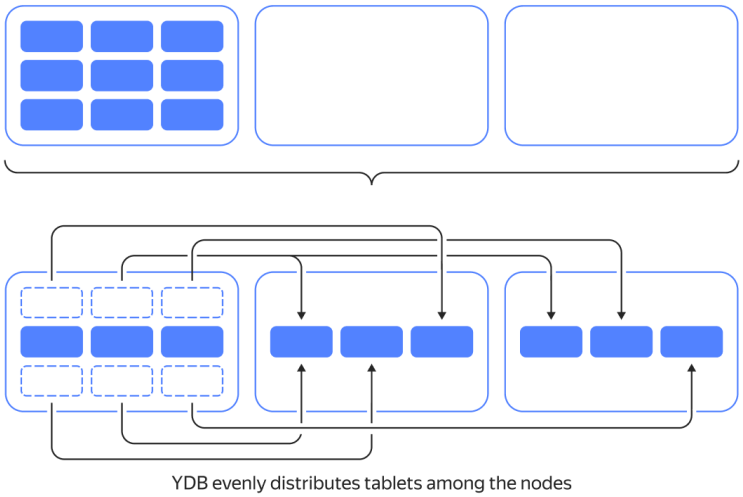
Regardless of the type, each table must have a primary key. Column-oriented tables can only have `NOT NULL` columns in primary keys. Table data is physically sorted by the primary key.

Partitioning works differently in row-oriented and column-oriented tables:

- Row-oriented tables are automatically partitioned by primary key ranges, depending on the data volume.
- Column-oriented tables are partitioned by the hash of the partitioning columns.

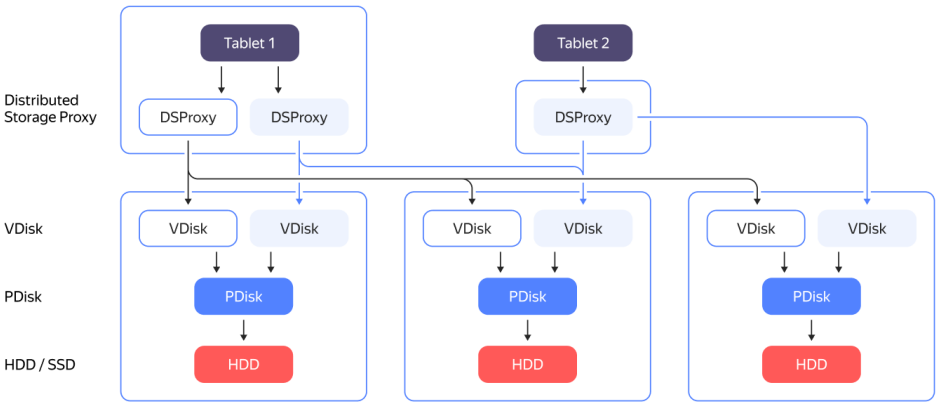
Each partition of a table is processed by a specific tablet, called a data shard for row-oriented tables and a column shard for column-oriented tables.

Split by Load



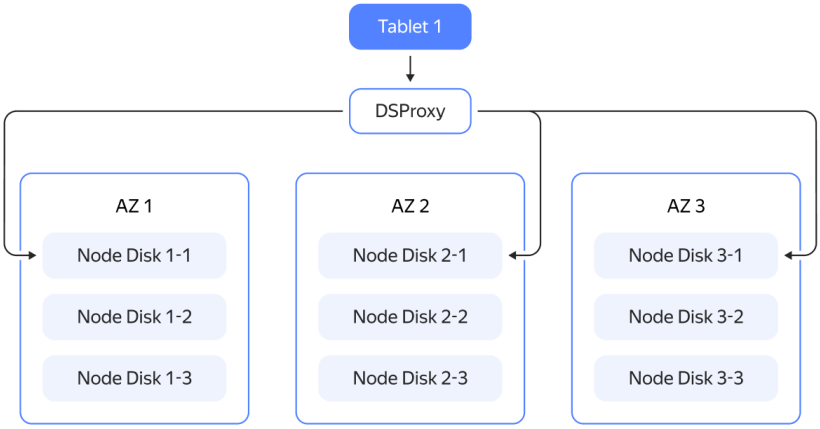
Data shards will automatically split into more as the load increases. They automatically merge back to the appropriate number when the peak load subsides.

Split by Size



Data shards will also automatically split when the data size increases. They automatically merge back if enough data is deleted.

Automatic Balancing



YDB evenly distributes tablets among available nodes. It moves heavily loaded tablets from overloaded nodes. CPU, memory, and network metrics are tracked to facilitate this.

YDB doesn't rely on any third-party filesystem. It stores data by directly working with disk drives as block devices. All major disk kinds are supported: NVMe, SSD, or HDD. The PDisk component is responsible for working with a specific block device. The abstraction layer above PDisk is called VDisk. There is a special component called DSProxy between a tablet and VDisk. DSProxy analyzes disk availability and characteristics and chooses which disks will handle a request and which won't.

Distributed Storage Proxy (DSProxy)

YDB writes data to 3 Availability Zones

A common fault-tolerant setup of YDB spans three datacenters or availability zones (AZ). When YDB writes data to three AZs, it doesn't send requests to obviously bad disks and continues to operate without interruption even if one AZ and a disk in another AZ are lost.

What's Next?

Overview of metadata distribution services

Metadata distribution services are three interconnected subsystems of the YDB cluster that deliver service information between nodes: **StateStorage**, **Board**, and **SchemeBoard**. All of them are built on a distributed quorum service with deterministic replica placement.

This article provides an overview of the purpose of the services without diving into internal identifiers and core mechanisms. A detailed description for core developers is in the Metadata distribution subsystems section. Configuration instructions are in the Configuring metadata distribution subsystems section.

Why metadata distribution services are needed

The YDB cluster is a distributed system in which millions of tablets can run simultaneously on thousands of nodes. Cluster components need to know:

- where the leader of a specific tablet runs and how to reach it (**StateStorage**).
- which nodes provide services, such as connection points for clients (**Board**).
- what the current database schema is (**SchemeBoard**).

Distributing this data from a single cluster node is bad — it creates high load and problems when that node fails. Therefore, metadata is distributed across many cluster nodes using three specialized subsystems.

StateStorage

StateStorage stores the current state of tablets: who is the leader now, the generation and step of leader election, and the list of replicas. By tablet id, through this service you can find out the current actor id, which allows interacting with it through the actor system.

> **Note**
>
> Data in StateStorage is **volatile**: it is stored in the memory of replicas and is restored on restart. This is not a long-term storage.

Board

Board is a service for publishing and subscribing to metadata in the format «path → set of records». The main use case is storing database endpoints: nodes publish addresses, clients and other components subscribe to changes.

SchemeBoard

SchemeBoard distributes schema metadata: tables, indexes, topics, access rights. Database nodes use it as a schema cache to avoid contacting SchemeShard on every query.

Comparison of services

Characteristic	StateStorage	Board	SchemeBoard
Purpose	Tablet state and leadership	Publishing service metadata	Schema distribution
Data type	Tablet leader state	Path → payload pairs	Schema object descriptions
Key	Tablet identifier	Path (string)	Path to schema object
Main consumers	Components interacting with tablets	gRPC proxies, clients	Database nodes

General principle

All three services use one architectural approach: a record is addressed by key, the set of replicas for a key is computed deterministically, and operations are performed by quorum. This ensures scalability and fault tolerance during rolling restarts and rack failures.

Details (replica rings, quorum, configuration changes, placement across failure domains) are described in the article Metadata distribution subsystems.

Connecting to a Database

To connect to a YDB database from the YDB CLI or an app running the YDB SDK, specify your endpoint and database path.

Endpoint

An endpoint is a string structured as `protocol://host:port` and provided by a YDB cluster owner for proper routing of client queries to its databases by way of a network infrastructure as well as for proper network connections. Cloud databases display the endpoint in the management console on the requisite DB page and also normally send it via the cloud provider's CLI. In corporate environments, YDB endpoint names are provided by the administration team or obtained in the internal cloud management console.

Examples:

- `grpc://localhost:7135` is an unencrypted data interchange protocol (gRPC) with the server running on port 7135 of the same host as the client.
- `grpcs://ydb.example.com` is an encrypted data interchange protocol (gRPCs) with the server running on the ydb.example.com host on an isolated corporate network and listening for connections on YDB default port 2135.
- `grpcs://ydb.serverless.yandexcloud.net:2135` is an encrypted data interchange protocol (gRPCs), public Yandex.Cloud Serverless YDB server at ydb.serverless.yandexcloud.net, port 2135.

Database Path

Database path (`database`) is a string that defines where the queried database is located in the YDB cluster. It has the format and uses the `/` character as separator. It always starts with a `/`.

A YDB cluster may have multiple databases deployed, with their paths determined by the cluster configuration. Like the endpoint, `database` for cloud databases is displayed in the management console on the desired database page, and can also be obtained via the CLI of the cloud provider.

For cloud solutions, databases are created and hosted on the YDB cluster in self-service mode without the involvement of the cluster owner or administrators.

> **Warning**
>
> Applications should not in any way interpret the number and value of `database` directories, since they are set in the YDB cluster configuration. When using YDB in Yandex.Cloud, `database` has the format `region_name/cloud_id/database_id`; however, this format may change going forward for new DBs.

Examples:

- `/ru-central1/b1g8skpblkos03malf3s/etn01q5ko6sh271beftr` is a Yandex.Cloud database with `etn01q3ko8sh271beftr` as ID deployed in the `b1g8skpbljhs03malf3s` cloud in the `ru-central1` region.
- `/local` is the default database for custom deployment using Docker.

Connection String

A connection string is a URL-formatted string that specifies the endpoint and path to a database using the following syntax:

```
<endpoint>?database=<database>
```

Examples:

- `grpc://localhost:7135?database=/local`
- `grpcs://ydb.serverless.yandexcloud.net:2135?database=/ru-central1/b1g8skpblkos03malf3s/etn01q5ko6sh271beftr`

Using a connection string is an alternative to specifying the endpoint and database path separately and can be used in tools that support this method.

A Root Certificate for TLS

When using an encrypted protocol (gRPC over TLS, or gRPCS), a network connection can only be continued if the client is sure that it receives a response from the genuine server that it is trying to connect to, rather than someone in-between intercepting its request on the network. This is assured by verifications through a chain of trust, for which you need to install a root certificate on your client.

The OS that the client runs on already includes a set of root certificates from the world's major certification authorities. However, the YDB cluster owner can use its own CA that is not associated with any of the global ones, which is often the case in corporate environments, and is almost always used for self-deployment of clusters with connection encryption support. In this case, the cluster owner must somehow transfer its root certificate for use on the client side. This certificate may be installed in the operating system's certificate store where the client runs (manually by a user or by a corporate OS administration team) or built into the client itself (as is the case for Yandex.Cloud in YDB CLI and SDK).

YDB Schema Objects

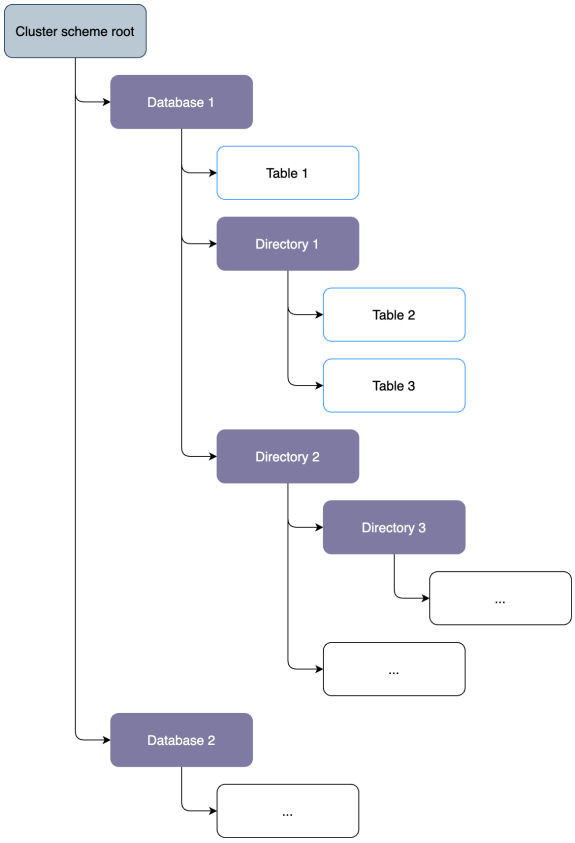
YDB supports the following types of schema objects:

- Directories
- Tables
- Views
- Topics
- Coordination nodes
- Secrets
- External tables
- External data sources

Schema objects are placed within the cluster namespace and are named according to the common naming rules that apply to all schema objects.

See Also

- Concepts YDB
- YDB Cluster Topology



Cluster Namespace and Object Naming

In YDB, all schema objects are organized into a hierarchical namespace called the **cluster schema**. This structure determines how databases, directories, and other objects are arranged and named, providing a clear and scalable way to manage data.

Cluster Schema

The cluster schema forms a tree-like hierarchy where:

- The **root** represents the top level of the namespace.
- At the first level are databases.
- Inside each database, you can create nested directories to build a custom hierarchy.
- Schema objects—such as tables, views, and indexes—can reside either at the database root or within any directory.

Naming Rules for Schema Objects

Every schema object in YDB has a name. In YQL expressions, object names are used as identifiers, which can be unquoted or enclosed in backticks (`` ` ``). For details on identifier syntax, see Keywords and identifiers.

Valid names for schema objects must meet the following criteria:

- **Allowed characters**:
  - Latin letters (`A-Z`, `a-z`)
  - Digits (`0-9`)
  - Special characters: `.`, `-`, and `_`
- **Maximum length**: 255 characters
- **Placement restrictions**: Objects cannot be created in directories with names that start with a dot (for example, `.sys`, `.metadata`, `.sys_health`)

Directory

For convenience, YDB supports creating directories similar to a filesystem, meaning the entire database consists of a directory tree, and scheme objects, such as tables, are located in the leaves of this tree. A directory can host multiple subdirectories and several scheme objects. The names of scheme objects within a single directory are unique.

Table

A table is a relational table containing a set of related data, composed of rows and columns. Tables represent entities. For instance, a blog article can be represented by a table named `article` with columns: `id`, `date_create`, `title`, `author`, and so on. Rows contain data, and columns define data types. For example, the `id` column cannot be empty (`NOT NULL`) and should contain only unique integer values. A record in YQL might look like this:

```
CREATE TABLE article (
    id Int64 NOT NULL,
    date_create Date,
    author String,
    title String,
    PRIMARY KEY (id)
)
```

YDB supports creating row-based and column-based tables. Their main difference lies in the use case and the data storage format on the hard disk. For row-based tables, data is stored sequentially as rows, while for column-based tables, data is stored as columns. Each table type has its own purpose.

Column Naming Rules

Column names in YDB must meet the following requirements:

- A column name can consist of the following characters:
  - Uppercase Latin letters
  - Lowercase Latin letters
  - Digits
  - Special characters: `-` and `_`.
- The length of a column name must not exceed 255 characters.
- Column names must not start with the system prefix `__ydb_`.

Row-Oriented Tables

Row-based tables are well suited for transactional queries generated by Online Transaction Processing (OLTP) systems, such as backends for weather services or online stores. Row-based tables provide efficient access to a large number of columns at once. Search in row-based tables is very fast due to the use of indexes.

An index is a data structure that increases the speed of data retrieval operations based on one or more columns. It is analogous to an index in a book: instead of scanning every page to find the needed section, you can refer to the index at the end of the book and quickly jump to the relevant page.

When a query is executed based on a column (or columns) for which an index has been created, the DBMS can use that index to quickly find the matching rows, avoiding a full scan of all data. For example, if you have an index on the "author" column and you search for all articles written by the author "Gray", the DBMS uses the index to quickly find all rows with that surname.

You can create a row-based table via the YDB web interface, using the CLI or SDK. Regardless of how you interact with YDB, remember the general rule for creating a row-based table: the table must have at least one key column, and creating a table consisting only of key columns is allowed.

By default, when creating a row-oriented table, all columns are optional and can have `NULL` values. This behavior can be modified by setting the `NOT NULL` conditions for key columns that are part of the primary key. Primary keys are unique, and row-oriented tables are always sorted by this key. This means that point reads by the key, as well as range queries by key or key prefix, are efficiently executed (essentially using an index). It's permissible to create a table consisting solely of key columns. When choosing a key, it's crucial to be careful, so we recommend reviewing the article: "Choosing a Primary Key for Maximum Performance".

Partitioning Row-Oriented Tables

A row-based table in the database can be partitioned by ranges of primary key values. Each partition of the table is responsible for its own range of primary keys. The key ranges served by different partitions do not overlap. Different partitions of the table can be served by different servers of the distributed database (including those located in different locations), and can also move independently between servers for rebalancing or to maintain partition health in case of server or network equipment failures.

With a small amount of data or low load, a table can consist of a single partition. As the data volume of a partition or the load on a partition grows, YDB automatically splits it into two:

- If the data volume exceeds the partition size threshold, splitting occurs by the median value of the primary key.
- If load increases, the partition first collects a sample of requested keys (read, written, and deleted) and, based on this sample, selects a key for splitting so that the load is distributed evenly between the new partitions. Thus, in the case of load-based splitting, the new partitions may have substantially different sizes.

The partition size threshold for splitting and enabling or disabling automatic splitting can be configured individually for each database table.

Regardless of the AUTO_PARTITIONING_PARTITION_SIZE_MB parameter value, YDB forcibly splits partitions whose size exceeds the force_shard_split_data_size parameter (2 GiB by default). At the same time, YDB does not restrict user settings and works in parallel with them. For example, if you set the partition size to 100 MiB and the limit to 10 partitions, the table stops splitting when it reaches 10 partitions of 100 MiB each, and partition sizes begin to grow. When any partition exceeds the `force_shard_split_data_size` parameter value, it splits, and the table has 11 partitions. If the combined size of two adjacent partitions drops to 50% of the AUTO_PARTITIONING_PARTITION_SIZE_MB parameter value, they merge, and the table has 10 partitions again.

In addition to automatic splitting, you can create an empty table with a predefined number of partitions. You can manually set exact key split boundaries for partitions or specify uniform distribution across a predefined number of partitions. In the latter case, boundaries are created based on the first component of the primary key. Uniform distribution can be specified for tables whose first primary key component is an integer with data type `Uint64` or `Uint32`.

Partitioning parameters apply only to the table itself, not to secondary indexes built on its data. Each index is served by its own set of partitions, and decisions to split or merge its partitions are made independently based on default settings. In the future, these settings may become available to users, similar to the settings of the main table.

The typical duration of a split or merge operation is about 500 ms. During this time, the data involved in the operation becomes briefly unavailable for reads and writes. Specialized wrapper methods in the YDB SDK automatically retry when they detect that a partition is in the process of splitting or merging, without surfacing this information to the application level. It is important to note that if the system is overloaded for any reason (for example, due to insufficient CPU or bandwidth of the allocated disk resources), split and merge operations may take longer.

The data schema defines the following table partitioning parameters:

AUTO_PARTITIONING_BY_SIZE

- Type: `Enum` (`ENABLED`, `DISABLED`).
- Default value: `ENABLED`.

Automatic partitioning by partition size. If a partition size exceeds the value specified by the AUTO_PARTITIONING_PARTITION_SIZE_MB parameter, it is enqueued for splitting. If the total size of two or more adjacent partitions is less than 50% of the AUTO_PARTITIONING_PARTITION_SIZE_MB value, they are enqueued for merging.

AUTO_PARTITIONING_BY_LOAD

- Type: `Enum` (`ENABLED`, `DISABLED`).
- Default value: `DISABLED`.

Load-based automatic partitioning mode. If a partition consumes more than 50% CPU for several tens of seconds, it is queued for splitting (split). If the total load on two or more adjacent partitions is less than 35% of one CPU core for an hour, they are queued for merging (merge).

When deciding to split a partition by load or merge multiple partitions by load, YDB considers the CPU load on both the leader of the partition and all its replicas.

Performing split or merge operations uses the CPU and takes time. Therefore, when dealing with a variable load, we recommend both enabling this mode and setting AUTO_PARTITIONING_MIN_PARTITIONS_COUNT to a value other than 1. This ensures that a decreased load does not cause the number of partitions to drop below the required value, resulting in a need to split them again when the load increases.

When choosing the minimum number of partitions, it makes sense to consider that a single table partition can reside on only one server and use no more than 1 CPU core for data modification operations. Based on this, for a table that may experience high load, you can set the minimum number of partitions to at least the number of nodes (servers), or better, on the order of the number of CPU cores allocated to the database.

AUTO_PARTITIONING_PARTITION_SIZE_MB

- Type: `Uint64`.
- Default value: `2000 MB` (`2 GB`).

The desired partition size threshold in megabytes. Recommended values range from `10 MB` to `2000 MB`. If this threshold is exceeded, a shard may split.
The specified value serves only as a recommendation for splitting. Splitting may not occur even if the configured size is exceeded.
This setting applies when the `AUTO_PARTITIONING_BY_SIZE` mode is enabled.

AUTO_PARTITIONING_MIN_PARTITIONS_COUNT

- Type: `Uint64`.
- Default value: `1`.

Partition merging (merge) is performed only if the actual number of partitions exceeds the value set by this parameter. When using load-based automatic partitioning, it is recommended to set this parameter to a value other than 1 so that periodic load drops do not reduce the number of partitions below the required level.

AUTO_PARTITIONING_MAX_PARTITIONS_COUNT

- Type: `Uint64`.
- Default value: `50`.

Partition splitting (split) is performed only if the number of partitions does not exceed the value set by this parameter. With any enabled automatic partitioning modes, it is recommended to set a meaningful value for this parameter and monitor the actual number of partitions approaching it; otherwise, partitions will eventually stop splitting as data or load grows, leading to a failure.

UNIFORM_PARTITIONS

- Type: `Uint64`.
- Default value: not applicable.

The number of partitions for uniform initial table partitioning. The primary key's first column must have type `Uint64` or `Uint32`. A created table is immediately divided into the specified number of partitions.

When automatic partitioning is enabled, make sure to set the correct value for AUTO_PARTITIONING_MIN_PARTITIONS_COUNT to avoid merging all partitions into one immediately after creating the table.

PARTITION_AT_KEYS

- Type: `Expression`.
- Default value: not applicable.

Boundary values of keys for initial table partitioning. It's a list of boundary values separated by commas and surrounded with brackets. Each boundary value can be either a set of values of key columns (also separated by commas and surrounded with brackets) or a single value if only the values of the first key column are specified. Examples: `(100, 1000)`, `((100, "abc"), (1000, "cde"))`.

When automatic partitioning is enabled, make sure to set the correct value for AUTO_PARTITIONING_MIN_PARTITIONS_COUNT to avoid merging all partitions into one immediately after creating the table.

Reading Data from Replicas

When executing queries in YDB, the actual execution of a query to each partition is performed at a single point that serves the distributed transaction protocol. However, thanks to storing data on shared storage, it is possible to launch one or more replicas of a partition without allocating additional storage space — the data is already stored replicated, and more than one reader can be served

(but the writer is still strictly one at any given moment).

Using read replicas provides the following capabilities:

- Serve clients that are critical to minimal latencies that cannot be achieved otherwise in a multi-DC cluster. This is achieved by bringing the query execution point closer to the query submission point, which eliminates the inter-DC transfer latency. As a result, while preserving all the multi-DC cluster's storage reliability guarantees, point read queries can be answered in milliseconds.
- Serve read requests from replicas without affecting modifying requests running on the partition. This can be useful both for isolating different scenarios and for increasing the partition's throughput.
- Continue serving during partition leader moves (both routine during balancing and during failures). This allows surviving cluster processes without affecting read clients.
- Overall, increase the read performance limit of partitions if many read requests hit the same keys.

In the table data schema, you can specify the need to launch read replicas for each table partition. Read replica accesses typically occur without leaving the data center network, which ensures response times in milliseconds:

Parameter name	Description	Type	Allowed values	Can be changed	Can be reset
`READ_REPLICAS_SETTINGS`	`PER_AZ` means using the specified number of replicas in each AZ and `ANY_AZ` in all AZs in total.	String	`"PER_AZ:<count>"`, `"ANY_AZ:<count>"`, where `<count>` is the number of replicas. To remove replicas, set the value to 0. For example: "PER_AZ:0".	Yes	No

The internal state of each replica is restored exactly from the leader's state and is fully consistent.

Besides the data state in storage, followers also receive a stream of updates from the leader. Updates are sent in real time, immediately after the commit to the log. However, they are sent asynchronously, resulting in some delay (usually no more than dozens of milliseconds, but sometimes longer in the event of cluster connectivity issues) in applying updates to followers relative to their commit on the leader. Therefore, reading data from followers is only supported in the transaction mode `StaleReadOnly()`.

If there are multiple replicas, their lag behind the leader may differ, i.e., although each replica of each partition maintains internal consistency, artifacts may be observed between different partitions. Application code must be prepared for this. For the same reason, it is currently impossible to execute cross-shard transactions from replicas.

Deleting Expired Data (TTL)

YDB supports automatic background deletion of expired data. A table data schema may define a column of a suitable type; the value in this column is compared with the current time for all rows in the background. Rows for which the current time becomes greater than the column value plus the specified delay are deleted.

Parameter name	Type	Allowed values	Can be changed	Can be reset
`TTL`	Expression	`Interval("<literal>") ON <column> [AS <unit>]` or `Interval("literal1") action1, ..., Interval("literal1") action1 ON <column> [AS <unit>]`	Yes	Yes

Syntax of TTL value is described in the article Time to Live (TTL). For more information about deleting expired data, see Time to Live (TTL).

Renaming a Table

YDB allows you to rename an existing table, move it to another directory in the same database, and replace one table with another, in which case the data of the replaced table is deleted. When performing operations, only the table metadata changes, such as its path and name. The table data is not moved or overwritten.

Operations are performed in isolation; the external process sees only two states of the table: before and after the operation. This is critical, for example, for table replacement: the data of the replaced table is deleted by the same transaction that renames the replacing table. During the replacement, there might be errors in queries to the replaced table that have retryable statuses.

The speed of the rename operation is determined by the type of data transactions currently running on the table and does not depend on the amount of data in the table.

- Renaming a table in YQL
- Renaming a table via the CLI

Local Bloom skip indexes

Using a Bloom filter allows more efficiently determining the absence of keys in a table during multiple point lookups by primary key, reducing the number of required disk I/O operations at the cost of increased memory consumption.

The recommended way to manage bloom filters on row-oriented tables is via local Bloom skip indexes (`LOCAL USING bloom_filter`), created with ALTER TABLE ... ADD INDEX and removed with ALTER TABLE ... DROP INDEX. For details, see Bloom skip indexes.

Warning

Parameter name	Type	Allowed values	Can be changed	Can be reset
`KEY_BLOOM_FILTER`	Enum	`ENABLED`, `DISABLED`	Yes	No

The `KEY_BLOOM_FILTER` setting is deprecated. It enables a bloom filter over the full primary key and, when set to `DISABLED`, clears all bloom filters on the table.

Column Groups

YDB allows you to group columns in a table to optimize their storage and usage. The column group mechanism improves the performance of partial row read operations by splitting the storage of table columns into multiple groups. The most common scenario is storing rarely used attributes in a separate column group. This way, you can enable data compression and/or store them on slower storage devices.

Each column group has its own name, unique within the table. Column group composition is set during table creation and can be modified later. Removing column groups from an existing table is not supported.

A column group can contain any number of columns from its table. Each table column belongs to one and only one column group (column groups do not overlap).

Every table has a primary column group named `default` containing all columns not explicitly assigned to another group. Primary key columns always belong to the primary column group and cannot be moved to another group. Also, if there are no other column groups, changing attributes of the primary column group lets you set attributes for the entire table.

For a column group, attributes that affect data storage and caching are set:

- the type of storage devices used (SSD or HDD, with availability depending on the YDB cluster configuration)
- Data compression mode (no compression or LZ4 algorithm compression);
- caching mode.

Column group attributes are set during table creation and can be modified later. Storage attribute changes aren't immediately applied to existing data; instead, they take effect during subsequent background LSM compaction. Caching attribute changes take effect immediately.

Access to data stored in the fields of the main column group is faster and requires fewer resources than access to data of the same table row stored in the fields of additionally created column groups. Primary key lookup is always performed in the main column group. When accessing fields in other column groups, in addition to the primary key lookup, additional lookup operations are required to determine the specific storage position of these fields. Changing the caching mode does not affect the need for additional operations for non-main columns, so with the same caching modes, access to the main column group will also be faster.

Thus, moving some table columns to a separate column group speeds up reading of the most important and frequently used columns (those in the main column group) at the cost of somewhat slower access to the remaining columns. In addition, column groups allow you to manage data storage parameters, such as the type of storage devices, compression mode, and caching parameters.

Caching modes

You can set caching modes for column groups. Caching modes in YDB allow you to control the strategy for caching table data in RAM. This is especially important for optimizing response time when reading small, frequently used tables. Two caching modes are supported:

- `regular` (default);
- `in_memory`.

In the `regular` caching mode, column group data is loaded into the shared cache only on first access. If a column group uses the `in_memory` mode, its data is automatically preloaded into the cache when the system starts.

When the total amount of data in the cache exceeds the configured limit, memory occupied by pages with the `regular` mode is freed first. If that is not enough, pages with the `in_memory` mode are evicted. Thus, the `in_memory` mode provides priority storage in RAM, but the cache size remains limited by the configuration — memory is not used without limit.

The `in_memory` caching mode can be useful in various scenarios. One common scenario is storing small lookup tables that fit entirely in RAM. In this case, using the `in_memory` mode minimizes access latency because the table always remains in memory, even if it is accessed irregularly.

However, this is not the only use case. For example, in some cases it may be advisable to store all data of a particular table in memory, regardless of its purpose, if the application business logic requires constant fast access to the full version of the table.

When using the `in_memory` mode, remember that memory allocated to such tables reduces the amount available for caching regular tables, which may negatively affect their performance (increase latency).

Note that the `in_memory` caching mode affects read operations only. Write operations are written to disk regardless of the mode, so data durability guarantees remain unchanged. This distinguishes YDB caching modes from some other in-memory DBMSs that may keep entire tables in memory at the cost of reduced data durability guarantees.

Custom attributes

User attributes allow you to add arbitrary information to table metadata. This information is not interpreted by the server, but can be interpreted by the database client (a person or, more often, a program).

Attributes are specified as a key-value pair. The key and value of an attribute can only be a string or a type that can be represented as a string (for example, using base64 encoding).

User attribute keys and values have the following restrictions:

- Key length: 1–100 bytes
- Value length: 1–4096 bytes
- Maximum total size of attributes (sum of lengths of all keys and values): 10240 bytes.

To add, change, retrieve current values, or delete attributes, see Custom attributes in tables.

Column-Oriented Tables

Columnar tables YDB store data of each column separately (independently) from other columns. This data storage principle is optimized for Online Analytical Processing (OLAP) workloads, because when executing a query, only the columns that directly participate in the query are read. Another advantage of this approach is a high degree of data compression, since columns often store repeated or similar data. The downside is that performing operations on rows becomes more expensive.

At the moment, the main use case for YDB column-oriented tables is writing data with an increasing primary key (for example, event time), analyzing this data, and deleting outdated data based on TTL. The optimal way to add data to YDB column-oriented tables is batch upload, performed in MB-sized blocks. Data packet insertion is atomic: data will be written either to all partitions or none.

In most cases, working with columnar tables YDB is similar to working with row-based tables, but there are differences:

- Only `NOT NULL` columns can be used as the primary key.
- Data is partitioned not by the primary key, but by the hash of the partitioning columns.
- Columnar tables support a limited set of data types:
  - Available in both the primary key and other columns: `Date`, `Datetime`, `Timestamp`, `Int32`, `Int64`, `Uint8`, `Uint16`, `Uint32`, `Uint64`, `Utf8`, `String`;
  - Available only in columns not included in the primary key: `Decimal`, `Double`, `Float`, `Int8`, `Int16`, `JsonDocument`, `Json`, `Yson`.
- You can configure compression and encoding individually for each column. For details, see CREATE TABLE request parameters.

Let's recreate the `article` table, this time in column-oriented format, using the following YQL command:

```
CREATE TABLE article_column_table (
    id Int64 NOT NULL,
    author String,
    title String,
    PRIMARY KEY (id)
)
WITH (STORE = COLUMN);
```

Local Bloom skip indexes

In column-oriented and row-oriented tables you can define local Bloom skip indexes on columns with `LOCAL USING bloom_filter` or `LOCAL USING bloom_ngram_filter`, either during table creation or with ALTER TABLE ADD INDEX. See local indexes and Bloom skip indexes.

Local min_max index

In columnar tables, you can define a local min_max index on columns using `LOCAL USING min_max`. The index is defined when creating a table or added via ALTER TABLE ADD INDEX. For more details: local indexes, min_max index.

Partitioning Column-Oriented Tables

Unlike row-based tables YDB, columnar tables partition data not by primary keys, but by dedicated keys: partitioning keys. Partitioning keys are a subset of the table's primary keys.

Unlike data partitioning in row-based tables YDB, data partitioning for columnar tables is performed not by key values, but by hash values of the keys, which allows data to be evenly distributed across all existing partitions. Such partitioning helps avoid hotspots during insertion and speeds up analytical queries that process (read) large amounts of data.

The choice of partitioning keys substantially affects the performance of column-oriented tables. For more information, see "Choosing a primary key for maximum performance of column-oriented tables".

To manage data partitioning, an additional partitioning parameter is used: AUTO_PARTITIONING_MIN_PARTITIONS_COUNT. Other partitioning parameters are ignored for columnar tables.

AUTO_PARTITIONING_MIN_PARTITIONS_COUNT defines the minimum physical number of partitions for storing data.

Type: `Uint64`.

Default value: 64.

Given that other partitioning parameters are ignored, this same value also determines the maximum number of partitions.

Column-oriented table limitations

Currently, not all columnar table functionality is implemented. The following are not supported:

- Reading from replicas.
- Global secondary indexes.
- Vector and full-text indexes.
- Bloom filter for the primary key (`KEY_BLOOM_FILTER`; see Bloom filter for row-oriented tables).
- Change Data Capture.
- User-defined table attributes.

View

A view logically represents a table formed by a given query. The view itself contains no data. The content of a view is generated every time you `SELECT` from it. Thus, any changes in the underlying tables are reflected immediately in the view.

Views are often used to:

- Hide query complexity
- Limit access to underlying data
- Provide a backward-compatible interface to emulate a table that used to exist but whose schema has changed

> **Warning**
>
> The scenario of creating a view to grant other users partial `SELECT` privileges on a table that has sensitive data has not been implemented yet. In YDB, the view's stored query can only be executed on behalf of the user querying the view. A user cannot access data from a view that reads from a table that they don't have privileges to `SELECT` from. See the `security_invoker` option description on the `CREATE VIEW` page for details.

View Invalidation

If you drop a table that a view references, the view will become invalid. Queries against it will fail with an error caused by referencing a table that does not exist. To make the view valid again, you must provide a queryable entity with the same name (by creating or renaming a table or another view). It needs to have a schema compatible with the deleted one. The dependencies of views on tables and other views are not tracked. A `SELECT` from a view is executed like a `SELECT` from a subquery would, without any prior checks of validity. You would know that the view's query became invalid only at the moment of its execution. This approach will change in future releases: YDB will start tracking the view's dependencies, and the default behavior would be to forbid dropping a table if there's a view referencing it.

Performance

Queries are executed in two steps:

1. Compilation
2. Execution of the compiled code

The resulting compiled code contains no evidence that the query was made using views because all the references to views should have been replaced during compilation by the queries that they represent. In practice, there must be no difference in the execution time of the compiled code (step 2) for queries made using views versus queries directly reading from the underlying tables.

However, users might notice a slight increase in the compilation time of the queries made using views compared to the compilation time of the same queries written directly. It happens because a statement reading from a view:

```
SELECT * FROM a_view;
```

is compiled similarly to a statement reading from a subquery:

```
SELECT * FROM (SELECT * FROM underlying_table);
```

but with an additional overhead of loading data from the schema object `a_view`.

Please note that if you execute the same query over and over again, like:

```
-- execute multiple times
SELECT * FROM hot_view;
```

compilation results will be cached on the YDB server side, and you will not notice any difference in the performance of queries using views and direct queries.

View Redefinition Lag

> **Warning**
>
> Execution plans of queries containing views are currently cached. It might lead to the usage of an old query plan for a short while after a given view has been redefined. This is going to be fixed in future releases. See below for a more detailed explanation.

Query Compilation Cache

YDB caches query compilation results on the server side for efficiency. For small queries like `SELECT 1;` compilation can take significantly more time than the execution.

The cache entry is searched by the text of the query and some additional information, such as a user SID.

The cache is automatically updated by YDB to stay on track with the changes made to the objects the query references. However, in the case of views, the cache is not updated in the same transaction in which the object's definition changes. It happens with a slight delay.

Example of the Problem

Let's consider the following situation. Alice repeatedly executes the following query:

```
-- Alice's session
SELECT * FROM some_view_which_is_going_to_be_redefined;
```

while Bob redefines the view's query like this:

```
-- Bob's session
DROP VIEW some_view_which_is_going_to_be_redefined;
CREATE VIEW some_view_which_is_going_to_be_redefined ...;
```

The text of Alice's query does not change, which means that the compilation will happen only once, and the results are going to be taken from the cache since then. Bob changes the definition of the view, and the cache entry for Alice's query should theoretically be evicted from the cache in the same transaction in which the view was redefined. However, this is not the case. Alice's query will be recompiled with a slight delay, which means that for a short period of time, Alice's query will produce results that are inconsistent with the updated definition of the view. This is going to be fixed in future releases.

Topic

A topic in YDB is an entity for storing unstructured messages, designed to deliver them to multiple subscribers. In fact, a topic is a named set of messages.

A writer application writes messages to a topic. Reader applications are independent of each other; they receive, or "read", messages from the topic in the order they were written. The topic implements the publisher-subscriber architectural pattern.

The YDB topic has the following properties:

- At-least-once guarantees when reading messages by subscribers.
- Exactly-once guarantees when publishing messages (message deduplication).
- Guarantees of sequential message processing (FIFO) for messages published with the same source identifier.
- Scaling of message throughput for messages published with different sequence identifiers.

Messages

Data is transmitted as message streams. A message is the minimum indivisible unit of user information. Messages consist of a body and attributes, as well as additional system properties. The content of messages is a set of bytes that is not interpreted by YDB in any way.

Messages can contain user attributes in the "key-value" format. They are returned together with the message body when reading. User attributes allow the reader to decide whether to process the message without unpacking the message body. Message attributes are set when initializing a write session. This means that all messages written within a single write session will have the same attributes when read.

Partitioning

For horizontal scaling, a topic is divided into separate elements, *partitions*, which are units of parallelism. Each partition has limited throughput; the recommended write speed is up to 1 MB/s.

> **Note**
>
> Currently, reducing the number of partitions in a topic is only supported by deleting and recreating the topic with fewer partitions.

There are two types of partitions:

- **Active.** All partitions by default; both writing and reading are supported.
- **Inactive.** Only reading is possible from them. Inactive partitions appear after a partition split when auto-partitioning is enabled. Inactive partitions are automatically deleted when all messages from such a partition have been deleted after the retention period expires.

Offset

All messages within a partition have a unique sequence number called `offset` (offset). The offset increases monotonically as new messages are written.

Auto-partitioning

The number of topic partitions and their throughput are set when creating the topic and determine the total write throughput of the topic. If the maximum required write speed to the topic is unknown at creation time or will change over time, you can use auto-partitioning to dynamically scale the topic. If auto-partitioning up is enabled on the topic, the number of partitions in such a topic automatically increases as the write speed grows (see Auto-partitioning modes for details).

Guarantees

1. The SDK and server provide exactly-once write guarantees in case of partition splits. This means that any message will be written either to the parent partition or to one of the child partitions. A message cannot be written to both the parent and child partitions simultaneously. Moreover, a message cannot be written to the same partition multiple times.
2. The SDK and server ensure read order. Data will be read from parent partitions first, and only then from child partitions.
3. Thus, the exactly-once write and read order guarantees continue to hold for a specific source identifier (producer-id).

Auto-partitioning modes

The following auto-partitioning modes are available for any topic.

Disabled (DISABLED)

Auto-partitioning is disabled. In this case, the number of partitions remains unchanged, and automatic scaling does not occur.

The initial number of partitions is specified when creating the topic. When manually changing the number of partitions in this mode, new partitions are added. All previously existing partitions remain active.

Increase (UP)

The topic has auto-partitioning 'up' enabled, meaning that when the write speed increases, the number of partitions increases. When the write speed decreases, the number of partitions remains unchanged.

Algorithm for increasing the number of partitions: if within a specified time the write speed to a partition exceeds the specified threshold (as a percentage of the maximum write speed to the partition), that partition is split into two. The original partition becomes inactive, and data can only be read from it. When the message retention period for that partition expires and all messages are deleted, the partition itself is also deleted. The two new child partitions become active, and both reading and writing are possible in them.

Pause (PAUSED)

Auto-partitioning on the topic is paused. Automatic increase in the number of partitions does not occur. If necessary, you can re-enable the partition increase mode.

Examples of YQL queries for switching the topic to various auto-partitioning modes can be found here.

Note

The DOWN and UP_AND_DOWN auto-partitioning modes are currently under development and are not supported in the current version.
The UP_AND_DOWN mode is currently implemented as UP.

Limitations

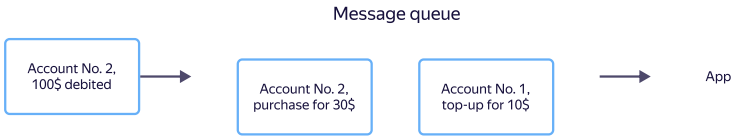
The following limitations apply when using auto-partitioning:

1. If auto-partitioning is enabled on a topic, it cannot be disabled, only paused.
2. If auto-partitioning is enabled on a topic, writing to or reading from such a topic via the Kafka API protocol is not possible.
3. Auto-partitioning cannot be enabled on a topic with the local storage mode.

Sources

A source identifier, `producer_id`, is a way to order a set of messages. The order of written messages is preserved within `producer_id`.

On first use, the source identifier `producer_id` is bound to a topic partition using a round-robin algorithm, and all messages with this `producer_id` end up in the same partition. The binding is removed if no new messages using this source identifier appear within 14 days.



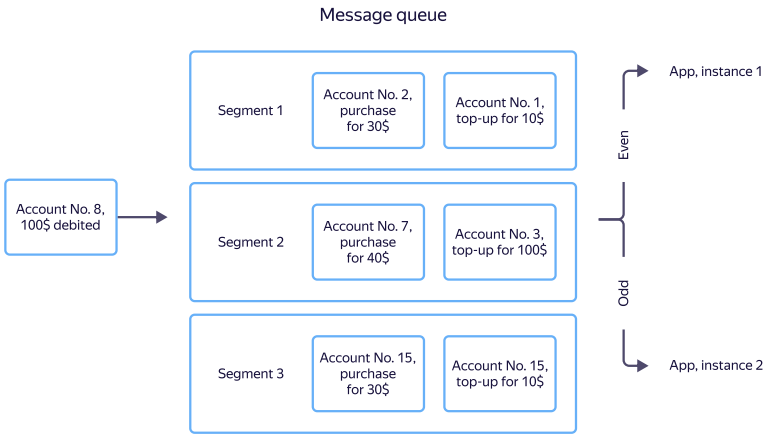
Warning

The recommended maximum number of `producer_id` is up to 100,000 per partition over the last 14 days. For reference, this is approximately 5 new `producer_id` per minute around the clock.

When message processing order matters

Consider a financial application whose task is to calculate the user's account balance and allow or deny debiting funds.

To solve such problems, you can use a message queue. When a deposit, withdrawal, or purchase is made, a message with the account ID, amount, and operation type is written to the queue. The application processes incoming messages and calculates the balance.



For correct balance calculation, the order of message processing is important. If a user first deposits money and then makes a purchase, the messages with information about these operations must be processed by the application in the same sequence. Otherwise, a business logic error may occur, and, for example, the application will reject the purchase due to insufficient funds. Message queues have mechanisms for guaranteed delivery order, but they cannot ensure the order of messages within a single queue for arbitrary data volumes.

When multiple application instances read messages from a stream, one instance may receive the deposit message and another the withdrawal message. In this case, there is no instance that is guaranteed to have the correct balance information. To solve this problem, you can store data in a DBMS, exchange information between application instances, build a distributed cache, etc.

In YDB, you can write data so that messages from one source arrive at the same application instance. To do this, messages from each source are written with their unique source identifiers (`producer_id`), and a message sequence number from the source (`seqno`) is used to protect against duplicates. In YDB, messages with the same `producer_id` end up in the same partition. When reading from a topic, each reader instance serves its own subset of partitions, thus eliminating the need for synchronization between instances. For example, using this approach, you can ensure that messages about transactions for the same account always end up in the same partition and are processed by the application instance associated with that partition.

Below is an example where all transactions for accounts with even identifiers are sent to the first application instance, and those with odd identifiers to the second.

If processing order is not important

For some tasks, the order of message processing is not critical. For example, sometimes it is important just to deliver the data, and the storage system will handle ordering.

For such cases, you can use a simplified write mode called "write without deduplication". In this mode, you do not need to specify message source identifiers (`producer_id`) and message sequence numbers — `sequence number`. Write without deduplication is faster and consumes fewer server resources, but message ordering and deduplication do not occur on the server. This means that if you send the same message again (for example, after a crash and subsequent restart of the writing process), it may be written more than once.

Message sequence numbers

All messages from one source have a sequence number, `sequence number`, used for deduplication. The message sequence number must increase monotonically within the pair `topic`, `source`. When the server receives a message with a sequence number less than or equal to the maximum recorded for the pair `topic`, `source`, the message will be skipped as a duplicate. Gaps in the sequence of message numbers are allowed. Message sequence numbers must be unique only within the pair `topic`, `source`.

Not used if the write mode without deduplication is selected.

Examples of message sequence numbers

Type	Example	Description
File	Offset of transmitted data from the beginning of the file	You cannot delete rows from the beginning of the file, as this will lead to skipping part of the data, duplicates, or loss of part of the data.
Database table	Auto-increment record identifier	

Message retention time

Each topic has a defined message retention time. After the retention time expires, messages are automatically deleted. An exception is data that has not yet been acknowledged by an "important" reader — it will be stored until the reader processes it. If there is a reader with an explicitly specified availability time, the retention time of unprocessed messages is increased to the specified value.

Data compression

During transmission, the writer application indicates that the message can be compressed using one of the supported codecs. The codec name is passed during writing and stored with the message, and is also returned on reading. Message compression is performed individually for each message; batch compression is not supported. Data compression and decompression operations are performed on the reader and writer application side.

The list of supported codecs is explicitly specified in each topic. Attempting to write data to a topic with an unsupported codec will result in a write error.

Codec	Description
`raw`	No compression.
`gzip`	Compression using the gzip algorithm.

| | Compression using the `lzop` algorithm. |

| | Compression using the `zstd` algorithm. |

Reader

A reader is a named entity for reading data from a topic. The reader contains read positions confirmed by the reader for each topic read on its behalf.

A read session is a client connection to a topic to receive messages on behalf of a reader. Read sessions work through the Topic API. A single reader can establish multiple read sessions: in this case, topic partitions are distributed among these sessions. To work with read sessions, it is recommended to use the YDB SDK (see Working with topics).

In YDB, readers can be of the following types:

- **streaming** — a reader type where a partition is exclusively assigned to one consumer, and all messages from that partition are processed by that consumer.
- **shared (common)** — a reader type that allows multiple consumers to jointly process messages from a single topic without exclusive assignment of partitions to each of them.

Streaming reader

A streaming reader is designed for streaming data processing from a topic. In this mode, multiple instances of the consumer application read messages in parallel and process them as they arrive. Typical scenarios include collecting and analyzing application logs, building real-time aggregates, and replicating events to external systems.

You can read from a topic using a streaming reader via the Topic API and the Kafka protocol.

In streaming mode, each partition of a topic is assigned to at most one consumer at any given time. All messages from the assigned partition are processed by that consumer.

The YDB server is responsible for distributing partitions among consumers. When consumers connect and disconnect, the server redistributes partitions and aims to distribute them as evenly as possible among active consumers.

The number of partitions determines the maximum degree of parallelism: no more consumers than partitions can read from a topic simultaneously. If there are more consumers than partitions, some instances remain without assigned partitions and are idle until free partitions become available or the number of consumers decreases.

Shared (common) reader

A shared (common) reader in YDB is a reading model from a topic where one or more messages from the topic are assigned to the reader, rather than an entire topic partition. This allows a single partition to be processed simultaneously by a large number of consumers.

A typical use case is message exchange between microservices. Reading from a topic using a shared (common) reader is possible via the Amazon SQS protocol.

A message is locked for a consumer for a certain period of time. If during this time the consumer has not reported completion of message processing and has not extended its processing time, it means that the consumer could not process the message, and the message becomes available for reading and will be read again. The processing time is configured in the reader parameters, but can also be set for each message read request.

A Dead letter policy is applied to messages that cannot be processed. The Dead letter policy can be configured in one of the following ways:

- **none** — the message is returned to the queue after unsuccessful processing and will later be given for re-reading.
- **move** — the message is moved to a DLQ after several processing attempts; any other database topic can be specified as the DLQ.
- **delete** — the message is deleted after several processing attempts.

By default, the Dead letter policy is disabled (none). The number of message processing attempts before moving it to a DLQ (move) or deleting it (delete) is configured on the reader. If the message cannot be moved to the DLQ, it is returned to the queue (as when the Dead letter policy is disabled), and on the next unsuccessful attempt to process the message, another attempt will be made to move the message to the DLQ. For example, if you delete the topic specified as the DLQ, messages after unsuccessful processing will be returned to the queue until the topic specified as the DLQ is created or another existing topic is specified.

Depending on the configuration of the shared (common) reader, reading from a topic can be performed either with or without preserving message order. Message order is preserved among messages with the same message-group-id, which can be set for each message when it is written. If the shared (common) reader is configured to read with message order preservation, then at any given time, such a reader delivers no more than one message from a single message-group-id to consumers for processing.

When placing a message in the queue, you can specify a delay before the message is given for processing for the first time. Message order is determined by the time the message was added to the topic — if reading is performed with message order preservation, a delayed message will pause the delivery for processing of all subsequent messages with the same message-group-id.

See also Shared topic consumer: architecture and limitations.

Reading position

The reading position is the saved offset of the reader for each partition of the topic. The reading position is saved by the reader after sending an acknowledgment of the read data. When establishing a new reading session, messages are delivered to the reader starting from the saved reading position. This allows users not to store the reading position on their side.

Reading limit from a single partition

The `partition_max_in_flight_bytes` parameter can be set when creating a reading session.

This parameter sets the upper limit of in-flight - the amount of data for a single partition that has already been issued by the server in read responses but not yet confirmed by an offset commit.

- `0` — no separate in-flight limit per partition is applied.
- positive value — when the limit is reached, the server temporarily stops delivering new portions for this partition until the client performs a commit and reduces in-flight.

A value that is too small, with slow processing or infrequent commits, can cause reading pauses on a partition. In such a case, increase the limit or perform commits more often.

Important reader

A reader can have the "important" attribute. The presence of this attribute means that messages in the topic will not be deleted until the reader reads and confirms the messages. This attribute can be set for the most critical readers that must process all data even during long downtime.

> **Warning**
>
> Since a prolonged idle period of an important reader can lead to using all available data storage space with unread messages, it is necessary to monitor the read lag of important readers.

Message availability time for the reader

A time availability period can be set for the reader, during which messages from the topic that have not yet been processed will be available to them.

This option allows extending the message retention time in the topic from the retention time up to the specified availability time, if the reader does not acknowledge processing.
Unlike the "important" reader attribute, this parameter limits the maximum age of messages that will be stored in the topic.
If the option is not set or all readers acknowledge processing without significant delay (less than the topic's retention time), then data will be deleted according to the usual rules.

Protocols for working with topics

The YDB SDK is used for working with topics (see Working with topics).

Also, the Kafka API version 3.4.0 (see Kafka API) and Amazon SQS API (see Amazon SQS API) protocols are partially supported.

Work with a single topic can be carried out simultaneously using multiple protocols. For example, writing can be done using the Topic API, and reading using the Amazon SQS API, and vice versa.

Transactions involving topics

YDB supports working with topics within transactions.

Transactional reading from a topic

Data in topics is not modified when reading from a topic. Therefore, when reading from a topic in a transaction, the only transactional operation is changing the offset. When reading transactionally via the SDK, offsets are not committed. Deferred offset commit occurs automatically when the transaction is committed; the SDK hides this from the user.

Transactional writing to a topic

When writing transactionally to a topic, data is stored outside the partition before commit, and then published (becomes visible) at the moment of transaction commit. In this case, data will be added to the end of the partition at sequential offsets. Visibility of own changes in topics within transactions involving topics is not provided.

Limitations when working with topics in a transaction

Transactions do not impose additional restrictions on working with topics. Within a transaction, you can write large amounts of data to a topic, write to multiple partitions, and read with multiple consumers.

Nevertheless, it is recommended to choose the transaction mode taking into account the specifics of transactional work with topics: data is published at the moment of transaction commit. That is, if the transaction is long-running, data will become visible only after a significant amount of time.

YQL queries to topics

To work with topics, you can use YQL queries with familiar constructs: SELECT for reading messages from a topic and INSERT for writing messages to a topic.

Coordination Node

A coordination node is an object in YDB that allows client applications to coordinate their actions in a distributed manner. Typical use cases for coordination nodes include:

- Distributed semaphores and mutexes.
- Service discovery.
- Leader election.
- Task queues.
- Publishing small amounts of data with the ability to receive change notifications.
- Ephemeral locking of arbitrary entities not known in advance.

Semaphores

Coordination nodes allow you to create and manage semaphores within them. Typical operations with semaphores include:

- Create.
- Acquire.
- Release.
- Describe.
- Subscribe.
- Delete.

A semaphore can have a counter that limits the number of simultaneous acquisitions, as well as a small amount of arbitrary data attached to it.

YDB supports two types of semaphores: persistent and ephemeral. A persistent semaphore must be created before acquisition and will exist either until it is explicitly deleted or until the coordination node in which it was created is deleted. Ephemeral semaphores are automatically created at the moment of their first acquisition and deleted at the last release, which is convenient to use, for example, in distributed locking scenarios.

> **Note**
>
> Semaphores in YDB are **not** recursive. Thus, semaphore acquisition and release are idempotent operations.

Usage

Working with coordination nodes and semaphores is done through dedicated methods in YDB SDK.

Similar Systems

YDB coordination nodes can solve tasks that are traditionally performed using systems such as Apache Zookeeper, etcd, Consul, and others. If a project uses YDB for data storage along with one of these third-party systems for coordination, switching to YDB coordination nodes can reduce the number of systems that need to be operated and maintained.

Secrets

Various access credentials are used for authentication in external systems. These credentials are stored in separate objects called secrets. Secrets are only available for writing and updating; their values cannot be retrieved.
In YDB, secrets are used, for example, in federated queries and data transfers.

Syntax

The following YQL operators are used to manage secrets:

- CREATE SECRET — create a secret.
- ALTER SECRET — modify an existing secret.
- DROP SECRET — delete a secret.

Usage

Examples of using secrets and working with them are provided in the following sections:

- Configuring Time to Live (TTL)
- Working with S3 Buckets (Yandex Object Storage)

Access management

Secrets are schema objects, so rights to them are granted using the GRANT command and revoked using the REVOKE command. To use a secret in a query, for example, when creating an external data source or data transfer, the right `SELECT ROW` is required.

External Tables

Some external data sources, such as database management systems, store data in a structured format, while others, like S3 (Yandex Object Storage), store data as individual files. To work with file-based data sources, you need to understand both the file placement rules and the formats of the stored data.

A special entity, `EXTERNAL TABLE`, describes the stored data in such sources. External tables allow you to define the schema of the stored files and the schema of file placement within the source.

A record in YQL might look like this:

```
CREATE EXTERNAL TABLE s3_test_data (
  key Utf8 NOT NULL,
  value Utf8 NOT NULL
) WITH (
  DATA_SOURCE="bucket",
  LOCATION="folder",
  FORMAT="csv_with_names",
  COMPRESSION="gzip"
);
```

Data can be inserted into external tables just like regular tables. For example, to write data to an external table, you need to execute the following query:

```
INSERT INTO s3_test_data
SELECT * FROM Table
```

More details on working with external tables describing S3 buckets (Object Storage) can be found in section Reading Data from an External Table Pointing to S3 (Object Storage).

External data sources

An external data source is an object in YDB that describes connection parameters to an external data source. For example, in the case of ClickHouse, the external data source describes the network address, login, and password for authentication in the ClickHouse cluster, and in the case of S3 (Object Storage), it describes access credentials and the path to the bucket.

The following example shows how to create an external data source pointing to a ClickHouse cluster:

```
CREATE EXTERNAL DATA SOURCE test_data_source WITH (
  SOURCE_TYPE="ClickHouse",
  LOCATION="192.168.1.1:8123",
  DATABASE_NAME="default",
  AUTH_METHOD="BASIC",
  USE_TLS="TRUE",
  LOGIN="login",
  PASSWORD_SECRET_PATH="test_password_path",
  PROTOCOL="NATIVE"
);
```

After creating an external data source, you can read data from the created `EXTERNAL DATA SOURCE` object. The example below illustrates reading data from the `test_table` table in the `default` database in the ClickHouse cluster:

```
SELECT * FROM test_data_source.test_table;
```

Using external data sources, you can run federated queries for cross-system data analytics tasks.

You can use the following data sources:

- S3

Experimental sources data

- ClickHouse
- Greenplum
- Microsoft SQL Server
- MySQL
- PostgreSQL
- YDB (federated queries between YDB databases)

Backup collection

A backup collection organizes full and incremental backups of selected row tables into manageable chains. It allows you to **restore data to the state of the latest backup in the chain**, providing protection against accidental data loss — erroneous deletions or modifications.

> **Note**
>
> For practical instructions on creating and managing backup collections, see the Backup collections section of the 'Backup and Restore' document.

Overview

Backup collections solve typical backup tasks for production workloads:

- **Storage efficiency**: Incremental backups capture only changes since the previous backup, significantly reducing storage requirements compared to multiple full backups.
- **Consistent restore**: All tables in the collection are created from a single global snapshot, ensuring referential integrity between tables when restoring.
- **Chain restore**: Restore to the state of the **latest** backup in the current chain — see `RESTORE`.

For comparison with other backup methods (export/import, dump/restore), see Backup concepts.

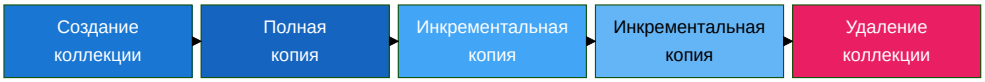
Key concepts

These terms are essential for understanding backup collections. For detailed definitions, see the glossary.

- **Full backup**: A complete snapshot of all data in the collection at a specific point in time. Serves as the basis for subsequent incremental backups.
- **Incremental backup**: Captures only changes (inserts, updates, deletes) since the previous backup. Requires the entire backup chain for restoration.
- **Backup chain**: An ordered sequence starting with a full backup, followed by zero or more incremental backups.

Limitations

Before using backup collections, consider these limitations:



- **Row tables only**: Column tables are not supported.
- **One collection per table**: A table can belong to only one backup collection. To include a table in another collection, run `DROP BACKUP COLLECTION` for the current collection and create a new one with the desired set of tables.
- **Immutable composition**: After creation, the list of tables in a collection cannot be changed. To add new tables, create a new collection with all the required tables.
- **No partial restore**: You cannot restore individual tables from a collection; the entire collection is restored.
- **External scheduling**: YDB does not provide built-in backup scheduling. Use external tools, such as cron, for automation.

Architecture

Backup collections use a copy-on-write mechanism combined with change streams for efficient incremental backups. This section explains how the components work together.

How backup collections work

The following diagram illustrates the backup process:

Creating a collection defines which tables to include and creates a schema object. This is a fast, metadata-only operation.

Full backup creates a consistent snapshot of all tables in the collection. Key characteristics:

- Uses a **global snapshot**, which ensures consistency across all tables in the collection.
- Creates **change streams** for each table to track subsequent modifications.
- Uses **copy-on-write**: The backup is created quickly by referencing existing data; actual data copying occurs only when the source data is modified.

Incremental backup captures all changes since the previous backup:

- Uses a **distributed transaction** to read change streams from all tables at a consistent point, ensuring referential integrity of the entire collection.
- Reads accumulated changes from change streams created during the full backup and accumulating changes **since the previous backup (full or incremental)**.
- Records all modifications: inserts, updates, and deletes (including as deletion records).
- Saves change stream data to incremental backup tables.

> **Warning**
>
> Schema changes (ALTER TABLE) of tables in the backup collection are not tracked by incremental backups. If you need to change the schema of a table with a backup, create a new full backup after the schema change so that the backup chain reflects the new structure.

> **Note**
>
> Change streams created during a full backup are automatically deleted when the backup collection is deleted. They cannot be manually deleted or used for other purposes while the collection exists.

Storage

Backup collections are stored in the YDB cluster in a dedicated directory structure:

```
/Root/database/.backups/collections/
├── my_collection/
│   ├── 20250821141425Z_full/
│   │   ├── table_1/
│   │   └── table_2/
│   └── 20250821151519Z_incremental/
│       ├── table_1/
│       └── table_2/
```

Note

The `.backups` directory is created automatically when the first backup collection is created and is managed by the system. After it is created, you can manage backup tables inside it (for example, when exporting or importing backups).

Cluster storage

By default, backups are stored in the cluster. Backups in the cluster are intended for recovery from **logical errors**, such as accidental `DROP TABLE`, `TRUNCATE TABLE`, or erroneous data changes. Advantages:

- Fast backup and restore operations.
- Integrated security mechanisms.
- No external infrastructure required.

Warning

Backups in the cluster are in the same failure zone as the protected data. If the cluster fails beyond its fault tolerance (for example, complete cluster loss or catastrophic events in the data center), both data and backups may be lost. To protect against such scenarios, use external storage.

External storage

For **disaster recovery** and protection against failures of the entire cluster, regularly export backup collections to external storage (S3-compatible storage or file system) using export/import operations.

To export backups to external storage, use the YDB CLI:

- `ydb export s3` for S3-compatible storage.
- `ydb export nfs` for NFS on cluster hosts.
- `ydb tools dump` for file system on a local computer.

Each backup in the chain must be exported separately. Preserve the chain order during export/import for successful recovery.

Background operations

All backup and restore operations are performed asynchronously, allowing you to continue normal database operations. Track progress using `ydb operation list incbackup`.

Restore from backups

Restore returns data to the state of the latest backup in the chain that is in the cluster. To restore to an earlier state, import only the required chain prefix from external storage — see Import and restore.

Restore process

1. **Import from external storage** (if necessary): If backups were exported, import the full backup and all incremental backups up to the desired restore point.
2. **Perform restore**: Run `RESTORE collection_name` to restore all tables from the backup collection. The system applies the full backup and all incremental backups sequentially to reach the latest backup point.

Warning

The restore operation will fail if at least one of the tables being restored already exists at the same path. Rename or delete conflicting tables before restoring.

All tables in the collection are restored to the same point in time: data from different tables will be mutually consistent.

Note

During the restore operation, the target tables are unavailable for modifications. Partially restored data may be visible to read workloads. Plan the restore for a maintenance window or disable application access to the affected tables until the operation completes.

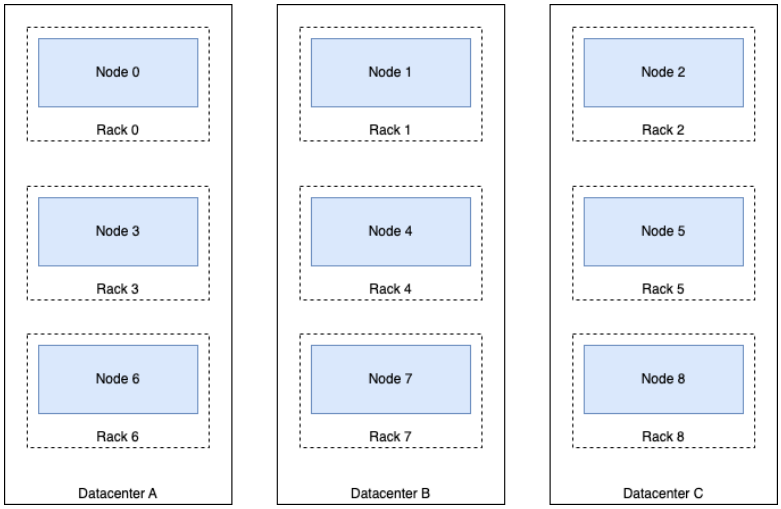
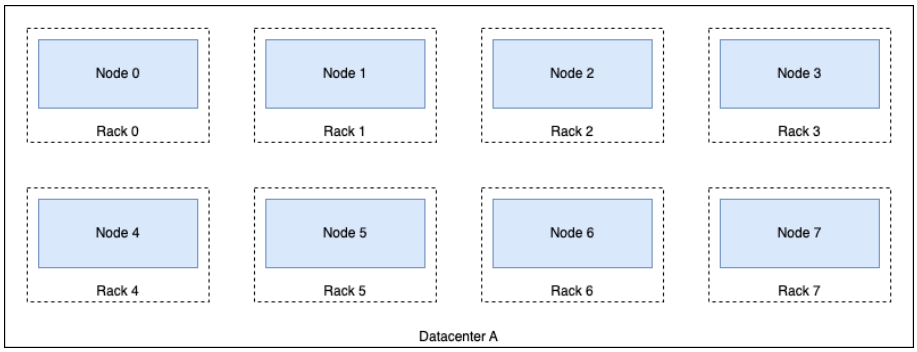
YDB Cluster Topology



A YDB cluster consists of storage and database nodes. As the data stored in YDB is available only via queries and API calls, both types of nodes are essential for database availability. However, distributed storage consisting of storage nodes has the most impact on the cluster's fault tolerance and ability to persist data reliably. During the initial cluster deployment, an appropriate distributed storage operating mode needs to be chosen according to the expected workload and database availability requirements. The operation mode cannot be changed after the initial cluster setup, making it one of the key decisions to consider when planning a new YDB deployment.

Cluster Operating Modes



Cluster topology is based on the chosen distributed storage operating mode, which needs to be determined according to the fault tolerance requirements. YDB's failure model is based on the concepts of fail domain and fail realm.

The following YDB distributed storage operating modes are available:

- `mirror-3-dc`. Data is replicated to 3 failure realms (usually availability zones or data centers) using 3 failure domains (usually racks) within each realm. YDB cluster remains available even if one failure realm completely fails; additionally, one failure domain in the remaining zones can fail at the same time. This mode is recommended for multi-datacenter clusters with high availability requirements.

- `block-4-2`. Erasure coding is applied with two blocks of redundancy added to the four blocks of source data. Storage nodes are placed in at least 8 failure domains (usually racks). YDB cluster remains available if any two domains fail, continuing to record all 6 data parts in the remaining domains. This mode is recommended for clusters deployed within a single availability zone or data center.

- `none`. There is no redundancy. Any hardware failure causes data to become unavailable or permanently lost. This mode is only recommended for development and functional testing.

> **Note**
>
> Server failure refers to both total and partial unavailability. For example, the failure of a single disk is also considered a server failure in this context.

Fault-tolerant operation modes of distributed storage require a significant amount of hardware to provide the maximum level of high availability guarantees supported by YDB. However, for some use cases, the investment into hardware might be too high upfront. Therefore, YDB offers variations of these operation modes that require less hardware while still providing a reasonable level of fault tolerance. The requirements and guarantees of all these operation modes and their variants are shown in the table below, while the implications of choosing a particular mode are discussed further in the article.

Mode	Storage volume multiplier	Minimum number of nodes	Fail domain	Fail realm	Number of data centers	Number of server racks
`mirror-3-dc`, can stand a failure of a data center and 1 rack in one of the remaining data centers	3	9 (12 recommended[1])	Rack	Data center	3	3 in each data center
`mirror-3-dc` *(reduced)*, can stand a failure of a data center and 1 server in one of the two other data centers	3	12	½ a rack	Data center	3	6

`mirror-3-dc` *(3 nodes)*, can stand a failure of a single server, or a failure of a data center	3	3	Server	Data center	3	Doesn't matter
`block-4-2`, can stand a failure of 2 racks	1.5	8 (10 recommended[1])	Rack	Data center	1	8
`block-4-2` *(reduced)*, can stand a failure of 1 rack	1.5	10	½ a rack	Data center	1	5
`none`, no fault tolerance	1	1	Node	Node	1	1

> **Note**
>
> The storage volume multiplier specified above only applies to the fault tolerance factor. Other influencing factors (for example, slot fragmentation and granularity) must be taken into account for storage capacity planning.

For information about how to set the YDB cluster topology, see Blob Storage Configuration.

Bridge mode

Bridge mode is a special cluster operating mode that differs significantly from the distributed storage modes listed above. In bridge mode, cluster nodes are divided into several pile (typically corresponding to data centers), each of which stores data using one of the distributed storage modes described above, with synchronous replication organized between pile.

It is important to understand that pile are not independent YDB clusters but parts of a single cluster with complex topology.

Bridge mode provides explicit control over replication stop and resume. The YDB cluster becomes unavailable when any pile fails until the replication stop command is executed for that pile. After it is executed, the cluster resumes operation. Thus, the cluster remains available until the last pile fails.

Resuming replication in a pile after it has been disconnected may take significant time, since YDB synchronizes storage in that pile with the others, replicating missing data. The cluster remains available during synchronization.

Bridge mode is recommended for clusters deployed in two data centers, as well as for systems with high fault tolerance requirements — for example, when it is necessary to maintain availability when three out of four data centers fail.

When using bridge mode, each pile must have enough nodes, domains, and fail realms for the chosen storage mode to work correctly. The resulting storage volume multiplier will equal the sum of storage volume multipliers of all pile.

Cluster response time in bridge mode for most operations is limited by the response time of the slowest pile.

Reduced Configurations

If it is impossible to use the recommended amount of hardware, you can divide servers within a single rack into two dummy fail domains. In this configuration, the failure of one rack results in the failure of two domains instead of just one. In such reduced configurations, YDB will continue to operate if two domains fail. The minimum number of racks in a cluster is five for `block-4-2` mode and two per data center (e.g., six in total) for `mirror-3-dc` mode.

The minimal fault-tolerant configuration of a YDB cluster uses the 3 nodes variant of `mirror-3-dc` operating mode, which requires only three servers with three disks each. In this configuration, each server acts as both a fail domain and a fail realm, and the cluster can withstand the failure of only a single server. Each server must be located in an independent data center to provide reasonable fault tolerance.

YDB clusters configured with one of these approaches can be used for production environments if they don't require stronger fault tolerance guarantees.

Capacity and Performance Considerations

The system can function with fail domains of any size. However, if there are few domains with varying numbers of disks, the number of storage groups that can be created will be limited. In such cases, hardware in overly large fail domains may be underutilized. If all hardware is fully utilized, significant differences in domain sizes may prevent reconfiguration.

For example, consider a cluster in `block-4-2` mode with 15 racks. The first rack contains 20 servers, while the other 14 racks each contain 10 servers. To fully utilize the 20 servers from the first rack, YDB will create groups that include 1 disk from this largest fail domain in each group. Consequently, if any other fail domain's hardware fails, the load cannot be redistributed to the hardware in the first rack.

YDB can group disk drives of different vendors, capacities, and speeds. The resulting characteristics of a group depend on the set of the worst characteristics of the hardware serving the group. Generally, the best results can be achieved by using homogeneous hardware.

> **Note**
>
> Hardware from the same batch is more likely to have similar defects and may fail simultaneously. It is essential to consider this when building large-scale YDB clusters.

Therefore, the optimal initial hardware configurations for production YDB clusters are as follows:

- **A cluster hosted in one availability zone**: This setup uses the `block-4-2` mode and consists of nine or more racks, each with an identical number of servers.
- **A cluster hosted in three availability zones**: This setup uses the `mirror-3-dc` mode and is distributed across three data centers, with four or more racks in each, all containing an identical number of servers.

Database Availability

A database within a YDB cluster is available if both its storage and compute resources are operational:

- All storage groups allocated for the database must be operational, i.e., stay within the allowed level of failures.

- The compute resources of the currently available database nodes (primarily the amount of main memory) must be sufficient to start all the tablets managing objects like tables or topics within the database and to handle user sessions.

To survive an entire data center outage at the database level, assuming a cluster configured with the `mirror-3-dc` operating mode:

- The storage nodes need to have at least double the I/O bandwidth and disk capacity compared to what is required for normal operation. In the worst case, the load on the remaining nodes during the maximum allowed outage might triple, but that's only temporary until self-heal restores failed disks in operating data centers.
- The database nodes must be evenly distributed between all 3 data centers and include sufficient resources to handle the entire workload when running in just 2 of the 3 data centers. To achieve this, database nodes in each datacenter need at least 35% extra spare CPU and RAM resources when running normally without ongoing failures. If database nodes are typically utilized above this threshold, consider adding more of them or moving them to servers with more resources.

[1] Using fewer nodes will limit the cluster's ability to automatically recover.

Bridge cluster operation mode

> **Feature of Yandex Enterprise Database**
>
> This functionality is available only in the Yandex Enterprise Database. In the open-source version of YDB it is absent.

This article describes a special operating mode of the YDB cluster in which data is stored with synchronous replication between multiple parts of the cluster called pile.

The bridge mode is an extension on top of the basic distributed storage modes: each pile is built using one of the YDB operating modes (for example, `mirror-3-dc` or `block-4-2`) and is fault-tolerant on its own; bridge adds synchronous replication between piles on top of that, plus managed failover/switchover of load between them. This provides an extra layer of fault tolerance on top of the chosen topologies. Bridge mode requires more hardware and is more complex to operate; it is especially useful for clusters deployed across two data centers and for systems with higher availability requirements — for example, when you need to remain available if three out of four data centers fail.

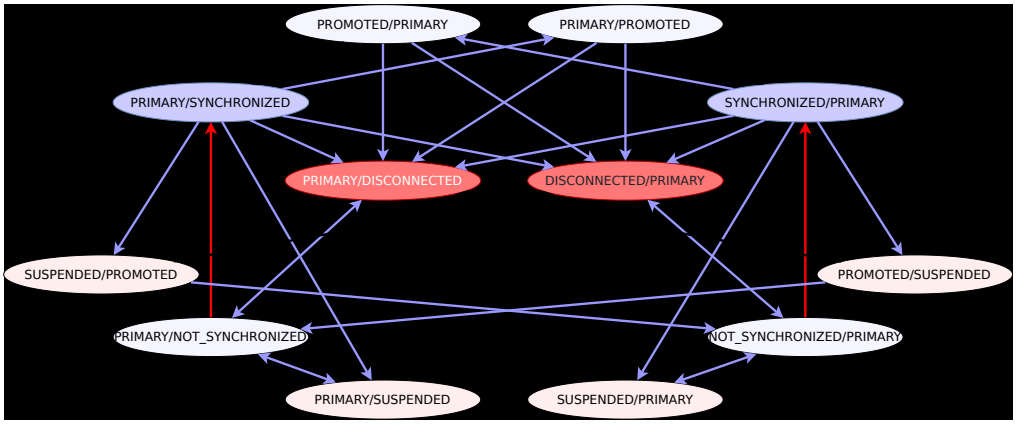
Description of the mode

In bridge mode, cluster nodes are split into several piles (typically one pile per datacenter). If one of the piles fails, the cluster becomes unavailable until the command to disable that pile is executed. After it is disabled, the cluster resumes operation.

YDB supports an arbitrary number of piles; however, for simplicity, the following discussion considers the case of two piles.

At the distributed storage level, bridge mode implements synchronous Active/Active replication between piles. At the database node level, Active/Passive redundancy is possible.

Data is stored in pairs of storage groups from different piles. Within each pile, any YDB operating mode supported for data storage may be used.



Bridge mode can achieve zero-downtime switchover. On failover, the cluster requires explicit disabling of replication to the failed pile before it can resume. When any pile is disabled, request processing is suspended until the command to disable replication to that pile is executed.

Piles are not standalone YDB clusters; they are parts of a single cluster with a complex topology:

- Tablets in bridge mode run as a single instance;
- each pile runs its own static group and set of independent storage groups with regular VDisks. Storage groups are accessed via DS-proxy-proxy, which exposes the DS-proxy interface to tablets and performs operations using two DS-proxy instances — one for the groups in each pile;
- each pile runs its own set of replicas of StateStorage, SchemeBoard, and Board. Access to StateStorage, SchemeBoard, and Board is through similar proxy-proxy components.

Pile states

Cluster operation is determined by the states of all its piles. For example, for a cluster of pile A and pile B, the pile states are written as (A, B), where order matters.

Each pile can be in one of the following states:

- `PRIMARY`. The main pile where tablets run. Only one pile can be in the `PRIMARY` state.
- `SYNCHRONIZED`. A follower pile whose storage groups are fully synchronized with `PRIMARY`.
- `DISCONNECTED`. Disconnected from `PRIMARY`; does not participate in operations.
- `NOT_SYNCHRONIZED`. A pile whose storage groups are not yet synchronized with `PRIMARY`. When synchronization completes, YDB automatically transitions the pile to `SYNCHRONIZED`.
- `PROMOTED`. A pile being smoothly transitioned from `SYNCHRONIZED` to `PRIMARY`. The pile remains in this state until the transition completes, after which YDB automatically transitions it to `PRIMARY`.
- `SUSPENDED`. A pile being smoothly transitioned to `DISCONNECTED`. When the transition completes, YDB automatically moves the pile to `DISCONNECTED`.

Normally, a pair of piles operates in `PRIMARY/SYNCHRONIZED` or `SYNCHRONIZED/PRIMARY`. That is, one pile is `PRIMARY` (tablets run there) and the other is `SYNCHRONIZED` (all its storage groups are synchronized with `PRIMARY`). In this configuration, a write is considered committed only after it has been successfully written to the storage groups of each pile with the required redundancy.

Transitions between states

From state	To state	How	Description
`PRIMARY`	`SYNCHRONIZED`	Automatically	Planned switchover complete.

PRIMARY	DISCONNECTED	Manually — failover	Emergency disable of unavailable PRIMARY and selection of new PRIMARY.
PRIMARY	SUSPENDED	Manually — takedown	Planned disable of current PRIMARY and selection of new PRIMARY.
SYNCHRONIZED	PRIMARY	Manually — failover	Emergency disable of unavailable PRIMARY and selection of new PRIMARY.
SYNCHRONIZED	DISCONNECTED	Manually — failover	Emergency disable of unavailable SYNCHRONIZED.
SYNCHRONIZED	PROMOTED	Manually — switchover	Start planned change of PRIMARY.
SYNCHRONIZED	SUSPENDED	Manually — takedown	Start planned disable of SYNCHRONIZED pile.
DISCONNECTED	NOT_SYNCHRONIZED	Manually — rejoin	Return pile to cluster after maintenance or recovery.
NOT_SYNCHRONIZED	SYNCHRONIZED	Automatically	Data synchronization complete.
NOT_SYNCHRONIZED	DISCONNECTED	Manually — failover	Emergency disable of unavailable NOT_SYNCHRONIZED.
PROMOTED	PRIMARY	Automatically	Planned switchover complete.
PROMOTED	PRIMARY	Manually — failover	Emergency disable of unavailable PRIMARY and selection of new PRIMARY.
PROMOTED	DISCONNECTED	Manually — failover	Emergency disable of unavailable PROMOTED.
SUSPENDED	NOT_SYNCHRONIZED	Manually — rejoin	Cancel planned disable of pile.
SUSPENDED	DISCONNECTED	Automatically	Planned disable complete.
SUSPENDED	DISCONNECTED	Manually — failover	Emergency disable of unavailable SUSPENDED.

State change scenarios

Pile failure

When a pile fails, the cluster becomes unavailable. To resume cluster operation, the failed pile must be disabled by moving it to the DISCONNECTED state.

The administrator can issue a transition from PRIMARY/SYNCHRONIZED or SYNCHRONIZED/PRIMARY to either PRIMARY/DISCONNECTED or DISCONNECTED/PRIMARY. The command updates the storage group configuration and changes how data is written to those groups. Interconnect tears down sessions with all nodes of the pile in DISCONNECTED; data exchange sessions are not established (TCP connections for exchanging pile state metadata may remain active). Subsequent read and write operations run without the pile in DISCONNECTED. If the PRIMARY pile has changed, tablets are restarted on it.

The same kind of transition applies when the failed pile was in any state and the pile being designated PRIMARY is in one of the allowed states: PRIMARY, SYNCHRONIZED, or PROMOTED.

If the pile being designated PRIMARY was in DISCONNECTED, NOT_SYNCHRONIZED, or SUSPENDED, a normal transition is not possible, because that pile may not hold a complete, up-to-date replica of the data.

Pile recovery

After the nodes of the failed pile are back up, the pile must be reattached to the cluster by moving it to NOT_SYNCHRONIZED.

The administrator can issue a transition from PRIMARY/DISCONNECTED to PRIMARY/NOT_SYNCHRONIZED or from DISCONNECTED/PRIMARY to NOT_SYNCHRONIZED/PRIMARY. Configuration is exchanged between nodes; interconnect sessions are established only between nodes with the same configuration. The command starts storage group synchronization. When synchronization finishes, an automatic transition occurs from PRIMARY/NOT_SYNCHRONIZED to PRIMARY/SYNCHRONIZED or from NOT_SYNCHRONIZED/PRIMARY to SYNCHRONIZED/PRIMARY.

Planned PRIMARY pile switchover

To change the PRIMARY pile in a planned way, the pile that will become the new PRIMARY must be moved to the PROMOTED state.

The administrator can issue a transition from PRIMARY/SYNCHRONIZED to PRIMARY/PROMOTED or from SYNCHRONIZED/PRIMARY to PROMOTED/PRIMARY. The command does not change how data is written to storage groups but updates their configuration and initiates the change of PRIMARY pile with a smooth migration of tablets to the new PRIMARY. When the transition completes, the former PRIMARY becomes SYNCHRONIZED and PROMOTED becomes PRIMARY.

Planned pile disable

To disable a pile in a planned way, it must be moved to the SUSPENDED state.

The administrator can issue a transition from PRIMARY/SYNCHRONIZED to PRIMARY/SUSPENDED or from SYNCHRONIZED/PRIMARY to SUSPENDED/PRIMARY. A planned disable of the nodes of the pile moved to SUSPENDED is performed, and they are moved to DISCONNECTED. The system aims to minimize the impact of this process on cluster operation. After the pile has been moved to DISCONNECTED, its nodes can be shut down for maintenance.

Then perform normal pile recovery by moving it to NOT_SYNCHRONIZED.

Recovery from cluster split with incompatible configuration (split brain)

A situation can occur where the administrator has put the cluster in a state where pile A and pile B are isolated from each other, and then pile A was reconfigured so that it became PRIMARY and pile B became SYNCHRONIZED, while at the same time pile B was reconfigured so that it became PRIMARY and pile A became SYNCHRONIZED. This results in a cluster split with incompatible configuration (split-brain). In this state, each part of the cluster may remain operational.

To restore a single cluster, choose which pile will be wiped. Then stop all nodes of that pile, wait for them to stop completely, wipe all disks on all nodes, and bring the nodes of the pile being wiped back up.
Then perform normal pile recovery by moving it to `NOT_SYNCHRONIZED`.

Non-standard pile recovery

In complex situations (for example, after sequential pile failures), the following scenario can occur: first pile A failed, was moved to `DISCONNECTED`, and the cluster continued operating; then pile B failed irreversibly; after that, pile A was recovered. In such cases, the cluster can be recovered based on pile A.

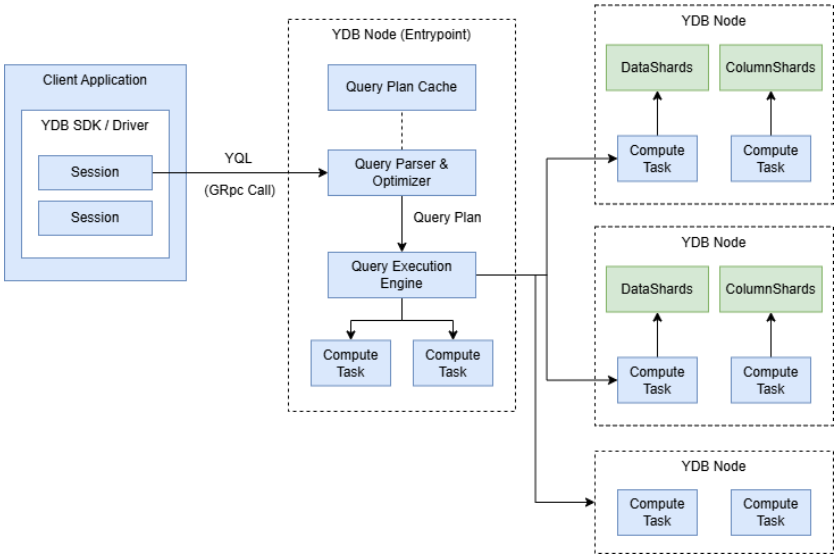
If the cluster must be brought back up when only a pile in `DISCONNECTED`, `NOT_SYNCHRONIZED`, or `SUSPENDED` is available, the administrator can run a transition from `PRIMARY/DISCONNECTED` to `DISCONNECTED/PRIMARY` (or similarly for `NOT_SYNCHRONIZED` or `SUSPENDED`) with the special `force` parameter. This causes a cluster split with incompatible configuration. Depending on the actual state of data in the pile being moved to `PRIMARY`, the cluster may be restored to a correct or internally inconsistent state. Correct operation of such a cluster is not guaranteed.

If the cluster turns out to be operational, you can proceed to restore it to normal state. Before recovering the disabled pile, fully wipe data and metadata on all its nodes, then move the pile to `NOT_SYNCHRONIZED`.

Bridge mode implementation details

For more on how bridge mode works, see Bridge mode.

Query Execution



This article provides an overview of query execution in YDB. It is intended to familiarize users with the capabilities and limitations of YDB's query execution engine, including key features such as the supported query language and execution flow. The article also introduces essential terminology and concepts related to query processing, which are used throughout the rest of the documentation.

YDB provides a unified query interface capable of efficiently handling diverse workloads — from high-throughput Online Transaction Processing (OLTP) to large-scale analytical Online Analytical Processing (OLAP) queries. With this approach, applications can run transactional and analytical queries transparently, without having to use different APIs for different workloads.

YDB uses a distributed query execution engine designed for high scalability and efficiency in large, distributed environments. When you run a query, YDB automatically breaks the work down across multiple nodes, taking advantage of data locality — processing data where it is stored whenever possible. This reduces unnecessary data movement across the network. Additionally, YDB leverages advanced features like compute pushdown, where filters and computations are pushed closer to the data storage layer, further improving performance. These techniques enable YDB to efficiently handle complex queries and large workloads across clusters of machines.

General Workflow

This section provides a step-by-step overview of how SQL queries are handled in YDB. Understanding this process helps you become familiar with YDB components and gain insight into what happens under the hood.

1. **Connecting to the Database**
   Your application uses one of the official YDB SDKs to connect to the database. The SDK automatically manages a pool of sessions, logical connections required to execute queries. Behind the scenes, each session is physically connected to one of the nodes in the YDB cluster. When you need to run a query, the SDK provides a session from this pool, so you don't need to manage connections manually.
2. **Starting a Transaction and Sending a Query**
   With your session in hand, your application can begin a new transaction. You then issue your query in the YQL query language based on your application logic and send it to the YDB cluster using the session.
3. **Parsing and Plan Cache Lookup**
   On the server side, the YDB node that receives your query first parses and analyzes it for correctness. Before planning execution, YDB checks whether a physical execution plan for this query already exists in the query cache. If a cached plan is found, it can be reused to save time and resources.
4. **Query Optimization and Plan Preparation**
   If no existing plan is found in the cache, YDB's query optimizer creates a new physical query plan. This plan determines the most efficient way to execute your query across the distributed cluster. For more detailed information about query optimization and query plans, see the Query Optimization in YDB article.
5. **Distributed Query Execution**
   Using the prepared physical plan, YDB starts distributed execution of the query. Work is distributed across multiple nodes in the database, with each node undertaking a part of the computation or data access as defined by the plan. This parallel processing enables fast and scalable query execution, even on large datasets.
6. **Streaming Results Back to the Client**
   For queries that produce results (such as `SELECT` statements), they are returned to your application as one or more result sets, which look like strongly typed tables. Instead of sending all results at once, YDB streams the data back in portions (parts). This allows your application to start processing results immediately and handle large result sets efficiently without needing to load everything into memory at once.
7. **Continuing or Completing the Transaction**
   After receiving and processing the results, your application can choose to continue the transaction by sending additional queries within the same transaction context, or complete the transaction by committing it to save changes.

Further details and explanations of the concepts introduced in this section are provided in the following sections.

Sessions

A session in YDB is a logical "connection" to the database that maintains the context required to execute queries and manage transactions. Sessions store transaction state and other essential context, enabling a series of related queries to be executed as part of a single transaction. Most query execution operations occur within the context of an active session.

Sessions are designed to be long-living objects. One of their key roles is to enable efficient load balancing: by distributing sessions and their associated queries across different nodes in the cluster, YDB can make better use of resources and achieve high availability and scalability.

In practice, you don't need to worry about creating, reusing, or closing sessions yourself. All official YDB SDKs provide session pooling out of the box. A session pool automatically manages the lifecycle of sessions—creating them when needed, reusing existing ones, and returning them to the pool—so that you can focus on writing your application's logic rather than handling session management details.

Transactions

Every query in YDB is executed within the context of a transaction, ensuring data consistency and reliability. Transactions can be managed either explicitly, or by specifying appropriate transaction control parameters during query execution.

YDB also supports Interactive transactions, which give you the flexibility to execute multiple queries within the same transaction, while allowing your application to perform custom logic between those queries. This makes it possible to build complex workflows that require several related operations to be treated as a single atomic unit.

For comprehensive information on transactions and the available transaction modes in YDB, see the Transactions article.

Retries

YDB employs Optimistic concurrency control for transaction management. This means that a transaction may be aborted during execution if YDB detects a conflict and cannot guarantee the requested isolation level — for example, when two transactions attempt to modify the same data concurrently. Additionally, because YDB operates as a distributed system across potentially large clusters, some nodes may become temporarily unavailable due to network partitions, hardware failures, or maintenance. Such events can also cause transaction failures that require retries.

Retries should always be handled at the transaction level, not at the level of individual queries. In Interactive transactions, the sequence of queries and their intermediate results may influence subsequent operations, making it unsafe or impossible to retry only a single failed query. Therefore, if a query fails due to a conflict or a transient error, the entire transaction should be retried from the beginning to ensure correctness and consistency.

All official YDB SDKs provide built-in retry logic and transaction management helpers to simplify application development. By using the standard transaction methods provided by your SDK, you automatically get correct and robust retry behavior without having to implement it manually. For details about retry mechanisms in specific SDKs, see the Handling errors.

Query language

Queries for YDB are written in YQL — an SQL dialect designed with scalable distributed databases in mind. While YQL is not fully ANSI SQL compatible, it closely follows familiar SQL syntax and concepts for most common use cases, making it easy to learn for those with SQL experience. The complete language reference is available in the YQL documentation.

Most interactions with YDB are performed using YQL, making it the primary tool for querying and managing data in YDB. Because of this, understanding YQL's features and capabilities is essential for effectively working with YDB. Learning YQL enables you to take full advantage of the database's advanced query functionality, express complex business logic, and utilize YDB's distributed architecture efficiently.

YQL supports most common SQL constructs, including:

- Data Manipulation Language (DML) — `SELECT`, `INSERT`, `REPLACE`, `UPDATE`, `DELETE`, `UPSERT`.
- Data Definition Language (DDL) — `CREATE`, `ALTER`, `DROP` for tables, indexes, and other schema objects.
- Joins — all standard `JOIN` types, plus special joins such as `LEFT SEMI`, `RIGHT SEMI`, and `ANY` joins.
- Aggregations — `GROUP BY` and window functions.
- Named expressions for better query text organization.
- A collection of built-in functions for processing various data types, empowering users to handle complex logic directly in queries.
- Pragmas and hints to fine-tune execution plans.

Result Sets

When you execute a query in YDB, the result can consist of one or more result sets. Each result set is similar to a table: it contains rows and columns, where every column has a defined, explicit data type. This strong typing guarantees that the structure of the returned data is always predictable and consistent.

Result sets in YDB can be arbitrarily large. To efficiently handle large amounts of data, YDB streams result sets back to the client in parts (chunks). This streaming approach lets clients begin processing the results right away without waiting for the entire result set to be transferred. As a result, applications can handle large datasets quickly and with minimal memory usage.

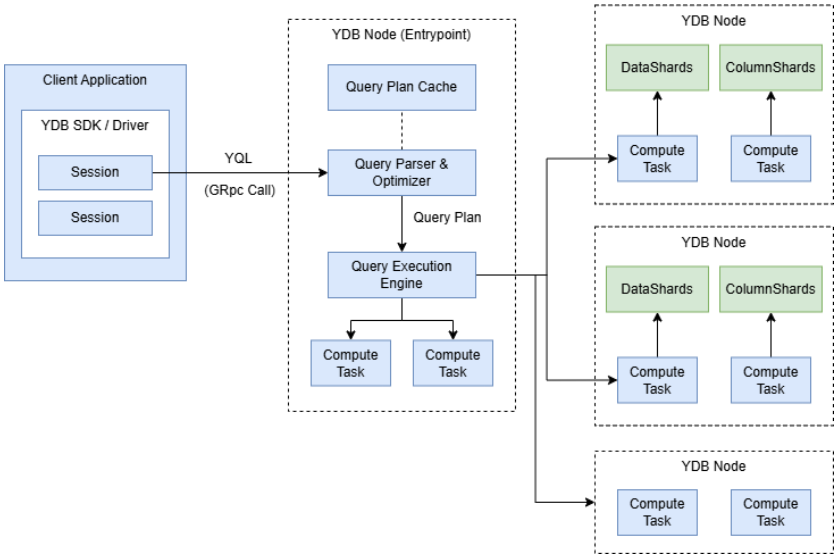
Limitations

When working with queries in YDB, there are several important limitations to keep in mind:

- **No schema transactions**
  YDB does not support schema transactions. This means that DDL statements (such as creating or altering tables) cannot be combined with DML statements (such as inserts, updates, or deletes) within the same transaction or query.
- **Large updates and optimistic locking**
  YDB uses optimistic concurrency control. When performing very large updates or deletes within a transaction, the probability of lock conflicts increases, making such operations impractical. For bulk modifications, it is recommended to use `BATCH UPDATE` / `BATCH DELETE` statements.
- **Transaction size limits**
  The amount of data that can be written in a single transaction is limited. For detailed thresholds, see the Limits on Query Execution section.

For a full overview of YDB limitations, see Database Limits.

Query Execution



This article provides an overview of query execution in YDB. It is intended to familiarize users with the capabilities and limitations of YDB's query execution engine, including key features such as the supported query language and execution flow. The article also introduces essential terminology and concepts related to query processing, which are used throughout the rest of the documentation.

YDB provides a unified query interface capable of efficiently handling diverse workloads — from high-throughput Online Transaction Processing (OLTP) to large-scale analytical Online Analytical Processing (OLAP) queries. With this approach, applications can run transactional and analytical queries transparently, without having to use different APIs for different workloads.

YDB uses a distributed query execution engine designed for high scalability and efficiency in large, distributed environments. When you run a query, YDB automatically breaks the work down across multiple nodes, taking advantage of data locality — processing data where it is stored whenever possible. This reduces unnecessary data movement across the network. Additionally, YDB leverages advanced features like compute pushdown, where filters and computations are pushed closer to the data storage layer, further improving performance. This allows your application to start processing results immediately and handle large result sets efficiently without needing to load everything into memory at once.
7. **Continuing or Completing the Transaction**
   After receiving and processing the results, your application can choose to continue the transaction by sending additional queries within the same transaction context, or complete the transaction by committing it to save changes.

Further details and explanations of the concepts introduced in this section are provided in the following sections.

Sessions

A session in YDB is a logical "connection" to the database that maintains the context required to execute queries and manage transactions. Sessions store transaction state and other essential context, enabling a series of related queries to be executed as part of a single transaction. Most query execution operations occur within the context of an active session.

Sessions are designed to be long-living objects. One of their key roles is to enable efficient load balancing: by distributing sessions and their associated queries across different nodes in the cluster, YDB can make better use of resources and achieve high availability and scalability.

In practice, you don't need to worry about creating, reusing, or closing sessions yourself. All official YDB SDKs provide session pooling out of the box. A session pool automatically manages the lifecycle of sessions—creating them when needed, reusing existing ones, and returning them to the pool—so that you can focus on writing your application's logic rather than handling session management details.

Transactions

Every query in YDB is executed within the context of a transaction, ensuring data consistency and reliability. Transactions can be managed either explicitly, or by specifying appropriate transaction control parameters during query execution.

YDB also supports Interactive transactions, which give you the flexibility to execute multiple queries within the same transaction, while allowing your application to perform custom logic between those queries. This makes it possible to build complex workflows that require several related operations to be treated as a single atomic unit.

For comprehensive information on transactions and the available transaction modes in YDB, see the Transactions article.

Retries

YDB employs Optimistic concurrency control for transaction management. This means that a transaction may be aborted during execution if YDB detects a conflict and cannot guarantee the requested isolation level — for example, when two transactions attempt to modify the same data concurrently. Additionally, because YDB operates as a distributed system across potentially large clusters, some nodes may become temporarily unavailable due to network partitions, hardware failures, or maintenance. Such events can also cause transaction failures that require retries.

Retries should always be handled at the transaction level, not at the level of individual queries. In Interactive transactions, the sequence of queries and their intermediate results may influence subsequent operations, making it unsafe or impossible to retry only a single failed query. Therefore, if a query fails due to a conflict or a transient error, the entire transaction should be retried from the beginning to ensure correctness and consistency.

All official YDB SDKs provide built-in retry logic and transaction management helpers to simplify application development. By using the standard transaction methods provided by your SDK, you automatically get correct and robust retry behavior without having to implement it manually. For details about retry mechanisms in specific SDKs, see the Handling errors.

Query language

Queries for YDB are written in YQL — an SQL dialect designed with scalable distributed databases in mind. While YQL is not fully ANSI SQL compatible, it closely follows familiar SQL syntax and concepts for most common use cases, making it easy to learn for those with SQL experience. The complete language reference is available in the YQL documentation.

Most interactions with YDB are performed using YQL, making it the primary tool for querying and managing data in YDB. Because of this, understanding YQL's features and capabilities is essential for effectively working with YDB. Learning YQL enables you to take full advantage of the database's advanced query functionality, express complex business logic, and utilize YDB's distributed architecture efficiently.

YQL supports most common SQL constructs, including:

- Data Manipulation Language (DML) — `SELECT`, `INSERT`, `REPLACE`, `UPDATE`, `DELETE`, `UPSERT`.
- Data Definition Language (DDL) — `CREATE`, `ALTER`, `DROP` for tables, indexes, and other schema objects.
- Joins — all standard `JOIN` types, plus special joins such as `LEFT SEMI`, `RIGHT SEMI`, and `ANY` joins.
- Aggregations — `GROUP BY` and window functions.
- Named expressions for better query text organization.
- A collection of built-in functions for processing various data types, empowering users to handle complex logic directly in queries.
- Pragmas and hints to fine-tune execution plans.

Result Sets

When you execute a query in YDB, the result can consist of one or more result sets. Each result set is similar to a table: it contains rows and columns, where every column has a defined, explicit data type. This strong typing guarantees that the structure of the returned data is always predictable and consistent.

Result sets in YDB can be arbitrarily large. To efficiently handle large amounts of data, YDB streams result sets back to the client in parts (chunks). This streaming approach lets clients begin processing the results right away without waiting for the entire result set to be transferred. As a result, applications can handle large datasets quickly and with minimal memory usage.

Limitations

When working with queries in YDB, there are several important limitations to keep in mind:

- **No schema transactions**
  YDB does not support schema transactions. This means that DDL statements (such as creating or altering tables) cannot be combined with DML statements (such as inserts, updates, or deletes) within the same transaction or query.
- **Large updates and optimistic locking**
  YDB uses optimistic concurrency control. When performing very large updates or deletes within a transaction, the probability of lock conflicts increases, making such operations impractical. For bulk modifications, it is recommended to use `BATCH UPDATE` / `BATCH DELETE` statements.
- **Transaction size limits**
  The amount of data that can be written in a single transaction is limited. For detailed thresholds, see the Limits on Query Execution section.

For a full overview of YDB limitations, see Database Limits.

Query Optimization in YDB

YDB uses two types of query optimizers: a rule-based optimizer and a cost-based optimizer. The cost-based optimizer is used for complex queries, typically analytical (OLAP), while rule-based optimization works on all queries.

A query plan is a graph of operations, such as reading data from a source, filtering a data stream by a predicate, or performing more complex operations such as JOIN and GROUP BY. Optimizers in YDB take an initial query plan as input and transform it into a more efficient plan that is equivalent to the initial one in terms of the returned result.

Rule-Based Optimizer

A significant part of the optimizations in YDB applies to almost any query plan, eliminating the need to analyze alternative plans and their costs. The rule-based optimizer consists of a set of heuristic rules that are applied whenever possible. For example, it is beneficial to filter out data as early as possible in the execution plan for any query. Each optimizer rule comprises a condition that triggers the rule and a rewriting logic that is executed when the plan is applied. Rules are applied iteratively as long as any rule conditions match.

Cost-Based Query Optimizer

The cost-based optimizer is used for more complex optimizations, such as choosing an optimal join order and join algorithms. The cost-based optimizer considers a large number of alternative execution plans for each query and selects the best one based on the cost estimate for each option. Currently, this optimizer only works with plans that contain JOIN operations. It chooses the best order for these operations and the most efficient algorithm implementation for each join operation in the plan.

The cost-optimizer consists of three main components:

- Plan enumerator
- Cost estimation function
- Statistics module, which is used to estimate statistics for the cost function

Plan Enumerator

The current Cost-based optimizer in YDB enumerates all useful join trees, for which the join conditions are defined. It first builds a join hypergraph, where the nodes are tables and edges are join conditions. Depending on how the original query is written, the join hypergraph may have quite different topologies, ranging from simple chain-like graphs to complex cliques. The resulting topology of the join graph determines how many possible alternative plans need to be considered by the optimizer.

For example, a star is a common topology in analytical queries, where a main fact table is joined to multiple dimension tables:

```
SELECT
    P.Brand,
    S.Country AS Countries,
    SUM(F.Units_Sold)

FROM Fact_Sales F
INNER JOIN Dim_Date D    ON (F.Date_Id = D.Id)
INNER JOIN Dim_Store S   ON (F.Store_Id = S.Id)
INNER JOIN Dim_Product P ON (F.Product_Id = P.Id)

WHERE D.Year = 1997 AND  P.Product_Category = 'tv'

GROUP BY
    P.Brand,
    S.Country
```

In this query graph, all `Dim...` tables are joined to the `Fact_Sales` fact table:

Common topologies also include chains and cliques. A "chain" is a topology where tables are connected to each other sequentially and each table participates in no more than one join. A "clique" is a fully connected graph where each table is connected to every other table.

In practice, OLAP queries often have a topology that is a combination of "star" and "chain" topologies, while complex topologies like "cliques" are very rare.

The topology significantly impacts the number of alternative plans that the optimizer needs to consider. Therefore, the cost-based optimizer limits the number of joins that are compared by exhaustive search, depending on the topology of the original plan. The capabilities of exact optimization in YDB are listed in the following table:

Topology	Number of supported joins
Chain	110
Star	18
Clique	15

YDB uses a modification of the DPHyp algorithm to search for the best join order. DPHyp is a modern dynamic programming algorithm for query optimization that avoids enumerating unnecessary alternatives and allows you to optimize plans with `JOIN` operators, complex predicates, and even `GROUP BY` and `ORDER BY` operators.

Cost Estimation Function

To compare plans, the optimizer needs to estimate their costs. The cost function estimates the time and resources required to execute an operation in YDB. The primary parameters of the cost function are estimates of the input data size for each operator and the size of its output. These estimates are based on statistics collected from YDB tables, along with an analysis of the plan itself.

Statistics for the Cost-Based Optimizer

The cost-based optimizer relies on table statistics and individual column statistics. YDB collects and maintains these statistics in the background. You can manually force statistics collection using the ANALYZE query.

The current set of table statistics includes:

- Number of records
- Table size in bytes

The current set of column statistics includes:

- Count-min sketch

Cost Optimization Levels

In YDB, you can configure the cost optimization level via the CostBasedOptimizationLevel pragma.

To force the cost-based optimizer to be enabled for the current query, set the pragma `PRAGMA ydb.CostBasedOptimization = "on";`. To disable the cost-based optimizer, set the pragma to `off`.

Multi-Version Concurrency Control (MVCC)

This article describes how YDB uses MVCC.

YDB Transactions

YDB transactions run at serializable isolation level by default, which in layman's terms means it's as if they executed in some serial order without overlapping. While technically any order is allowed, in practice, YDB also guarantees non-stale reads (modifications committed before the transaction started will be visible). With YDB you may run these transactions interactively (users may have client-side logic between queries), which uses optimistic locks for conflict detection. When two transactions overlap in time and have conflicts (e.g., both transactions read the same key, observe its current value, and then try to update it), one of them will commit successfully, but the other will abort and will need to be retried.

YDB is a distributed database that splits OLTP tables into DataShard tablets, partitioned using the table's primary key, and each storing up to ~2GB of user data. Tablets are fault-tolerant replicated state machines over the shared log and shared storage, which may quickly migrate between different compute nodes. DataShards tablets implement low-level APIs for accessing corresponding partition data and support distributed transactions.

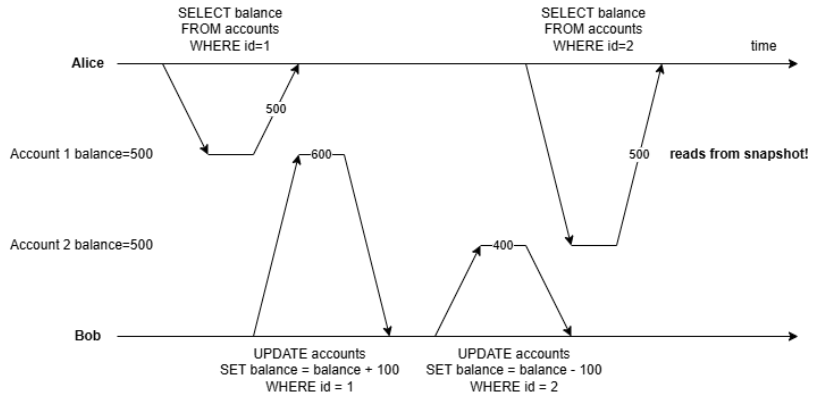
Distributed transactions in YDB are based on the ideas of Calvin, distributing deterministic transactions across multiple participants using a predetermined order of transactions. Every participant receives a substream of the global transaction stream (that involves this participant). Since each participant receives deterministic transactions in the same relative order, the database as a whole eventually reaches a consistent deterministic state (where each participant reached the same decision to commit or abort), even when different participants execute their substreams at different speeds. It's important to note that this does not make YDB eventually consistent and transactions always observe a consistent state at their point in time. Deterministic distributed transactions have a limitation in that they need to know all participants ahead of time, but YDB uses them as a building block, executing multiple deterministic transactions as phases of a larger user transaction. In practice, only the final commit phase runs as a distributed transaction since YDB tries to transform other phases into simple single-shard operations as much as possible while preserving serializable isolation guarantees.

Having a predetermined order of transactions becomes a concurrency bottleneck, as when you have a slow transaction that has to wait for something, all transactions down the line have to wait as well. This necessitates a good out-of-order execution engine that is able to reorder transactions that don't conflict while preserving externally visible guarantees. Out-of-order execution alone can't help when transactions actually conflict, however. One example from the past is when a wide read was waiting for data from a disk, it blocked all writes that fell into the same range, stalling the pipeline. Implementing MVCC reads lifted that restriction.

What Is MVCC

MVCC (Multi-Version Concurrency Control) is a way to improve database concurrency by storing multiple row versions as they have been at different points in time. This allows readers to keep reading from a database snapshot without blocking writers. Databases don't overwrite rows but make a modified copy of them instead, tagged with some version information, keeping older row versions intact. Older row versions are garbage collected eventually, e.g., when there are no readers left that could possibly read them.

A simple and naive way of adding MVCC to a sorted KV store is to store multiple values for each key, e.g., using keys tagged with a version suffix and skipping versions that are not visible to the current transaction/snapshot. Many databases go this route one way or another. Bear in mind that such a naive approach leads to data bloat, as multiple copies of data need to be stored and older versions may be difficult to find and remove. It also causes degraded range query performance, as the query execution engine needs to skip over many unnecessary versions until it finds the right one or until it finds the next key.



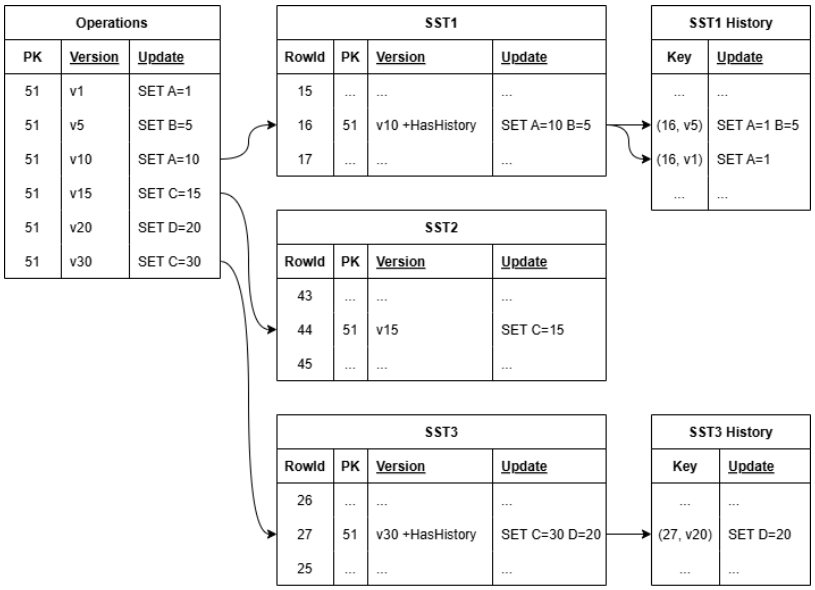
Why YDB Needs MVCC

YDB table shards store data in a sorted KV store, implemented as a write-optimized LSM tree, and historically they did not use MVCC. Since the order of transactions is predetermined externally (using Coordinators, somewhat similar to sequencers in the original Calvin paper), YDB heavily relies on reordering transaction execution at each participant, which is correct as long as such reordering cannot be observed externally, and it doesn't change the final outcome. Without MVCC, reordering is impeded by read-write conflicts, e.g., when a write cannot start execution until a particularly wide read is complete. With MVCC, writes no longer need to wait for conflicting reads to complete, and reads only ever need to wait for preceding conflicting writes to commit. This makes the out-of-order engine's job easier and improves the overall throughput.

Timestamp	Statement	Without MVCC	With MVCC	Description
v1000:123	`UPSERT`	☑️	☑️	Executed
v1010:124	`SELECT`	⏳	⏳	Reading from disk
v1020:126	`UPSERT`	❌	☑️	UPSERT without MVCC has to wait for SELECT to finish
v1030:125	`SELECT`	❌	⏳	SELECT needs to wait for UPSERT to finish before reading from disk

YDB without MVCC also had to take additional steps to preserve data consistency. Interactive transactions may consist of multiple read operations, where each read was performed at a different point in time, and YDB had to perform special checks to ensure conflicting transactions did not perform writes between the read and commit time. This was not ideal for our users, as even pure read-only transactions were often failing with serializability errors and had to be retried.

After implementing MVCC using global versions (shared with deterministic distributed transactions), it became possible to perform reads in a transaction using a global snapshot. This means pure read-only transactions no longer fail with serializability errors and rarely need to be retried by the user, improving throughput in read-heavy use cases. Transactions also acquired a "repeatable read" property, which means if you perform several selects from the same table, the transaction will not fail and will observe the same (globally consistent) result.



How YDB Stores MVCC Data

A DataShard tablet stores one table shard as a write-optimized LSM tree in which, for each primary key, we keep a list of operations that change column values in the row. The current row state is built on every access by merging individual change operations. Background compaction likewise merges value changes across LSM levels and writes an aggregated state for each row.

When MVCC was added to YDB, one goal was to avoid hurting performance for existing workloads. A typical example is queries for the latest row state in a table over a range of primary-key values. A naive MVCC design that appends a version suffix to the primary key was ruled out by the developers because it inevitably hurts query performance. Instead, YDB always keeps the latest row versions in the main SST structure (sorted string table, part of the LSM tree). When several versions of a row exist, the newest version is marked with a flag meaning "change history" is present. Older versions of rows marked this way live in an additional SST; version data for each row is sorted in descending version order.

When reading from a snapshot, YDB checks whether the latest row version in the main SST is "too new" and, if needed, runs a binary search in the SST that holds historical data. The changes in the row version that matches the current snapshot are used to reconstruct the row's data state. Because LSM levels roughly correspond to when they were created, the search for row versions in the SST for the current level can stop as soon as a suitable version is found. To build the full row state at the snapshot, we take the newest version of that row in each older LSM level. The number of row-version merge operations is therefore bounded by the number of LSM levels, which is usually small.

Operations

PK	Version	Update
51	v1	SET A=1
51	v5	SET B=5
51	v10	SET A=10
51	v15	SET C=15
51	v20	SET D=20
51	v30	SET C=30

SST1

RowId	PK	Version	Update
15	...	...	...
16	51	v10 +HasHistory	SET A=10 B=5
17	...	...	...

SST1 History

Key	Update
...	...
(16, v5)	SET A=1 B=5
(16, v1)	SET A=1
...	...

SST2

RowId	PK	Version	Update
43	...	...	...
44	51	v15	SET C=15
45	...	...	...

SST3

RowId	PK	Version	Update
26	...	...	...
27	51	v30 +HasHistory	SET C=30 D=20
25	...	...	...

SST3 History

Key	Update
...	...
(27, v20)	SET D=20
...	...

Rows stored in SSTs do not hold a full set of attributes; in practice they store only data changes. Each row stored in a given SST contains the full set of data changes for the row relative to the latest version of the same row in the previous SST in the LSM tree. This redundant storage format makes lookups and compaction more efficient.

Consider a hypothetical case where a user applies one million updates to a row with key K, each time changing only one of many table columns. To keep writes efficient, YDB avoids reading the row state at update time and instead records a change in the form "update column C for key K". Row versions accumulate in memory in a MemTable and are periodically flushed to new SSTs, each of which in this example will hold a (typically large) number of versions of the updated row. If each row version stored only a delta compared to the previous version, building the current row state would require merging data from one million accumulated versions and scanning a large amount of data. Instead, at each SST level YDB stores aggregated row changes, starting from the MemTable as LSM level 0 (where the previous row state is always available in RAM, so disk reads are not needed).

During compaction, when several SST levels are merged into a new SST, each changed row is merged with its latest versions from older SSTs. That reduces the cost of row merges (still bounded per row by the number of LSM levels) for both compaction and reads, while still allowing "blind" writes without reconstructing the full row when updating its columns.

PK=51 at different versions

Version	SST3	SST2	SST1
v35	SET C=30 D=20	no updates (C=15 overridden by C=30)	SET A=10 B=5
v25	SET D=20 found (27, v20) <= v25	SET C=15	SET A=10 B=5
v19	no data for v19	SET C=15	SET A=10 B=5
v7	no data for v7	no data for v7	SET A=1 B=5 found (16, v5) <= v7

Eventually, we mark version ranges as deleted and no longer readable, after which compactions allow us to garbage collect unnecessary row versions automatically (unreachable versions are skipped over and not emitted when writing new SSTs). We also store a small per-version histogram for each SST, so we can detect when too much unnecessary data accumulates in the LSM tree and trigger additional compactions for garbage collection.

How YDB Uses MVCC

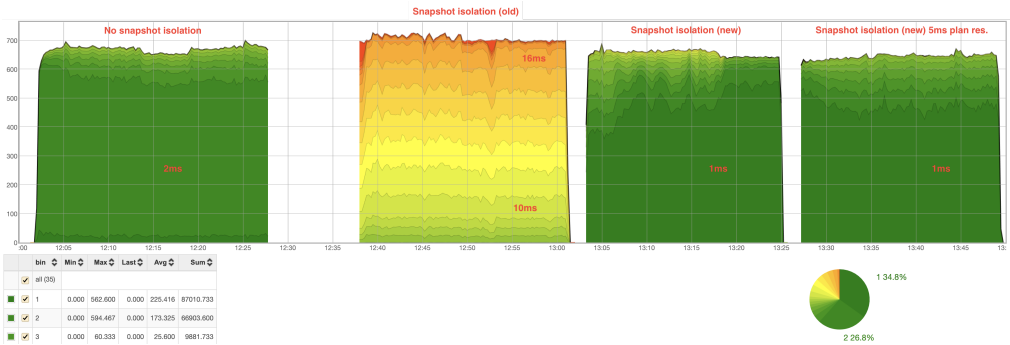
MVCC allows DataShards to improve the reordering of transactions, but we can do even better by leveraging global snapshots, so we use global timestamps as version tags, which correspond to global order already used by deterministic distributed transactions. This allows us to create global snapshots by choosing a correct global timestamp. Using such snapshots to read from DataShards effectively allows the database to observe a consistent snapshot at that point in logical time.

When we perform the first read in an interactive or multi-stage transaction, we choose a snapshot timestamp that is guaranteed to include all previously committed transactions. Currently, this is just a timestamp that corresponds to the last timestamp sent out by Coordinators. This timestamp may be slightly in the future (as some transactions in-flight from Coordinators to DataShards may not have started executing yet), but usually not by much, and since transactions are inflight, they are expected to be executed soon. Most importantly, this timestamp is guaranteed to be equal to or larger than any commit timestamp already observed by the client, so when this timestamp is generated for new reads, those reads are guaranteed to include all previously finished writes.

We then use this snapshot for reads without any additional coordination between participants, as snapshots are already guaranteed to be globally consistent across the database. To guarantee snapshots include all relevant changes and are not modified later, DataShards may need to wait until they received all write transactions that must have happened before that snapshot, but only conflicting writes need to execute before the read may start. DataShards also guarantee that any data observed by the snapshot is frozen and won't be modified later by concurrent transactions (effectively guaranteeing repeatable read), but this only applies to observed changes. Anything not yet observed is in a state of flux and is free to be modified until logical time advances well past the snapshot at every participant in the database. An interesting consequence of this is that some later writes may be reordered before the snapshot, which is allowed under serializable snapshot isolation.

When interactive transactions perform writes, their changes are buffered and the final distributed commit transaction checks (using optimistic locks) that the transaction did not have any conflicting changes between its read (snapshot) and commit time, which effectively simulates moving all reads forward to the commit point in time, only committing when it's possible. Interactive transactions also detect when they read from "history" data and mark such transactions as read-only, since we already know moving this read forward in time (to a future commit timestamp) would be impossible. If a user attempts to perform writes in such a transaction, we return a serialization error without any additional buffering or communication. If it turns out a transaction was read-only, there's no serialization violation (we have been reading from a consistent snapshot after all), and we only need to perform some cleanup, returning success to the user. Before YDB introduced global MVCC snapshots, we had to always check locks at commit time, which made it a struggle to perform wide reads under a heavy write load.

Keeping Fast KeyValue Performance



While YDB supports complicated distributed transactions between multiple shards and tables, it's important to also support fast single-shard transactions. Internally such transactions are called "immediate" and they historically don't use any additional coordination. For example, when a transaction only reads or writes a single key in a table, we only want to communicate with a single shard that the key belongs to and nothing else. At first glance, it runs contrary to the use of global MVCC timestamps; however, we may use local uncoordinated timestamps (possibly different at each DataShard), which are still correct global timestamps. Each distributed transaction is assigned a timestamp that consists of two numbers (step, txId), where a step is a coordination tick, often configured to increase every 10ms, and txId is a globally unique transaction id. Immediate transactions don't have a step, since they are not processed by coordinators, and while txId is unique, it is not guaranteed to always increase, so we cannot use it for write timestamps without risking these timestamps going back in time. There's an important distinction, however, since immediate transactions don't have to be repeatable, their read/write timestamp does not have to be unique. That's why we allow them to share a timestamp with some next transaction in the queue (effectively executing "just before" that transaction). When the queue is empty, we use a broadcasted coordinator time (the maximum step acknowledged by shards, so shard is guaranteed there will be no transactions up to that step's end) and a maximum number as txId (effectively executing "just before" that step ends).

Assigning such non-unique timestamps to immediate transactions guarantees there's always some new non-decreasing timestamp that allows them to execute without delay (subject to other out-of-order execution restrictions). It also helps with compactions, as we may have thousands of these transactions executed at the same timestamp, and all of that history is compacted into a single final row version for that step. This allows us to only keep versions in history that need to be consistent across multiple shards.

Prioritizing Reads

An interesting conundrum happened when we tried to enable MVCC snapshots for the first time: there was a severe degradation in read latency under some workloads! This was because time in YDB usually "ticks" every 10ms (tuned to be similar to typical multi-datacenter commit time of 4ms), and single-shard writes use "current time" as part of their timestamp. This meant snapshot reads had to wait for the next tick until the read timestamp is "closed" for new writes, as well as make sure it is actually safe. This added quite a bit of latency to reads, which in hindsight was entirely expected.

We had to go back to the drawing board and find ways to prioritize reads without penalizing writes too much. What we ended up doing was to "close" the read timestamp as soon as we perform a repeatable snapshot read, while choosing some "future" timestamp for new single-shard writes that is guaranteed to not corrupt previously read snapshots (ensuring repeatable read). However, since that write timestamp is in the future, and we must ensure any new snapshot includes committed data, we delay responses until that future timestamp matches the current timestamp, and pretend this new data is not committed (e.g., when running concurrent single-shard reads) until timestamps finally match. Interestingly, since writes are already in flight to storage and must be committed first in at least one other datacenter, this wait did not add much to average write latency even with many snapshot reads, but it did wonders to read latency:

	bin	Min	Max	Last	Avg	Sum
	all (35)					
1	1	0.000	562.600	0.000	225.416	87010.733
2	2	0.000	594.467	0.000	173.325	66903.600
3	3	0.000	60.333	0.000	25.600	9881.733

Secondary indexes

In YDB, an index is automatically created on the primary key, so queries with a condition on the primary key are always executed efficiently, affecting only the required rows. A query with a condition on one or more non-key columns typically results in a full table scan. To make such queries efficient, you should use *secondary indexes* — global structures with a separate index table.

Separately, there are local indexes: auxiliary structures that are stored together with the table data and are used when reading on the storage side, without materializing a separate index table (see the Local indexes section below).

In the current version of YDB, *synchronous* and *asynchronous* global secondary indexes are implemented. Each index is a hidden table that is updated:

- for synchronous indexes — transactionally when the main table is modified;
- for asynchronous indexes — in the background, receiving the necessary changes from the main table.

When a user sends an SQL query to insert, modify, or delete data, the database transparently generates commands to modify the index table. A table can have multiple secondary indexes. An index can include multiple columns, and the order of columns in the index is important. A single column can be included in multiple indexes. In addition to the specified columns, the values of the table's primary key columns are always implicitly stored in the index, so that from a found index entry you can navigate to the table entry.

Synchronous secondary index

A synchronous index is updated simultaneously with the table it indexes. Such an index provides strong data consistency and uses the distributed transactions mechanism for this. Thus, while read and blind write operations on a table without an index can be performed without a planning stage, thereby significantly reducing latency, such optimization is not possible for writes to a table with a synchronous index.

Asynchronous secondary index

An asynchronous index, unlike a synchronous one, does not use the distributed transaction mechanism, but receives changes from the indexed table in the background. Write transactions to a table with such an index are performed without additional planning overhead, at the cost of reduced guarantees: an asynchronous index provides eventual data consistency, but not strong consistency. Using an asynchronous index in read transactions is only possible in Stale Read Only mode.

Covering secondary index

It is possible to copy the contents of columns into the index (covering index), thus eliminating the need to read from the main table in index read operations, which significantly reduces latency. At the same time, such denormalization leads to increased disk space consumption and possible slowdown of insert and update operations due to the need for additional data copying.

Unique secondary index

This type of index implements the semantics of a unique value in a column or set of columns, and, like other indexes, allows efficient point reads on the set of indexed columns. YDB uses it to perform additional checks to ensure that each unique value of the indexed columns appears in the table no more than once. If a modifying query violates this constraint, it is aborted with the status `PRECONDITION_FAILED`. Therefore, user code must be prepared to handle this status.

A unique secondary index is a synchronous index, so from a transactional perspective, its update process is the same as that of the synchronous secondary index described above.

Vector index

Vector index is a special type of secondary index.

Unlike traditional secondary indexes, which optimize equality or range search, vector indexes allow performing vector search based on distance or similarity functions.

Full-text index

Full-text index is a special type of secondary index.

Unlike traditional secondary indexes, which optimize search by equality or range, full-text indexes allow scalable text search for words and phrases (and when using N-grams, also for substrings). See also: Full-text search.

JSON-index

JSON index is a special type of secondary index, like full-text index — both are built on top of an inverted index, but use different tokenizers.

JSON indexes allow you to speed up predicates with the JSON_EXISTS and JSON_VALUE functions on the content of a column of type `Json` or `JsonDocument`. The index is built by splitting JSON documents into path tokens and pairs of the form "path + value", which allows you to find matching rows by JsonPath paths without a full table scan. See also: JSON search.

Local indexes

Local indexes — auxiliary structures stored together with table data and used for reads on the storage side. They do not materialize a separate index table. Currently, Bloom indexes are implemented, and other types are planned in the future.

Online creation of a secondary index

In YDB, you can create a secondary index and delete an existing secondary index without stopping service. For one table, only one index can be created at a time.

The online index creation operation consists of the following steps:

1. Taking a snapshot of the table with data, creating an index table marked as available for writes.

   After this step, write transactions become distributed, and data is written to the main table and the index. The index is not yet available to the user.
2. Reading a snapshot of the main table and writing to the index.

   Implements "write to the past": situations are allowed where data updates in step 1 change data written in step 2.
3. Publishing the result, deleting the snapshot.

   The index is ready to use.

Possible impact on user transactions:

- Increased latency may be observed because transactions become distributed (when creating a synchronous index).
- An increased background of `OVERLOADED` errors is possible because automatic partitioning of index table shards is actively working during data writes.

> **Note**
>
> The data write speed is chosen to minimize the impact of the write process on user transactions. To control the speed, configure limits for the corresponding queue of the resource broker.

Creating an index is an asynchronous operation. If a client-server connection break occurs after starting the operation, the index building will continue. You can manage the asynchronous operation via YDB CLI.

Creating and deleting secondary indexes

A secondary index can be:

- Created when creating a table using the YQL CREATE TABLE command.
- Added to an existing table by the YQL ALTER TABLE command or by the YDB CLI table index add command.
- Deleted from an existing table by the YQL command ALTER TABLE or by the YDB CLI command table index drop.
- Deleted together with the table by the YQL command DROP TABLE or by the YDB CLI command `table drop`.

Using secondary indexes

Detailed information on using secondary indexes in applications is available in the article about them in the developer documentation section.

Vector search

Vector search concept

Vector search, also known as nearest neighbor search (NN), is an optimization problem of finding the nearest vector (or set of vectors) in a given dataset relative to a query vector. Proximity between vectors is determined using distance or similarity metrics.

A common approach, especially with large datasets, is approximate nearest neighbor (ANN) search, which yields faster results at the possible cost of some accuracy.

Vector search is widely used in:

- recommendation systems;
- semantic search;
- image similarity search;
- anomaly detection;
- classification systems.

In addition, **vector search** in YDB is widely applied in machine learning (ML) and artificial intelligence (AI) tasks. It is particularly useful in Retrieval-Augmented Generation (RAG) approaches, which utilize vector search to retrieve relevant information from large volumes of data, significantly enhancing the quality of generative models.

Vector search methods can be divided into three main categories:

- exact methods;
- approximate methods without index;
- approximate methods with index.

The choice of method depends on the number of vectors and the workload. Exact methods are slower to search and faster to update; indexes are the opposite.

Exact vector search

The foundation of the exact method is the calculation of the distance from the query vector to all the vectors in the dataset. This algorithm, also known as the naive approach or brute force method, has a runtime of `O(dn)`, where `n` is the number of vectors in the dataset, and `d` is their dimensionality.

Exact vector search is best utilized if the complete enumeration of the vectors occurs within acceptable time limits. This includes cases where they can be pre-filtered based on some condition, such as a user identifier. In such instances, the exact method may perform faster than the current implementation of vector indexes.

Main advantages:

- No need for additional data structures, such as specialized vector indexes.
- Full support for transactions, including in strict consistency mode.
- Instant execution of data modification operations: insertion, update, deletion.

For more information, see exact vector search examples.

Approximate vector search without index

Approximate methods do not perform a complete enumeration of the initial data. This allows significantly speeding up the search process, although it might lead to some reduction in the quality of the results.

Scalar Quantization is a method of reducing vector dimensionality, where a set of coordinates is mapped into a space of smaller dimensions.

YDB supports vector searching for vector types `Float`, `Int8`, `Uint8`, and `Bit`. Consequently, it is possible to apply scalar quantization to transform data from `Float` to any of these types.

Scalar quantization reduces the time required for reading and writing data by decreasing the number of bytes. For example, when quantizing from `Float` to `Bit`, each vector is reduced by 32 times.

Approximate vector search without an index uses a very simple additional data structure - a set of vectors with other quantization. This allows the use of a simple search algorithm: first, a rough preliminary search is performed on the compressed vectors, followed by refining the results on the original vectors.

Main advantages:

- Full support for transactions, including in strict consistency mode.
- Instant application of data modification operations: insertion, update, deletion.

Learn more about approximate vector search without index.

Approximate vector search with index

When the data volume significantly increases, non-index approaches cease to work within acceptable time limits. In such cases, additional data structures are necessary such as vector indexes, which accelerate the search process.

Main advantage:

- ability to work with a large number of vectors.

Disadvantages:

- index build can take considerable time;
- the current version does not support data modification operations: insert, update, delete.

Fulltext search

Concept of fulltext search

Fulltext search is a way to find documents by text content in a `String` or `Utf8` column by words, phrases, and (with special indexing) by substrings. Unlike simple string predicates, fulltext search typically involves **tokenization** and **normalization** (for example, lowercasing), so queries operate on "terms" rather than raw byte substrings. Typical use cases include:

- search in product catalogs and knowledge bases
- log/message search
- searching document metadata and descriptions

The core idea of a fulltext index is an **inverted index**: for each term, the index stores the list of documents (primary keys) that contain that term. This allows queries like "documents containing terms A and B" to avoid full table scans.

In YDB, fulltext search can be performed in two main ways:

- **without an index** — by scanning the table and applying string predicates (for example, `LIKE`). This approach is simple but does not scale well as data grows.
- **with a fulltext index** — by creating a fulltext index and executing queries through `VIEW IndexName`. This approach is designed for scalable search.

Fulltext search with a fulltext index

Fulltext indexes build an inverted index over a text column and allow:

- fulltext matching via FulltextMatch (query modes `Keywords` / `Query` / `Wildcard`, default operator `And` / `Or`)
- relevance ranking (BM25) via FulltextScore when using fulltext_relevance

Search behavior (what counts as a term, case/word-form handling, wildcard support) is configured at index creation time via tokenizers and filters (for example, lowercase, Snowball stemming, n-grams). For details, see the index creation syntax Fulltext index.

Hybrid search

Hybrid search concept

Hybrid search combines fulltext search and vector search into a single ranked result. Instead of choosing one signal, a hybrid query scores each document by both how well its text matches the query (lexical relevance) and how close its embedding is to the query vector (semantic similarity), and then **fuses** the two rankings into one.

The two signals are complementary:

- **Fulltext search** (BM25) is precise for exact terms, names, codes, and rare keywords, but misses documents that use different wording.
- **Vector search** (nearest neighbor over embeddings) captures semantic similarity and paraphrases, but can rank a topically related document above one that contains the exact term the user typed.

Fusing them yields results that are both lexically and semantically relevant. This is a common building block for search over knowledge bases and for the retrieval stage of Retrieval-Augmented Generation (RAG).

Hybrid search in YDB

In YDB, a hybrid query runs over a table that has **both**:

- a fulltext_relevance index over the text column, and
- a vector_kmeans_tree index over the embedding column.

The query expresses the fusion in the `ORDER BY` clause with the `HybridRank` function, which takes one scoring expression per branch — a FullTextScore for the text branch and a Knn distance or similarity for the vector branch:

```
$queryText = "machine learning";
$queryVector = Knn::ToBinaryStringFloat([0.1, 0.2, 0.3, 0.4]);

SELECT id, title
FROM documents
ORDER BY HybridRank(
    FullTextScore(text, $queryText),
    Knn::CosineDistance(embedding, $queryVector))
LIMIT 10;
```

Each branch runs against its own index and returns its own list of best-matching documents. YDB then merges these lists into a single ranking — in one of two ways:

- **Reciprocal Rank Fusion (RRF)** — the default. Each branch contributes a term based on a document's *rank* within that branch, so the absolute magnitudes of the scores (which are not comparable across branches) do not matter.
- **Linear** — a weighted sum of the (optionally min-max normalized) per-branch scores.

Per-branch weights, the RRF constant, and the candidate-pool sizes are all configurable. For the full query syntax and parameters, see Hybrid search (HybridRank).

Searching JSON document contents

JSON search is a way to find table rows by the content of a JSON document stored in a column of type `Json` or `JsonDocument`: by the existence of a path in the document and by the value located at the specified path. The path is specified using a JsonPath expression, and the checks are performed using the existing functions JSON_EXISTS and JSON_VALUE. Typical scenarios:

- Search for documents with a specific nested field
- Search for documents whose field at a given path equals the required value.
- filtering semi-structured data without a pre-defined schema.

In YDB, JSON search can be performed in two main ways:

- Without an index: scanning the table and applying the `JSON_EXISTS` or `JSON_VALUE` functions to each row. The approach is simple but scales poorly: the amount of scanning work grows with the table size.
- with a JSON index — creating a JSON index on a JSON column. This approach is designed for scalable search.

JSON search with a JSON index

The key idea of a JSON index is building an inverted index over paths and "path + value" pairs. Each path of a JSON document (and for equality checks, the scalar value at that path) is encoded into a token. For each token, the index stores a list of primary key values of the corresponding table rows. Queries to the index are reduced to an inverted search over these tokens — following the same scheme as a full-text index, but with its own JSON tokenizer.

The JSON index does not store a copy of the entire JSON document, but decomposes it into individual tokens:

- For each path in the JSON tree, a token 'path exists' is created.
- if the path leads to a scalar value (string, number, boolean, or `null`), a «path + value» token is additionally created.

Arrays are transparent in this case: array elements are indexed under the same path as the array itself, so the index responds equally to queries to `$.items`, `$.items[0]`, and `$.items[*]`.

For example, for a document:

```
{
    "id": 42042,
    "name": "Michael",
    "email": null,
    "items": [null, "str"],
    "parts": {
        "key": "k1",
        "value": false
    }
}
```

Conceptually, the following tokens are indexed (without regard to the specifics of the internal representation):

Token	What it finds
`$`	document is not equal to `NULL`
`$.id` / `$.id == 42042`	path `id` exists / equals `42042`
`$.name` / `$.name == "Michael"`	path `name` exists / equals `"Michael"`
`$.email` / `$.email == null`	path `email` exists / equals `null`
`$.items` / `$.items == null` / `$.items == "str"`	path `items` exists / contains element `null` / contains element `"str"`
`$.parts`	path `parts` exists
`$.parts.key` / `$.parts.key == "k1"`	nested path exists / equals `"k1"`
`$.parts.value` / `$.parts.value == false`	nested path exists or equals `false`

JSON index allows:

- find rows by path existence using JSON_EXISTS
- find rows by a value in a path using JSON_VALUE or a filter predicate within `JSON_EXISTS`.

When executing a query, the JSON index can be automatically used by the optimizer. It is enough to write a regular condition `WHERE` with expressions `JSON_EXISTS` or `JSON_VALUE` on an indexed JSON column. The optimizer recognizes such a predicate and applies reading by the JSON index instead of scanning records of the source table. Additionally, the JSON index, like any other secondary index, can be forcefully used by specifying its name in the section `VIEW IndexName`.

If the predicate cannot be converted into an index access, the behavior of YDB depends on whether the required JSON index was explicitly specified in the query:

- When the optimizer automatically selects an index, the query is simply executed without index acceleration (the result remains correct).
- When explicitly specifying an index via the `VIEW` expression, an error is returned.

For more information, see VIEW (JSON index).

Local indexes

Local index concept

A local index is an auxiliary structure that is stored together with the table data and is used when reading from storage. It does not materialize a separate index table.

Local indexes act as read filters for the main table: the query optimizer and the storage layer use them to skip irrelevant data fragments during scanning.

Currently, YDB implements local Bloom indexes and a min_max index.

Bloom indexes

Bloom indexes are a special case of a local index built on the Bloom filter.

When reading, for each data fragment the index checks whether the sought value (or a set of n-grams) can occur in it. If the filter reports that the value definitely does not occur, the fragment is skipped without reading the indexed columns. If the filter "passes" the check, the value may be present — including due to a false positive — and the fragment must be read. This reduces the amount of data actually read for selective queries.

Bloom index types

- `bloom_filter` — builds a filter on the exact values of the indexed column. Suitable for equality conditions (`=`), list membership checks (`IN`), and other equality comparisons for supported types.
- `bloom_ngram_filter` — builds a filter on n-grams of a string column (`String`, `Utf8`). When searching by substring or pattern (`LIKE`), the query is split into n-grams; if the fragment index lacks at least one of the required n-grams, the sought substring cannot be in it, and the fragment is skipped. Supported only in columnar tables.

Local Bloom indexes

Type `bloom_filter` works in both row-based (OLTP) and columnar (OLAP) tables, but the implementation differs:

- In row-based tables, the filter is built as a prefix Bloom filter on the left prefix of the primary key. The indexed columns must form a continuous leading subset of the primary key columns. This speeds up point reads and range scans that restrict the leading key columns. To create a prefix Bloom filter, use ALTER TABLE ... ADD INDEX; to drop it, use ALTER TABLE ... DROP INDEX.
- In columnar tables, the filter is built on the values of the indexed column in each data fragment (portion) and is used in analytical scans to skip fragments that do not contain the sought value.

Limitations

- `COVER (...)` and extra index columns are not supported.
- Column-oriented tables allow only one indexed column. Row-oriented tables allow multiple indexed columns.
- `bloom_ngram_filter` is not supported on row-oriented tables.
- On row-oriented tables, the indexed columns of a `bloom_filter` must be a left prefix of the primary key. Non-prefix column sets are rejected.
- On row-oriented tables, two `bloom_filter` indexes cannot share the same prefix length (the same set of leading primary-key columns).

Additional materials

- Bloom indexes
- ALTER TABLE ADD INDEX

min_max index

A min_max index is a special case of a local index that stores the minimum and maximum value of one indexed column for each data fragment.

When reading with a special kind of filter on a column with a min_max index, YDB first reads the minimum and maximum values stored for the fragment and checks whether the filter interval intersects this range. If the intervals do not intersect, the predicate is guaranteed to be false on all values of the fragment, so the fragment can be skipped. This is useful for range predicates and equality conditions (a special case of a range predicate) on columns with a small spread between the minimum and maximum values within stored fragments.

Example:

In storage, for the `events` table, one of the fragments of column `level` of type `Int32` contains values `[5, 5, 9, 5, 9, 13]`. Then the minimum value is 5, the maximum is 13. For query `SELECT * FROM events WHERE level = 15`, the filter interval is `[15, 15]`. It does not intersect with interval `[5, 13]`, so such a fragment does not need to be read from storage.

Min-max index predicates

The optimizer can use the min_max index for predicates `=`, `<`, `<=`, `>`, `>=`, `BETWEEN`, as well as compatible combinations with `AND` or `OR`.

Limitations

- Supported only for columnar tables.
- `ON (...)` must specify exactly one column.
- `COVER (...)` and additional data columns are not supported.
- Specific parameters of `WITH (...)` are not supported.
- `ALTER INDEX` is not supported for the min_max index.
- Columns of types `Json` and `JsonDocument` are not supported.

Additional materials

- min_max index
- ALTER TABLE ADD INDEX

Federated queries

Federated queries allow you to retrieve information from various data sources without the need to transfer data from those sources into YDB. Using YQL queries, you can access external databases without duplicating data between systems.

To work with data stored in external DBMSs, simply create an external data source. To work with unschematized data stored in S3 buckets, you additionally need to create an external table. In both cases, you must first create secrets that store confidential data required for authentication in external systems.

You can learn about the internal structure of the federated query processing system in the section on architecture. Detailed information on working with various data sources is provided in the respective sections:

- S3

Experimental sources data

- ClickHouse
- Greenplum
- Microsoft SQL Server
- MySQL
- PostgreSQL
- YDB (federated queries between YDB databases)

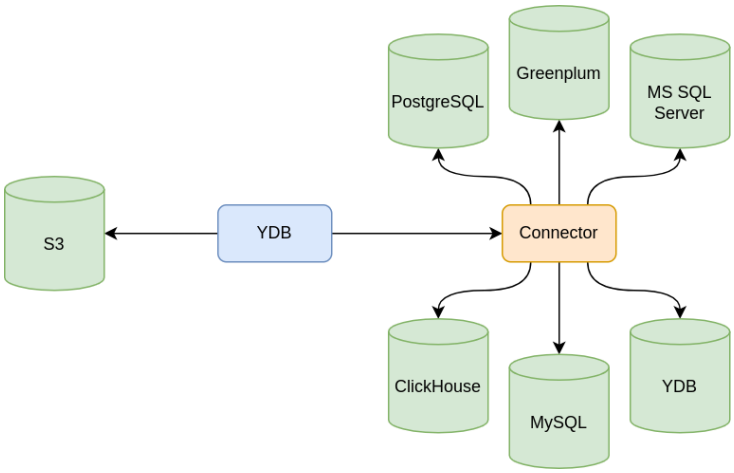
Federated query processing system architecture

External data sources and external tables

The key element of the YDB federated query processing system is the concept of an external data source. Such sources can include relational DBMSs, object storages, and other data storage systems. When processing a federated query, YDB streams data from external systems and allows performing the same range of operations on them as on local data.

To work with data stored in external systems, YDB must have information about the internal structure of this data (for example, the number, names, and types of columns in tables). Some sources provide such metadata about the data together with the data itself, while working with other, unschematized sources requires specifying this metadata externally. External tables serve this latter purpose.

After registering external data sources and (if necessary) external tables in YDB, the client can start describing federated queries.



Connectors

During the execution of federated queries, YDB needs to access third-party data storage systems over the network, which requires using their client libraries. The introduction of such dependencies negatively affects the size of the codebase, compilation time, and the size of binary files YDB, as well as the stability of the entire product.

The list of supported data sources for federated queries is constantly expanding.
The most popular sources, such as S3, are natively supported by YDB. However, not all users need support for all sources at the same time. It can be enabled optionally using *connectors* - special microservices that implement a unified interface for accessing external data sources.

The functions of connectors include:

- Translation of YQL queries into queries in a language specific to the external source (for example, into queries in another SQL dialect or into HTTP API calls).
- Establishing network connections to data sources.
- Conversion of data extracted from external sources into a columnar representation in the Arrow IPC Stream format supported by YDB.

Thus, connectors form an abstraction layer that hides the specifics of external data sources from YDB. The conciseness of the connector interface makes it easy to expand the list of supported sources with minimal changes to the YDB code.

Users can deploy one of the ready-made connectors or write their own implementation in any programming language according to the gRPC specification.

List of supported external data sources

YDB has built-in support in `ydbd` for the following external data sources:

- S3

Through the fq-connector-go connector, access to a number of experimental external DBMSs is additionally supported. For details, see the Federated queries section.

Working with ClickHouse databases

> **Warning**
>
> External connectors are an experimental feature of YDB. To work with external DBMS through connectors, you need to deploy fq-connector-go and explicitly enable the corresponding sources in the cluster configuration YDB. The functionality may change, so use in production is not recommended without thorough testing.

This section describes basic information about working with an external database ClickHouse.

To work with an external ClickHouse database, you need to follow these steps:

1. Create a secret containing the password for connecting to the database.

   ```
   CREATE SECRET clickhouse_datasource_user_password WITH (value = "<password>");
   ```

2. Create an external data source that describes the target database inside the ClickHouse cluster. To connect to ClickHouse, you can use either the native TCP protocol (`PROTOCOL="NATIVE"`) or the HTTP protocol (`PROTOCOL="HTTP"`). Enable encryption of connections to the external database using the `USE_TLS="TRUE"` parameter.

   ```
   CREATE EXTERNAL DATA SOURCE clickhouse_datasource WITH (
       SOURCE_TYPE="ClickHouse",
       LOCATION="<host>:<port>",
       DATABASE_NAME="<database>",
       AUTH_METHOD="BASIC",
       LOGIN="<login>",
       PASSWORD_SECRET_PATH="clickhouse_datasource_user_password",
       PROTOCOL="NATIVE",
       USE_TLS="TRUE"
   );
   ```

3. Deploy the connector and configure the YDB dynamic nodes to interact with it. Additionally, ensure network access from the YDB dynamic nodes to the external data source (at the address specified in the `LOCATION` parameter of the `CREATE EXTERNAL DATA SOURCE` request). If network connection encryption to the external source was enabled in the previous step, the connector will use the system's root certificates. More details on TLS configuration can be found in the guide on deploying the connector.
4. Execute a query to the database.

Query syntax

The following SQL query form is used to work with ClickHouse:

```
SELECT * FROM clickhouse_datasource.<table_name>
```

where:

- `clickhouse_datasource`: external data source identifier
- `<table_name>` is the name of the table inside the external data source.

Limitations

When working with ClickHouse clusters, there are a number of limitations:

1. External sources are available only for reading data through `SELECT` queries. The federated query processing engine currently does not support queries that modify tables in external sources.
2. If the date value stored in the external data source is outside the allowed range for YDB (all dates used must be later than 1970-01-01 but earlier than 2105-12-31), such a value in YDB will be converted to `NULL`.
3. The YDB federated query processing system is capable of delegating the execution of certain parts of a query to the system acting as the data source. Query fragments are passed through YDB directly to the external system and processed by them. This optimization, known as "predicate pushdown", significantly reduces the amount of data transferred from the source to the federated query processing engine. This reduces network load and saves computational resources for the federated YDB.

   A specific case of predicate pushdown, when the filtering expressions are specified after the `WHERE` keyword, are passed to the data source, is called "filter pushdown". Filter pushdown is possible when using:

Description	Example
`NULL` checks	`WHERE column1 IS NULL` or `WHERE column1 IS NOT NULL`
Logical conditions `OR`, `NOT`, `AND` and parentheses for controlling calculation priority.	`WHERE column1 IS NULL OR (column2 IS NOT NULL AND column3 > 10)`.
Comparison operators with other columns or constants.	`WHERE column1 > column2 OR column3 <= 10`, `WHERE column1 + column2 > 10`, `WHERE column1 = (10 + 10)`

   When using other types of filters, pushdown to the data source is not performed: filtering of the external table rows will be executed by the federated YDB, which means that YDB will perform a full scan of the external table when processing the query.

   Supported data types for filter pushdown:

Data type YDB
`Bool`
`Int8`

`Uint8`
`Int16`
`Uint16`
`Int32`
`Uint32`
`Int64`
`Uint64`
`Float`
`Double`
`String`

Supported data types

By default, ClickHouse columns physically cannot contain the `NULL` value; however, you can create a table with columns of optional, or nullable, types. The column types displayed by YDB when retrieving data from an external ClickHouse database will depend on whether the ClickHouse table uses primitive or optional types. However, due to the limitations of YDB types used for storing dates and times discussed above, all similar ClickHouse types are displayed in YDB as optional.

Below are the tables of correspondence between ClickHouse and YDB types. All other data types, except those listed, are not supported.

Primitive data types

ClickHouse data type	Data type YDB	Notes
`Bool`	`Bool`	
`Int8`	`Int8`	
`UInt8`	`Uint8`	
`Int16`	`Int16`	
`UInt16`	`Uint16`	
`Int32`	`Int32`	
`UInt32`	`Uint32`	
`Int64`	`Int64`	
`UInt64`	`Uint64`	
`Float32`	`Float`	
`Float64`	`Double`	
`Date`	`Date`	
`Date32`	`Optional<Date>`	Valid date range from 1970-01-01 to 2105-12-31. If the value goes outside the range, `NULL` is returned.
`DateTime`	`Optional<DateTime>`	Valid time range from 1970-01-01 00:00:00 to 2105-12-31 23:59:59. If the value goes out of range, the value `NULL` is returned.
`DateTime64`	`Optional<Timestamp>`	Valid time range from 1970-01-01 00:00:00 to 2105-12-31 23:59:59. If the value goes out of range, the value `NULL` is returned.
`String`	`String`	
`FixedString`	`String`	Null bytes `FixedString` are transferred to `String` unchanged.

Optional data types

ClickHouse data type	Data type YDB	Notes
`Nullable(Bool)`	`Optional<Bool>`	
`Nullable(Int8)`	`Optional<Int8>`	
`Nullable(UInt8)`	`Optional<Uint8>`	
`Nullable(Int16)`	`Optional<Int16>`	
`Nullable(UInt16)`	`Optional<Uint16>`	
`Nullable(Int32)`	`Optional<Int32>`	
`Nullable(UInt32)`	`Optional<Uint32>`	

`Nullable(Int64)`	`Optional<Int64>`	
`Nullable(UInt64)`	`Optional<Uint64>`	
`Nullable(Float32)`	`Optional<Float>`	
`Nullable(Float64)`	`Optional<Double>`	
`Nullable(Date)`	`Optional<Date>`	
`Nullable(Date32)`	`Optional<Date>`	Valid date range from 1970-01-01 to 2105-12-31. If the value goes beyond the range boundaries, `NULL` is returned.
`Nullable(DateTime)`	`Optional<DateTime>`	Allowed time value range from 1970-01-01 00:00:00 to 2105-12-31 23:59:59. If the value goes beyond the range boundaries, the `NULL` value is returned.
`Nullable(DateTime64)`	`Optional<Timestamp>`	Allowed time value range from 1970-01-01 00:00:00 to 2105-12-31 23:59:59. If the value goes beyond the range boundaries, the value `NULL` is returned.
`Nullable(String)`	`Optional<String>`	
`Nullable(FixedString)`	`Optional<String>`	Null bytes `FixedString` are transferred to `String` without changes.

Working with Greenplum databases

> **Warning**
>
> External connectors are an experimental feature of YDB. To work with external DBMS through connectors, you need to deploy fq-connector-go and explicitly enable the corresponding sources in the cluster configuration YDB. The functionality may change, so use in production is not recommended without thorough testing.

This section describes the basic information about working with an external Greenplum database. Since Greenplum is based on PostgreSQL, integrations with them work similarly, and some links below may lead to PostgreSQL documentation.

To work with an external Greenplum database, you need to perform the following steps:

1. Create a secret containing the password for connecting to the database.

   ```
   CREATE SECRET greenplum_datasource_user_password WITH (value = "<password>");
   ```

2. Create an external data source that describes a specific database within a Greenplum cluster. Pass the network address of the Greenplum master node in the `LOCATION` parameter. By default, the namespace `public` is used for reading, but this value can be changed using the optional `SCHEMA` parameter. You can enable encryption of connections to the external database using the `USE_TLS="TRUE"` parameter.

   ```
   CREATE EXTERNAL DATA SOURCE greenplum_datasource WITH (
       SOURCE_TYPE="Greenplum",
       LOCATION="<host>:<port>",
       DATABASE_NAME="<database>",
       AUTH_METHOD="BASIC",
       LOGIN="user",
       PASSWORD_SECRET_PATH="greenplum_datasource_user_password",
       USE_TLS="TRUE",
       SCHEMA="<schema>"
   );
   ```

3. Deploy the connector and configure the YDB dynamic nodes to interact with it. Additionally, ensure network access from the YDB dynamic nodes to the external data source (at the address specified in the `LOCATION` parameter of the `CREATE EXTERNAL DATA SOURCE` request). If network connection encryption to the external source was enabled in the previous step, the connector will use the system's root certificates. More details on TLS configuration can be found in the guide on deploying the connector.
4. Execute a query to the database.

Query syntax

The following SQL query form is used to work with Greenplum:

```
SELECT * FROM greenplum_datasource.<table_name>
```

where:

- `greenplum_datasource`: external data source identifier
- `<table_name>` is the name of the table inside the external data source.

Limitations

When working with Greenplum clusters, there are a number of limitations:

1. External sources are available only for reading data through `SELECT` queries. The federated query processing engine currently does not support queries that modify tables in external sources.
2. If the date value stored in the external data source is outside the allowed range for YDB (all dates used must be later than 1970-01-01 but earlier than 2105-12-31), such a value in YDB will be converted to `NULL`.
3. The YDB federated query processing system is capable of delegating the execution of certain parts of a query to the system acting as the data source. Query fragments are passed through YDB directly to the external system and processed by them. This optimization, known as "predicate pushdown", significantly reduces the amount of data transferred from the source to the federated query processing engine. This reduces network load and saves computational resources for the federated YDB.

   A specific case of predicate pushdown, when the filtering expressions are specified after the `WHERE` keyword, are passed to the data source, is called "filter pushdown". Filter pushdown is possible when using:

Description	Example
`NULL` checks	`WHERE column1 IS NULL` or `WHERE column1 IS NOT NULL`
Logical conditions `OR`, `NOT`, `AND` and parentheses for controlling calculation priority.	`WHERE column1 IS NULL OR (column2 IS NOT NULL AND column3 > 10)`.
Comparison operators with other columns or constants.	`WHERE column1 > column2 OR column3 <= 10`, `WHERE column1 + column2 > 10`, `WHERE column1 = (10 + 10)`

   When using other types of filters, pushdown to the data source is not performed: filtering of the external table rows will be executed by the federated YDB, which means that YDB will perform a full scan of the external table when processing the query.

   Supported data types for filter pushdown:

Data type YDB
`Bool`

`Int8`
`Int16`
`Int32`
`Int64`
`Float`
`Double`

Supported data types

In the Greenplum database, the optionality flag of column values (whether a column is allowed or not allowed to contain `NULL` values) is not part of the data type system. The `NOT NULL` constraint for each column is implemented as the `attnotnull` attribute in the pg_attribute system catalog, i.e., at the table metadata level. Consequently, all basic Greenplum types can contain `NULL` values by default, and in the YDB type system they must be mapped to optional types.

Below is a table of correspondence between Greenplum types and YDB. All other data types, except those listed, are not supported.

Greenplum data type	Data type YDB	Notes
`boolean`	`Optional<Bool>`	
`smallint`	`Optional<Int16>`	
`int2`	`Optional<Int16>`	
`integer`	`Optional<Int32>`	
`int`	`Optional<Int32>`	
`int4`	`Optional<Int32>`	
`serial`	`Optional<Int32>`	
`serial4`	`Optional<Int32>`	
`bigint`	`Optional<Int64>`	
`int8`	`Optional<Int64>`	
`bigserial`	`Optional<Int64>`	
`serial8`	`Optional<Int64>`	
`real`	`Optional<Float>`	
`float4`	`Optional<Float>`	
`double precision`	`Optional<Double>`	
`float8`	`Optional<Double>`	
`json`	`Optional<Json>`	
`date`	`Optional<Date>`	Valid date range from 1970-01-01 to 2105-12-31. If the value goes beyond the range boundaries, `NULL` is returned.
`timestamp`	`Optional<Timestamp>`	Valid time range from 1970-01-01 00:00:00 to 2105-12-31 23:59:59. If the value goes beyond the range boundaries, the value `NULL` is returned.
`bytea`	`Optional<String>`	
`character`	`Optional<Utf8>`	Default collation rules, the string is padded with spaces to the required length.
`character varying`	`Optional<Utf8>`	Default collation rules.
`text`	`Optional<Utf8>`	Default collation rules.

Working with Microsoft SQL Server databases

> **Warning**
>
> External connectors are an experimental feature of YDB. To work with external DBMS through connectors, you need to deploy fq-connector-go and explicitly enable the corresponding sources in the cluster configuration YDB. The functionality may change, so use in production is not recommended without thorough testing.

This section describes the basic information about working with an external Microsoft SQL Server database.

To work with an external Microsoft SQL Server database, you need to perform the following steps:

1. Create a secret containing the password for connecting to the database.

   ```
   CREATE SECRET ms_sql_server_datasource_user_password WITH (value = "<password>");
   ```

2. Create an external data source that describes a specific Microsoft SQL Server database. The `LOCATION` parameter contains the network address of the Microsoft SQL Server instance to which the connection is made. The `DATABASE_NAME` parameter specifies the database name (for example, `master`). The values of the `LOGIN` and `PASSWORD_SECRET_PATH` parameters are used for authentication to the external database. You can enable encryption of connections to the external database using the `USE_TLS="TRUE"` parameter.

   ```
   CREATE EXTERNAL DATA SOURCE ms_sql_server_datasource WITH (
       SOURCE_TYPE="MsSQLServer",
       LOCATION="<host>:<port>",
       DATABASE_NAME="<database>",
       AUTH_METHOD="BASIC",
       LOGIN="user",
       PASSWORD_SECRET_PATH="ms_sql_server_datasource_user_password",
       USE_TLS="TRUE"
   );
   ```

3. Deploy the connector and configure the YDB dynamic nodes to interact with it. Additionally, ensure network access from the YDB dynamic nodes to the external data source (at the address specified in the `LOCATION` parameter of the `CREATE EXTERNAL DATA SOURCE` request). If network connection encryption to the external source was enabled in the previous step, the connector will use the system's root certificates. More details on TLS configuration can be found in the guide on deploying the connector.
4. Execute a query on the database.

Query syntax

The following SQL query form is used to work with Microsoft SQL Server:

```
SELECT * FROM ms_sql_server_datasource.<table_name>
```

where:

- `ms_sql_server_datasource`: external data source identifier
- `<table_name>` is the name of the table inside the external data source.

Limitations

When working with Microsoft SQL Server clusters, there are a number of limitations:

1. External sources are available only for reading data through `SELECT` queries. The federated query processing engine currently does not support queries that modify tables in external sources.
2. If the date value stored in the external data source is outside the allowed range for YDB (all dates used must be later than 1970-01-01 but earlier than 2105-12-31), such a value in YDB will be converted to `NULL`.
3. The YDB federated query processing system is capable of delegating the execution of certain parts of a query to the system acting as the data source. Query fragments are passed through YDB directly to the external system and processed by them. This optimization, known as "predicate pushdown", significantly reduces the amount of data transferred from the source to the federated query processing engine. This reduces network load and saves computational resources for the federated YDB.

   A specific case of predicate pushdown, when the filtering expressions are specified after the `WHERE` keyword, are passed to the data source, is called "filter pushdown". Filter pushdown is possible when using:

Description	Example
`NULL` checks	`WHERE column1 IS NULL` or `WHERE column1 IS NOT NULL`
Logical conditions `OR`, `NOT`, `AND` and parentheses for controlling calculation priority.	`WHERE column1 IS NULL OR (column2 IS NOT NULL AND column3 > 10)`.
Comparison operators with other columns or constants.	`WHERE column1 > column2 OR column3 <= 10`, `WHERE column1 + column2 > 10`, `WHERE column1 = (10 + 10)`

   When using other types of filters, pushdown to the data source is not performed: filtering of the external table rows will be executed by the federated YDB, which means that YDB will perform a full scan of the external table when processing the query.

Data type YDB
`Bool`
`Int8`

`Int16`
`Int32`
`Int64`
`Float`
`Double`

Supported data types

In a Microsoft SQL Server database, the optionality flag of column values (whether the column is allowed or prohibited from containing `NULL` values) is not part of the data type system. The `NOT NULL` constraint for any column of any table is stored as the value of the `IS_NULLABLE` column of the INFORMATION_SCHEMA.COLUMNS system table, that is, at the table metadata level. Consequently, all basic Microsoft SQL Server data types can by default contain `NULL` values, and in the YDB type system they must be mapped to optional types.

Below is a table of correspondence between Microsoft SQL Server types and YDB. All other data types, except those listed, are not supported.

Microsoft SQL Server data type	Data type YDB	Notes
`bit`	`Optional<Bool>`	
`tinyint`	`Optional<Int8>`	
`smallint`	`Optional<Int16>`	
`int`	`Optional<Int32>`	
`bigint`	`Optional<Int64>`	
`real`	`Optional<Float>`	
`float`	`Optional<Double>`	
`date`	`Optional<Date>`	Valid date range from 1970-01-01 to 2105-12-31. If the value goes beyond the range boundaries, `NULL` is returned.
`smalldatetime`	`Optional<Datetime>`	Valid time range from 1970-01-01 00:00:00 to 2105-12-31 23:59:59. If the value goes beyond the range boundaries, the value `NULL` is returned.
`datetime`	`Optional<Timestamp>`	Valid time range from 1970-01-01 00:00:00 to 2105-12-31 23:59:59. If the value goes beyond the range boundaries, the value `NULL` is returned.
`datetime2`	`Optional<Timestamp>`	Valid time range from 1970-01-01 00:00:00 to 2105-12-31 23:59:59. If the value goes beyond the range boundaries, the value `NULL` is returned.
`binary`	`Optional<String>`	
`varbinary`	`Optional<String>`	
`image`	`Optional<String>`	
`char`	`Optional<Utf8>`	
`varchar`	`Optional<Utf8>`	
`text`	`Optional<Utf8>`	
`nchar`	`Optional<Utf8>`	
`nvarchar`	`Optional<Utf8>`	
`ntext`	`Optional<Utf8>`	

Working with MySQL databases

> **Warning**
>
> External connectors are an experimental feature of YDB. To work with external DBMS through connectors, you need to deploy fq-connector-go and explicitly enable the corresponding sources in the cluster configuration YDB. The functionality may change, so use in production is not recommended without thorough testing.

This section describes basic information about working with an external MySQL database.

To work with an external MySQL database, you need to perform the following steps:

1. Create a secret containing the password for connecting to the database.

   ```
   CREATE SECRET mysql_datasource_user_password WITH (value = "<password>");
   ```

2. Create an external data source describing a specific MySQL database. The `LOCATION` parameter contains the network address of the MySQL instance to connect to. `DATABASE_NAME` specifies the database name (for example, `mysql`). For authentication to the external database, the values of the `LOGIN` and `PASSWORD_SECRET_PATH` parameters are used. You can enable encryption of connections to the external database using the `USE_TLS="TRUE"` parameter.

   ```
   CREATE EXTERNAL DATA SOURCE mysql_datasource WITH (
       SOURCE_TYPE="MySQL",
       LOCATION="<host>:<port>",
       DATABASE_NAME="<database>",
       AUTH_METHOD="BASIC",
       LOGIN="user",
       PASSWORD_SECRET_PATH="mysql_datasource_user_password",
       USE_TLS="TRUE"
   );
   ```

3. Deploy the connector and configure the YDB dynamic nodes to interact with it. Additionally, ensure network access from the YDB dynamic nodes to the external data source (at the address specified in the `LOCATION` parameter of the `CREATE EXTERNAL DATA SOURCE` request). If network connection encryption to the external source was enabled in the previous step, the connector will use the system's root certificates. More details on TLS configuration can be found in the guide on deploying the connector.
4. Execute a query to the database.

Query syntax

The following SQL query form is used to work with MySQL:

```
SELECT * FROM mysql_datasource.<table_name>
```

where:

- `mysql_datasource`: external data source identifier
- `<table_name>` is the name of the table inside the external data source.

Limitations

When working with MySQL clusters, there are a number of limitations:

1. External sources are available only for reading data through `SELECT` queries. The federated query processing engine currently does not support queries that modify tables in external sources.
2. If the date value stored in the external data source is outside the allowed range for YDB (all dates used must be later than 1970-01-01 but earlier than 2105-12-31), such a value in YDB will be converted to `NULL`.
3. The YDB federated query processing system is capable of delegating the execution of certain parts of a query to the system acting as the data source. Query fragments are passed through YDB directly to the external system and processed by them. This optimization, known as "predicate pushdown", significantly reduces the amount of data transferred from the source to the federated query processing engine. This reduces network load and saves computational resources for the federated YDB.

   A specific case of predicate pushdown, when the filtering expressions are specified after the `WHERE` keyword, are passed to the data source, is called "filter pushdown". Filter pushdown is possible when using:

Description	Example
`NULL` checks	`WHERE column1 IS NULL` or `WHERE column1 IS NOT NULL`
Logical conditions `OR`, `NOT`, `AND` and parentheses for controlling calculation priority.	`WHERE column1 IS NULL OR (column2 IS NOT NULL AND column3 > 10)`.
Comparison operators with other columns or constants.	`WHERE column1 > column2 OR column3 <= 10`, `WHERE column1 + column2 > 10`, `WHERE column1 = (10 + 10)`

   When using other types of filters, pushdown to the data source is not performed: filtering of the external table rows will be executed by the federated YDB, which means that YDB will perform a full scan of the external table when processing the query.

   Supported data types for filter pushdown:

Data type YDB
`Bool`
`Int8`

`Uint8`
`Int16`
`Uint16`
`Int32`
`Uint32`
`Int64`
`Uint64`
`Float`
`Double`

Supported data types

In MySQL, the optionality of column values (whether a column is allowed or not allowed to contain `NULL` values) is not part of the data type system. The `NOT NULL` constraint for any column of any table is stored as the value of the `IS_NULLABLE` column of the INFORMATION_SCHEMA.COLUMNS system table, i.e., at the table metadata level. Consequently, all basic MySQL types can by default contain `NULL` values, and in the YDB type system they must be mapped to optional types.

Below is a table of correspondence between MySQL types and YDB. All other data types, except those listed, are not supported.

MySQL data type	Data type YDB	Notes
`bool`	`Optional<Bool>`	
`tinyint`	`Optional<Int8>`	
`tinyint unsigned`	`Optional<Uint8>`	
`smallint`	`Optional<Int16>`	
`smallint unsigned`	`Optional<Uint16>`	
`mediumint`	`Optional<Int32>`	
`mediumint unsigned`	`Optional<Uint32>`	
`int`	`Optional<Int32>`	
`int unsigned`	`Optional<Uint32>`	
`bigint`	`Optional<Int64>`	
`bigint unsigned`	`Optional<Uint64>`	
`float`	`Optional<Float>`	
`real`	`Optional<Float>`	
`double`	`Optional<Double>`	
`date`	`Optional<Date>`	Valid date range from 1970-01-01 to 2105-12-31. If the value goes beyond the range boundaries, `NULL` is returned.
`datetime`	`Optional<Timestamp>`	Valid time range from 1970-01-01 00:00:00 to 2105-12-31 23:59:59. If the value goes beyond the range boundaries, the value `NULL` is returned.
`timestamp`	`Optional<Timestamp>`	Valid time range from 1970-01-01 00:00:00 to 2105-12-31 23:59:59. If the value goes beyond the range boundaries, the value `NULL` is returned.
`tinyblob`	`Optional<String>`	
`blob`	`Optional<String>`	
`mediumblob`	`Optional<String>`	
`longblob`	`Optional<String>`	
`tinytext`	`Optional<String>`	
`text`	`Optional<String>`	
`mediumtext`	`Optional<String>`	
`longtext`	`Optional<String>`	
`char`	`Optional<Utf8>`	
`varchar`	`Optional<Utf8>`	
`binary`	`Optional<String>`	
`varbinary`	`Optional<String>`	

`json`	`Optional<Json>`	

Working with PostgreSQL databases

> **Warning**
>
> External connectors are an experimental feature of YDB. To work with external DBMS through connectors, you need to deploy fq-connector-go and explicitly enable the corresponding sources in the cluster configuration YDB. The functionality may change, so use in production is not recommended without thorough testing.

This section describes the basic information about working with an external PostgreSQL database.

To work with an external PostgreSQL database, you need to perform the following steps:

1. Create a secret containing the password for connecting to the database.

   ```
   CREATE SECRET postgresql_datasource_user_password WITH (value = "<password>");
   ```

2. Create an external data source that describes a specific database within a PostgreSQL cluster. By default, the namespace `public` is used for reading, but this value can be changed using the optional parameter `SCHEMA`. The network connection is established via the standard (Frontend/Backend Protocol) over TCP transport (`PROTOCOL="NATIVE"`). Encryption of connections to the external database can be enabled using the parameter `USE_TLS="TRUE"`.

   ```
   CREATE EXTERNAL DATA SOURCE postgresql_datasource WITH (
       SOURCE_TYPE="PostgreSQL",
       LOCATION="<host>:<port>",
       DATABASE_NAME="<database>",
       AUTH_METHOD="BASIC",
       LOGIN="user",
       PASSWORD_SECRET_PATH="postgresql_datasource_user_password",
       PROTOCOL="NATIVE",
       USE_TLS="TRUE",
       SCHEMA="<schema>"
   );
   ```

3. Deploy the connector and configure the YDB dynamic nodes to interact with it. Additionally, ensure network access from the YDB dynamic nodes to the external data source (at the address specified in the `LOCATION` parameter of the `CREATE EXTERNAL DATA SOURCE` request). If network connection encryption to the external source was enabled in the previous step, the connector will use the system's root certificates. More details on TLS configuration can be found in the guide on deploying the connector.
4. Execute a query to the database.

Query syntax

The following SQL query form is used to work with PostgreSQL:

```
SELECT * FROM postgresql_datasource.<table_name>
```

where:

- `postgresql_datasource`: external data source identifier
- `<table_name>` is the name of the table inside the external data source.

Limitations

When working with PostgreSQL clusters, there are a number of limitations:

1. External sources are available only for reading data through `SELECT` queries. The federated query processing engine currently does not support queries that modify tables in external sources.
2. If the date value stored in the external data source is outside the allowed range for YDB (all dates used must be later than 1970-01-01 but earlier than 2105-12-31), such a value in YDB will be converted to `NULL`.
3. The YDB federated query processing system is capable of delegating the execution of certain parts of a query to the system acting as the data source. Query fragments are passed through YDB directly to the external system and processed by them. This optimization, known as "predicate pushdown", significantly reduces the amount of data transferred from the source to the federated query processing engine. This reduces network load and saves computational resources for the federated YDB.

   A specific case of predicate pushdown, when the filtering expressions are specified after the `WHERE` keyword, are passed to the data source, is called "filter pushdown". Filter pushdown is possible when using:

Description	Example
`NULL` checks	`WHERE column1 IS NULL` or `WHERE column1 IS NOT NULL`
Logical conditions `OR`, `NOT`, `AND` and parentheses for controlling calculation priority.	`WHERE column1 IS NULL OR (column2 IS NOT NULL AND column3 > 10)`.
Comparison operators with other columns or constants.	`WHERE column1 > column2 OR column3 <= 10`, `WHERE column1 + column2 > 10`, `WHERE column1 = (10 + 10)`

   When using other types of filters, pushdown to the data source is not performed: filtering of the external table rows will be executed by the federated YDB, which means that YDB will perform a full scan of the external table when processing the query.

   Supported data types for filter pushdown:

Data type YDB
`Bool`

`Int8`
`Int16`
`Int32`
`Int64`
`Float`
`Double`
`Decimal`

Supported data types

In a PostgreSQL database, the optionality of column values (whether a column is allowed or not allowed to contain `NULL` values) is not part of the data type system. The constraint `NOT NULL` for each column is implemented as an attribute `attnotnull` in the system catalog pg_attribute, that is, at the table metadata level. Consequently, all basic PostgreSQL types can by default contain `NULL` values, and in the YDB type system they must be mapped to optional types.

Below is a table of correspondence between PostgreSQL types and YDB. All other data types, except those listed, are not supported.

PostgreSQL data type	Data type YDB	Notes
`boolean`	`Optional<Bool>`	
`smallint`	`Optional<Int16>`	
`int2`	`Optional<Int16>`	
`integer`	`Optional<Int32>`	
`int`	`Optional<Int32>`	
`int4`	`Optional<Int32>`	
`serial`	`Optional<Int32>`	
`serial4`	`Optional<Int32>`	
`bigint`	`Optional<Int64>`	
`int8`	`Optional<Int64>`	
`bigserial`	`Optional<Int64>`	
`serial8`	`Optional<Int64>`	
`real`	`Optional<Float>`	
`float4`	`Optional<Float>`	
`double precision`	`Optional<Double>`	
`float8`	`Optional<Double>`	
`date`	`Optional<Date>`	Valid date range from 1970-01-01 to 2105-12-31. If the value goes outside the range, `NULL` is returned.
`timestamp`	`Optional<Timestamp>`	Valid time range from 1970-01-01 00:00:00 to 2105-12-31 23:59:59. If the value goes outside the range, the value `NULL` is returned.
`bytea`	`Optional<String>`	
`character`	`Optional<Utf8>`	Default collation rules, the string is padded with spaces to the required length.
`character varying`	`Optional<Utf8>`	Default collation rules.
`text`	`Optional<Utf8>`	Default collation rules.
`json`	`Optional<Json>`	
`numeric(p,s)`	`Optional<Decimal(p,s)>`	`p` (precision) - the total number of digits in the number, `s` (scale) - the number of digits after the decimal point. Types `numeric` without parameters (so-called "unconstrained") are converted to `Optional<Decimal(35, 0)>`. Types `numeric` with `p > 35` or `s < 0` are not supported.

Working with YDB databases

> **Warning**
>
> External connectors are an experimental feature of YDB. To work with external DBMS through connectors, you need to deploy fq-connector-go and explicitly enable the corresponding sources in the cluster configuration YDB. The functionality may change, so use in production is not recommended without thorough testing.

YDB can act as an external data source for another YDB database. This section describes how to set up collaboration between two independent YDB databases in federated query processing mode.

To connect to an external YDB database from another YDB database that acts as a federated query processing engine, you need to perform the following steps on the latter:

1. Prepare authentication credentials to access the remote YDB database. Currently, in federated queries to YDB, the login and password authentication method is available (other methods are not supported). The password to the external database is stored as a secret:

   ```
   CREATE SECRET ydb_datasource_user_password WITH (value = "<password>");
   ```

2. Create an external data source describing an external YDB database. The `LOCATION` parameter contains the network address of the YDB instance to which a network connection is made. In `DATABASE_NAME`, specify the database name (for example, `local`). For authentication to the external database, use the values of the `LOGIN` and `PASSWORD_SECRET_PATH` parameters. You can enable encryption of connections to the external database using the `USE_TLS="TRUE"` parameter. If encryption is enabled, then in the `<port>` field of the `LOCATION` parameter, you must specify the gRPCs port of the external YDB; otherwise, specify the gRPC port.

   ```
   CREATE EXTERNAL DATA SOURCE ydb_datasource WITH (
       SOURCE_TYPE="Ydb",
       LOCATION="<host>:<port>",
       DATABASE_NAME="<database>",
       AUTH_METHOD="BASIC",
       LOGIN="user",
       PASSWORD_SECRET_PATH="ydb_datasource_user_password",
       USE_TLS="TRUE"
   );
   ```

3. Deploy the connector and configure the YDB dynamic nodes to interact with it. Additionally, ensure network access from the YDB dynamic nodes to the external data source (at the address specified in the `LOCATION` parameter of the `CREATE EXTERNAL DATA SOURCE` request). If network connection encryption to the external source was enabled in the previous step, the connector will use the system's root certificates. More details on TLS configuration can be found in the guide on deploying the connector.
4. Execute a query to an external data source.

Query syntax

To retrieve data from tables of an external YDB database, use the following SQL query form:

```
SELECT * FROM ydb_datasource.`<table_name>`
```

where:

- `ydb_datasource`: external data source identifier
- `<table_name>` is the full table name within the directory hierarchy in the YDB database, for example, `table`, `dir1/table1`, or `dir1/dir2/table3`.

If the table is at the top level of the hierarchy (does not belong to any directory), you may omit the backticks around the table name "`":

```
SELECT * FROM ydb_datasource.<table_name>
```

Limitations

When working with external YDB data sources, there are a number of limitations:

1. External sources are available only for reading data through `SELECT` queries. The federated query processing engine currently does not support queries that modify tables in external sources.
2. The YDB federated query processing system is capable of delegating the execution of certain parts of a query to the system acting as the data source. Query fragments are passed through YDB directly to the external system and processed by them. This optimization, known as "predicate pushdown", significantly reduces the amount of data transferred from the source to the federated query processing engine. This reduces network load and saves computational resources for the federated YDB.

   A specific case of predicate pushdown, when the filtering expressions are specified after the `WHERE` keyword, are passed to the data source, is called "filter pushdown". Filter pushdown is possible when using:

Description	Example	Limitation
Filters of the form `IS NULL` / `IS NOT NULL`	`WHERE column1 IS NULL` or `WHERE column1 IS NOT NULL`	
Logical conditions `OR`, `NOT`, `AND` and parentheses to control calculation priority.	`WHERE column1 IS NULL OR (column2 IS NOT NULL AND column3 > 10)`.	

Comparison operators with other columns or constants.	`WHERE column1 > column2 OR column3 <= 10`.	
Pattern matching operator `LIKE`.	`WHERE column1 LIKE '_abc%'`	Currently, only simple patterns based on prefixes (`'abc_'`, `'abc%'`), suffixes (`'_abc'`, `'%abc'`), or substring search (`'_abc_'`, `'%abc%'`, `'_abc%'`, `'%abc_'`) are supported for pushdown. If you need to push down more complex patterns, it is recommended to use `REGEXP`.
String pattern matching operator `REGEXP`.	`WHERE column1 REGEXP '.*abc.*'`	

When using other types of filters, pushdown to the source is not performed: filtering of the external table rows will be performed on the federated YDB side, which means that YDB will perform a full scan of the external table at the time of query processing.

Supported data types for filter pushdown:

Data type YDB
`Bool`
`Int8`
`Uint8`
`Int16`
`Uint16`
`Int32`
`Uint32`
`Int64`
`Uint64`
`Float`
`Double`
`String`
`Utf8`

Supported data types

When working with tables located in an external database YDB, users have access to a limited set of data types. All other types, except those listed below, are not supported. In some cases, type conversion is performed, meaning that columns of a table from the external database YDB change their type after the table is read by the database YDB processing the federated query.

Data type of the external source YDB	Data type in the federated YDB
`Bool`	`Bool`
`Int8`	`Int8`
`Int16`	`Int16`
`Int32`	`Int32`
`Int64`	`Int64`
`Uint8`	`Uint8`
`Uint16`	`Uint16`
`Uint32`	`Uint32`
`Uint64`	`Uint64`
`Float`	`Float`
`Double`	`Double`
`String`	`String`

`Utf8`	`Utf8`
`Date`	`Date`
`Datetime`	`Datetime`
`Timestamp`	`Timestamp`
`Json`	`Json`
`JsonDocument`	`Json`

Working with S3 Buckets (Yandex Object Storage)

To work with S3, you need to set up a data storage connection. There is a DDL for configuring such connections. Next, let's look at the SQL syntax and the management of these settings.

There are two types of buckets in S3: public and private. To connect to a public bucket, use `AUTH_METHOD="NONE"`. To connect to a private bucket, use `AUTH_METHOD="AWS"`. A detailed description of `AWS` can be found here. `AUTH_METHOD="NONE"` means that no authentication is used. If `AUTH_METHOD="AWS"` is specified, several additional parameters are required:

- `AWS_ACCESS_KEY_ID_SECRET_PATH` — the secret where `AWS_ACCESS_KEY_ID` is stored.
- `AWS_SECRET_ACCESS_KEY_SECRET_PATH` — the secret where `AWS_SECRET_ACCESS_KEY` is stored.
- `AWS_REGION` – region from which reading is performed, for example, `ru-central-1`.

To set up a connection to a public bucket, execute the following SQL query. The query creates an external connection named `object_storage`, which points to a specific S3 bucket named `bucket`.

```
CREATE EXTERNAL DATA SOURCE object_storage WITH (
  SOURCE_TYPE="ObjectStorage",
  LOCATION="https://object_storage_domain/bucket/",
  AUTH_METHOD="NONE"
);
```

To set up a connection to a private bucket, you need to run a few SQL queries. First, create secrets containing `AWS_ACCESS_KEY_ID` and `AWS_SECRET_ACCESS_KEY`.

```
CREATE SECRET aws_access_id WITH (value='<id>');
CREATE SECRET aws_access_key WITH (value='<key>');
```

The next step is to create an external connection named `object_storage`, which points to a specific S3 bucket named `bucket` and uses `AUTH_METHOD="AWS"`. The parameters `AWS_ACCESS_KEY_ID_SECRET_PATH`, `AWS_SECRET_ACCESS_KEY_SECRET_PATH`, and `AWS_REGION` are filled in for `AWS`. The values of these parameters are described above.

```
CREATE EXTERNAL DATA SOURCE object_storage WITH (
  SOURCE_TYPE="ObjectStorage",
  LOCATION="https://object_storage_domain/bucket/",
  AUTH_METHOD="AWS",
  AWS_ACCESS_KEY_ID_SECRET_PATH="aws_access_id",
  AWS_SECRET_ACCESS_KEY_SECRET_PATH="aws_access_key",
  AWS_REGION="ru-central-1"
);
```

Using an External Connection to an S3 Bucket

When working with Yandex Object Storage using external data sources, it is convenient to perform prototyping and initial data connection setup.

An example query to read data:

```
SELECT
  *
FROM
 object_storage.`*.tsv`
WITH
(
  FORMAT = "tsv_with_names",
  SCHEMA =
  (
    ts Uint32,
    action Utf8
  )
);
```

The list of supported formats and data compression algorithms for reading data in S3 (Yandex Object Storage) is provided in the section Data formats and compression algorithms.

Data Model

In Yandex Object Storage, data is stored in files. To read data, you need to specify the data format in the files, compression, and lists of fields. This is done using the following SQL expression:

```
SELECT
  <expression>
FROM
  <object_storage_connection_name>.`<file_path>`
WITH(
  FORMAT = "<file_format>",
  COMPRESSION = "<compression>",
  SCHEMA = (<schema_definition>),
  <format_settings>)
WHERE
  <filter>;
```

Where:

- `object_storage_connection_name` — the name of the external data source leading to the S3 bucket (Yandex Object Storage).

- `file_path` — the path to the file or files inside the bucket. Wildcards `*` are supported; more details in the section.
- `file_format` — the data format in the files.
- `compression` — the compression format of the files.
- `schema_definition` — the schema definition of the data stored in the files.
- `format_settings` — optional format settings

Data Schema Description

The data schema description consists of a set of fields:

- Field name.
- Field type.
- Required data flag.

For example, the data schema below describes a schema field named `Year` of type `Int32` with the requirement that this field must be present in the data:

```
Year Int32 NOT NULL
```

If a data field is marked as required (`NOT NULL`) but is missing in the processed file, processing such a file will result in an error. If a field is marked as optional (`NULL`), no error will occur if the field is absent in the processed file, but the field will take the value `NULL`. The keyword `NULL` is optional in this context.

Schema Inference

YDB can determine the data schema of the files inside the bucket so that you do not have to specify these fields manually.

> **Note**
>
> Schema inference is available for all data formats except `raw` and `json_as_string`. For these formats you must describe the schema manually.

To enable schema inference, use the `WITH_INFER` parameter:

```
SELECT
  <expression>
FROM
  <object_storage_connection_name>.`<file_path>`
WITH(
  FORMAT = "<file_format>",
  COMPRESSION = "<compression>",
  WITH_INFER = "true")
WHERE
  <filter>;
```

Where:

- `object_storage_connection_name` — the name of the external data source leading to the S3 bucket (Yandex Object Storage).
- `file_path` — the path to the file or files inside the bucket. Wildcards `*` are supported. For more information, see Data Path Formats Specified in `file_path`.
- `file_format` — the data format in the files. All formats except `raw` and `json_as_string` are supported.
- `compression` — the compression format of the files.

As a result of executing such a query, the names and types of fields will be inferred.

Data Path Formats Specified in `file_path`

In YDB, the followingdata paths are supported:

Path Format	Description	Example

Path ends with a `/`	Path to a directory	The path `/a/` addresses all contents of the directory:
		`/a/b/c/d/1.txt`
		`/a/b/2.csv`

Path contains a wildcard character `*`	Any files nested in the path	The path `/a/*.csv` addresses files in directories:
		`/a/b/c/1.csv`
		`/a/2.csv`
		`/a/b/c/d/e/f/g/2.csv`

Path does not end with `/` and does not contain wildcard characters	Path to a single file	The path `/a/b.csv` addresses the specific file `/a/b.csv`

Format Settings

In YDB, the following format settings are supported:

Setting name	Description	Possible values
`file_pattern`	File name template	File name template string. Wildcards `*` are supported.
`data.interval.unit`	Unit for parsing `Interval` type	`MICROSECONDS`, `MILLISECONDS`, `SECONDS`, `MINUTES`, `HOURS`, `DAYS`, `WEEKS`

`data.datetime.format_name`	Predefined format in which `Datetime` data is stored	`POSIX`, `ISO`
`data.datetime.format`	Strftime-like template which defines how `Datetime` data is stored	Formatting string, for example: `%Y-%m-%dT%H-%M`
`date.timestamp.format_name`	Predefined format in which `Timestamp` data is stored	`POSIX`, `ISO`, `UNIX_TIME_SECONDS`, `UNIX_TIME_MILLISECONDS`, `UNIX_TIME_MICROSECONDS`
`data.timestamp.format`	Strftime-like template which defines how `Timestamp` data is stored	Formatting string, for example: `%Y-%m-%dT%H-%M-%S`
`data.date.format`	The format in which `Date` data is stored	Formatting string, for example: `%Y-%m-%d`
`csv_delimiter`	Delimeter for `csv_with_names` format	Any character (UTF-8)

You can only specify `file_pattern` setting if `file_path` is a path to a directory. Any conversion specifiers supported by `strftime` (C99) function can be used in formatting strings. In YDB, the following `Datetime` and `Timestamp` formats are supported:

Name	Description	Example
`POSIX`	String in `%Y-%m-%d %H:%M:%S` format	2001-03-26 16:10:00
`ISO`	Format, corresponding to the ISO 8601 standard	2001-03-26 16:10:00Z
`UNIX_TIME_SECONDS`	Number of seconds that have elapsed since the 1st of january 1970 (00:00:00 UTC)	985623000
`UNIX_TIME_MILLISECONDS`	Number of milliseconds that have elapsed since the 1st of january 1970 (00:00:00 UTC)	985623000000
`UNIX_TIME_MICROSECONDS`	Number of microseconds that have elapsed since the 1st of january 1970 (00:00:00 UTC)	985623000000000

Example

Example query to read data from S3 (Yandex Object Storage):

```
SELECT
  *
FROM
  connection.`folder/`
WITH(
  FORMAT = "csv_with_names",
  COMPRESSION="gzip"
  SCHEMA =
  (
    Id Int32 NOT NULL,
    UserId Int32 NOT NULL,
    TripDate Date NOT NULL,
    TripDistance Double NOT NULL,
    UserComment Utf8
  ),
  FILE_PATTERN="*.csv.gz",
  `DATA.DATE.FORMAT`="%Y-%m-%d",
  CSV_DELIMITER='/'
);
```

Where:

- `connection` — the name of the external data source leading to the S3 bucket (Yandex Object Storage).
- `folder/filename.csv` — the path to the directory in the S3 bucket (Yandex Object Storage).
- `SCHEMA` — the data schema description in the file.
- `*.csv.gz` — file name template.
- `%Y-%m-%d` — format in which `Date` type is stored in S3.

Reading Data from an External Table Pointing to S3 (Object Storage)

Sometimes, the same data queries need to be executed regularly. To avoid specifying all the details of working with this data every time a query is called, use the mode with external tables. In this case, the query looks like a regular query to YDB tables.

Example query for reading data:

```
SELECT
    *
FROM
    `s3_test_data`
WHERE
    version > 1
```

Creating an External Table Pointing to an S3 Bucket (Object Storage)

To create an external table describing the S3 bucket (Object Storage), execute the following SQL query. The query creates an external table named `s3_test_data`, containing files in the `CSV` format with string fields `key` and `value`, located inside the bucket at the path `test_folder`, using the connection credentials specified by the external data source object `bucket`:

```
CREATE EXTERNAL TABLE `s3_test_data` (
  key Utf8 NOT NULL,
  value Utf8 NOT NULL
) WITH (
  DATA_SOURCE="bucket",
  LOCATION="folder",
  FORMAT="csv_with_names",
  COMPRESSION="gzip"
);
```

Where:

- `key, value` - list of data columns and their types;
- `bucket` - name of the external data source to S3 (Object Storage);
- `folder` - path within the bucket containing the data;
- `csv_with_names` - one of the permitted data storage formats;
- `gzip` - one of the permitted compression algorithms.

You can also specify format settings.

Data Model

Reading data using external tables from S3 (Object Storage) is done with regular SQL queries as if querying a normal table.

```
SELECT
  <expression>
FROM
  `s3_test_data`
WHERE
  <filter>;
```

Limitations

There are a number of limitations when working with S3 buckets (Object Storage).

Limitations:

1. Only data read requests - `SELECT` and `INSERT` are supported; other requests are not.
2. If the date value stored in the external data source is outside the allowed range for YDB (all dates used must be later than 1970-01-01 but earlier than 2105-12-31), such a value in YDB will be converted to `NULL`.

Writing Data to S3 Buckets (Yandex Object Storage)

In YDB, you can use external connections or external tables to write data to the Yandex Object Storage bucket.

Writing Data via External Connection

Using connections for data writing is convenient for prototyping and initial setup. The SQL expression demonstrates writing data directly to an external data source.

```
INSERT INTO `connection`.`test/`
WITH
(
  FORMAT = "csv_with_names"
)
SELECT
    "value" AS value, "name" AS name
```

The data will be written to the specified path. In this mode, the resulting files will not be partitioned. If you need to partition the resulting files, use writing via external tables. The files created during the writing process are assigned random names.

When working with external connections, only read (`SELECT`) and insert (`INSERT`) operations are possible; other types of operations are not supported.

Writing Data via External Tables

If you need to write data regularly, doing this using external tables is convenient. In this case, there is no need to specify all the details of working with this data in each query. To write data to the bucket, create an external table in S3 (Yandex Object Storage) and use the usual SQL `INSERT INTO` statement:

```
INSERT INTO `test`
SELECT
    "value" AS value, "name" AS name
```

Exporting data to S3 object storage

YDB supports exporting table data to S3 using an external data source.

To export, use a write query via external data source and specify the format of the exported files:

```
INSERT INTO external_source.`test/`
WITH
(
    FORMAT = "parquet"
)
SELECT
    *
FROM table
```

You can export both regular YDB tables and any external tables.

> **Tip**
>
> The recommended export format is `parquet`; import and export paths are optimized for it.

To export all tables under a given directory in the data schema, plus metadata about tables, directories, and table indexes, to S3-compatible storage, use the YDB CLI. For details, see Export to S3-compatible storage.

Data formats and compression algorithms

This section describes the data formats supported in YDB that are stored in S3, the supported compression algorithms, and the list of supported YQL types for each data format.

Supported data formats

The list of data formats supported in YDB is provided in the table below.

Format	Reading	Writing
`csv`	✓	
`csv_with_names`	✓	✓
`tsv_with_names`	✓	✓
`json_list`	✓	✓
`json_each_row`	✓	✓
`json_as_string`	✓	
`parquet`	✓	✓
`raw`	✓	✓

CSV format

This format is based on the CSV format and differs from `csv_with_names` in that it does not have a header with column names. All lines in the file are treated as data, and column names are taken from the schema of the query in the order they are declared in `SCHEMA`.

> **Note**
>
> The `csv` format is available only for reading data from S3. Writing in this format is not supported.

Example of data (without a header row):

```
1997,Man_1,Model_1,3000.00
1999,Man_2,Model_2,4900.00
```

Example query

```
SELECT
    *
FROM external_source.path
WITH
(
    FORMAT = "csv",
    SCHEMA =
    (
        Year Int32,
        Manufacturer Utf8,
        Model Utf8,
        Price Double
    )
)
```

The result of the query execution:

#	Manufacturer	Model	Price	Year
1	Man_1	Model_1	3000	1997
2	Man_2	Model_2	4900	1999

Csv_with_names format

This format is based on the CSV format. The data is arranged in columns, separated by commas, and the first line of the file contains the column names. Unlike the `csv` format, where column names are taken from the query schema and matched positionally, in the `csv_with_names` format, column names are read directly from the header line of the file and matched to the schema by name.

Example data:

```
Year,Manufacturer,Model,Price
1997,Man_1,Model_1,3000.00
1999,Man_2,Model_2,4900.00
```

Example query

```
SELECT
    *
FROM external_source.path
WITH
(
    FORMAT = "csv_with_names",
    SCHEMA =
    (
        Year Int32,
        Manufacturer Utf8,
        Model Utf8,
        Price Double
    )
)
```

The result of the query execution:

#	Manufacturer	Model	Price	Year
1	Man_1	Model_1	3000	1997
2	Man_2	Model_2	4900	1999

tsv_with_names format

This format is based on the TSV format. The data is arranged in columns and separated by tab characters (code `0x9`). The first line of the file contains the column names.

Example of data:

```
Year    Manufacturer    Model   Price
1997    Man_1   Model_1    3000.00
1999    Man_2   Model_2    4900.00
```

Example query

```
SELECT
    *
FROM external_source.path
WITH
(
    FORMAT = "tsv_with_names",
    SCHEMA =
    (
        Year Int32,
        Manufacturer Utf8,
        Model Utf8,
        Price Double
    )
)
```

The result of the query execution:

#	Manufacturer	Model	Price	Year
1	Man_1	Model_1	3000	1997
2	Man_2	Model_2	4900	1999

json_list format

This format is based on JSON representation of data. In this format, each file must contain an object in a valid JSON representation.

Example of valid data (data is presented as a list of JSON objects):

```
[
    { "Year": 1997, "Manufacturer": "Man_1", "Model": "Model_1", "Price": 3000.0 },
    { "Year": 1999, "Manufacturer": "Man_2", "Model": "Model_2", "Price": 4900.00 }
]
```

Example of **IN**correct data (each separate line contains a separate JSON object, but these objects are not combined into a list):

```
{ "Year": 1997, "Manufacturer": "Man_1", "Model": "Model_1", "Price": 3000.0 }
{ "Year": 1999, "Manufacturer": "Man_2", "Model": "Model_2", "Price": 4900.00 }
```

Example query

```
SELECT
    *
FROM external_source.path
WITH
(
    FORMAT = "json_list",
    SCHEMA =
    (
        Year Int32,
        Manufacturer Utf8,
        Model Utf8,
        Price Double
    )
)
```

Result of query execution:

#	Manufacturer	Model	Price	Year
1	Man_1	Model_1	3000	1997
2	Man_2	Model_2	4900	1999

json_each_row format

This format is based on JSON representation of data. In this format, each line of the file must contain a separate object in a valid JSON representation, but these objects are not combined into a JSON list. This format is used when transferring data through streaming systems, such as Apache Kafka or YDB topics (../../../datamodel/topic.md).

Example of correct data (each line contains a separate JSON object, but these objects are not combined into a list):

```
{ "Year": 1997, "Manufacturer": "Man_1", "Model": "Model_1", "Price": 3000.0 },
{ "Year": 1999, "Manufacturer": "Man_2", "Model": "Model_2", "Price": 4900.00 }
```

Example query

```
SELECT
    *
FROM external_source.path
WITH
(
    FORMAT = "json_each_row",
    SCHEMA =
    (
        Year Int32,
        Manufacturer Utf8,
        Model Utf8,
        Price Double
    )
)
```

The result of the query execution:

#	Manufacturer	Model	Price	Year
1	Man_1	Model_1	3000	1997
2	Man_2	Model_2	4900	1999

json_as_string format

This format is based on JSON representation. The `json_as_string` format does not split the input JSON document into fields, but represents each line of the file as a single JSON object (or a single string). This format is convenient if the list of fields is not the same in all lines and can vary.

In this format, each file should contain:

- a JSON object in a valid JSON representation on each separate line of the file;
- JSON objects in a valid JSON representation, combined into a list.

Example of valid data (data is presented as a list of JSON objects):

```
{ "Year": 1997, "Attrs": { "Manufacturer": "Man_1", "Model": "Model_1" }, "Price": 3000.0 }
{ "Year": 1999, "Attrs": { "Manufacturer": "Man_2", "Model": "Model_2" }, "Price": 4900.00 }
```

In this format, the schema of the data being read must consist of only one column with one of the allowed data types; see below for details.

Example query

```
SELECT
    CAST(JSON_VALUE(Data, "$.Year") AS Int32) AS Year,
    JSON_VALUE(Data, "$.Attrs.Manufacturer") AS Manufacturer,
    JSON_VALUE(Data, "$.Attrs.Model") AS Model,
    CAST(JSON_VALUE(Data, "$.Price") AS Double) AS Price
FROM external_source.path
WITH
(
    FORMAT = "json_as_string",
    SCHEMA =
    (
        Data Json
    )
)
```

The result of the query execution:

#	Manufacturer	Model	Price	Year
1	Man_1	Model_1	3000	1997
2	Man_2	Model_2	4900	1999

Parquet format

This format allows reading the contents of files in the Apache Parquet format.

Supported data compression algorithms inside Parquet files for reading from S3:

- No compression
- SNAPPY
- GZIP
- BROTLI
- LZ4
- ZSTD
- LZ4_RAW

Note

Parquet format records will be written using the Snappy compression algorithm.

Example query

```
SELECT
    *
FROM external_source.path
WITH
(
    FORMAT = "parquet",
    SCHEMA =
    (
        Year Int32,
        Manufacturer Utf8,
        Model Utf8,
        Price Double
    )
)
```

The result of the query execution:

#	Manufacturer	Model	Price	Year
1	Man_1	Model_1	3000	1997
2	Man_2	Model_2	4900	1999

Raw format

This format allows you to read the contents of files as is, in "raw" form. Data read in this way can be processed using YQL by dividing it into rows and columns.

Note

The size of each of the files read in `raw` format cannot exceed the overall memory consumption limit for a single query in YDB.

Example query

To parse the following data, where rows are separated by a semicolon and values by a comma:

```
1997,Man_1,Model_1,3000.00;
1999,Man_2,Model_2,4900.00;
```

You can use the following query:

```
$input = SELECT
    String::SplitToList(        -- splitting each row by ','
        String::Strip(RowData), -- removing all whitespace characters from the beginning and end of the r
ows
        ","
    ) AS Row
FROM external_source.path
WITH
(
    FORMAT = "raw",
    SCHEMA =
    (
        FileData Utf8
    )
)
FLATTEN LIST BY (String::SplitToList(FileData, ";", TRUE AS SkipEmpty) AS RowData); -- splitting the file
by ';'

SELECT -- Getting the required columns
    CAST(Row[0] AS Int32) AS Year,
    Row[1] AS Manufacturer,
    Row[2] AS Model,
    CAST(Row[3] AS Double) AS Price
FROM $input
```

The result of the query execution:

#	Manufacturer	Model	Price	Year
1	Man_1	Model_1	3000	1997
2	Man_2	Model_2	4900	1999

Supported compression algorithms

The use of compression algorithms depends on the file formats. For all file formats except Parquet, the following compression algorithms can be used:

Algorithm	Name in YDB	Reading	Writing
Gzip	gzip	✓	✓
Zstd	zstd	✓	✓
LZ4	lz4	✓	✓
Brotli	brotli	✓	✓
Bzip2	bzip2	✓	✓
Xz	xz	✓	✓

For Parquet file format, native internal compression algorithms are supported:

Compression format	Read	Write
None	✓	
Snappy	✓	✓
Gzip	✓	
Brotli	✓	
LZ4	✓	
Zstd	✓	
LZ4_RAW	✓	

In YDB, working with externally compressed Parquet files, such as files of the form `<myfile>.parquet.gz` or similar, is not supported. All Parquet files must be without external compression.

Supported data types

A table of all supported types when reading from S3 in the query schema:

Type	csv	csv_with_names	tsv_with_names	json_list	json_each_row	json_as_string	parquet	raw

`Bool`, `Int8`, `Int16`, `Int32`, `Int64`, `Uint8`, `Uint16`, `Uint32`, `Uint64`, `Float`, `Double`	✓	✓	✓	✓	✓		✓	
`DyNumber`				✓				
`String`, `Utf8`, `Json`	✓	✓	✓	✓	✓	✓	✓	✓
`JsonDocument`							✓	
`Yson`				✓			✓	✓
`Uuid`	✓	✓	✓		✓			
`Date`, `Datetime`, `Timestamp`, `TzDate`, `TzDateTime`, `TzTimestamp`	✓	✓	✓		✓		✓	
`Interval`	✓	✓	✓		✓		✓	
`Date32`, `Datetime64`, `Timestamp64`, `Interval64`, `TzDate32`, `TzDateTime64`, `TzTimestamp64`							✓	
`Optional<T>`	✓	✓	✓	✓	✓	✓	✓	✓

The table of all supported types for writing to S3:

Type	csv_with_names	tsv_with_names	json_list	json_each_row	parquet	raw
`Bool`, `Int8`, `Int16`, `Int32`, `Int64`, `Uint8`, `Uint16`, `Uint32`, `Uint64`, `Float`, `Double`	✓	✓	✓	✓	✓	
`DyNumber`			✓			
`String`, `Utf8`, `Json`	✓	✓	✓	✓	✓	✓
`JsonDocument`						
`Yson`			✓			✓
`Uuid`	✓	✓		✓		
`Date`, `Datetime`, `Timestamp`, `TzDate`, `TzDateTime`, `TzTimestamp`	✓	✓		✓	✓	
`Interval`						
`Date32`, `Datetime64`, `Timestamp64`, `Interval64`, `TzDate32`, `TzDateTime64`, `TzTimestamp64`						
`Optional<T>`	✓	✓	✓	✓	✓	

For all S3 read and write formats, except `json_list`, the `Optional<T>` type can be used only if `T` is a primitive YQL type. For more information about optional types, see the article column0.

Mapping types when reading and writing Parquet data

When reading and writing data in Parquet format, YDB uses the Apache Arrow logical type system — the standard Parquet uses to describe data semantics. The table below shows how YQL types map to Arrow logical types written in Parquet files.

YQL type	Arrow type on export	Arrow type on import	Notes
`Bool`	`UINT8`	`BOOL`, `UINT8`	
`Int8`	`INT8`	`INT8`	
`Int16`	`INT16`	`INT16`	
`Int32`	`INT32`	`INT32`	
`Int64`	`INT64`	`INT64`	
`Uint8`	`UINT8`	`UINT8`	
`Uint16`	`UINT16`	`UINT16`	
`Uint32`	`UINT32`	`UINT32`	
`Uint64`	`UINT64`	`UINT64`	
`Float`	`FLOAT (32)`	`FLOAT (32)`	
`Double`	`FLOAT (64)`	`FLOAT (64)`	
`Date`	`UINT16`	`UINT16`, `INT32`, `UINT32`, `INT64`, `UINT64`, `DATE`, `TIMESTAMP (s, ms, us)`	number of days since the Unix epoch
`Date32`	`DATE (s)`	`DATE (s)`	
`Datetime`	`UINT32`	`UINT16`, `INT32`, `UINT32`, `INT64`, `UINT64`, `DATE`, `TIMESTAMP (s, ms, us)`	number of seconds since the Unix epoch
`Datetime64`	`TIMESTAMP (us)`	`TIMESTAMP (s, ms, us)`	
`Timestamp`	`TIMESTAMP (us)`	`TIMESTAMP (s, ms, us)`	
`Timestamp64`	`TIMESTAMP (us)`	`TIMESTAMP (s, ms, us)`	
`Decimal(s, p)`	`DECIMAL (128, s, p)`	`DECIMAL (128, s, p)`	
`String`	`BINARY`	`BINARY`	
`Utf8`	`BINARY`	`BINARY`	
`Json`	`BINARY`	`BINARY`	

Data Partitioning in S3 (Yandex Object Storage)

In S3 (Yandex Object Storage), it is possible to store very large volumes of data. At the same time, queries to this data may not need to touch all the data but only a part of it. If you describe the rules for marking the storage structure of your data in YDB, then data that is not needed for the query can even be skipped from being read from S3 (Yandex Object Storage). This mechanism significantly speeds up query execution without affecting the result.

For example, data is stored in the following directory structure:

```
year=2021
    month=01
    month=02
    month=03
year=2022
    month=01
```

The query below explicitly implies that only the data for February 2021 needs to be processed, and other data is not needed.

```
SELECT
    *
FROM
    objectstorage.'/'
WITH
(
    SCHEMA =
    (
        data String,
        year Int32,
        month Int32
    )
)
WHERE
    year=2021
    AND month=02
```

If the data partitioning scheme is not specified, then *all* stored data will be read from S3 (Yandex Object Storage), but as a result of processing, data for all other dates will be discarded.

If you explicitly describe the storage structure, specifying that the data in S3 (Yandex Object Storage) is placed in directories by years and months

```
SELECT
    *
FROM
    objectstorage.'/'
WITH
(
    SCHEMA =
    (
        data String,
        year Int32,
        month Int32
    ),
    PARTITIONED_BY = "['year', 'month']"
)
WHERE
    year=2021
    AND month=02
```

then during the query execution, not all data will be read from S3 (Yandex Object Storage), but only the data for February 2021. This will significantly reduce the volume of data processed and speed up processing, while the results of both queries will be identical.

> **Note**
>
> The example above shows working with data at the level of connections. This example is chosen for illustrative purposes only. We strongly recommend using "data bindings" to work with data and not using direct work with connections.

Syntax

When working at the connection level, partitioning is set using the `partitioned_by` parameter, where the list of columns is specified in JSON format.

```
SELECT
    *
FROM
    <connection>.<path>
WITH
(
    SCHEMA=(<field1>, <field2>, <field3>),
    PARTITIONED_BY="['field2', 'field3']"
)
```

In the `partitioned_by` parameter, the columns of the data schema by which the data stored in S3 (Yandex Object Storage) are partitioned are listed. The order of specifying fields in the `partitioned_by` parameter determines the nesting of S3 (Yandex Object Storage) directories within each other.

For example, `PARTITIONED_BY=['year', 'month']` defines the directory structure

```
year=2021
    month=01
    month=02
    month=03
year=2022
    month=01
```

And `partitioned_by=['month', 'year']` defines another directory structure

```
month=01
    year=2021
    year=2022
month=02
    year=2021
month=03
    year=2021
```

Supported Data Types

Partitioning is possible only with the following set of YQL data types:

- Uint16, Uint32, Uint64
- Int16, Int32, Int64
- String, Utf8

When using other types for specifying partitioning, an error is returned.

Supported Storage Path Formats

The storage path format, where the name of each directory explicitly specifies the column name, is called the "Hive-Metastore format" or simply the "Hive format."

This format looks as follows:

```
month=01
    year=2021
    year=2022
month=02
    year=2021
month=03
    year=2021
```

Warning

The basic partitioning mode in YDB supports only the Hive format.

Use the Extended Data Partitioning mode to specify arbitrary storage paths.

Extended Partitioning in S3 (Yandex Object Storage)

Partitioning allows you to specify rules for YDB data placement in S3 (Yandex Object Storage).

Assume the data in S3 (Yandex Object Storage) is stored in the following directory structure:

```
year=2021
    month=01
    month=02
    month=03
year=2022
    month=01
```

When executing the query below, YDB will perform the following actions:

1. Retrieve a full list of subdirectories within '/'.
2. Attempt to process the name of each subdirectory in the format `year=<DIGITS>`.
3. For each subdirectory `year=<DIGITS>`, retrieve a list of all subdirectories in the format `month=<DIGITS>`.
4. Process the read data.

```
SELECT
    *
FROM
    objectstorage.'/'
WITH
(
    SCHEMA =
    (
        data String,
        year Int32,
        month Int32
    ),
    PARTITIONED_BY = "['year', 'month']"
)
WHERE
    year=2021
    AND month=02
```

When working with partitioned data, a complete listing of the contents of S3 (Yandex Object Storage) is performed, which can take a considerable amount of time on large buckets.

To optimize performance on large data volumes, use "advanced partitioning". In this mode, S3 (Yandex Object Storage) directories are not scanned; instead, all paths are calculated in advance, and access is made only to these paths.

To enable advanced partitioning, specify the working rules through a special parameter - "projection". This parameter describes all the rules for data placement in the S3 (Yandex Object Storage) directories.

Syntax

Advanced partitioning is called "partition projection" and is specified through the `projection` parameter.

Example of specifying advanced partitioning:

```
SELECT
    *
FROM
    <connection>.`/`
WITH
(
    SCHEMA =
    (
        data String,
        year Int32,
        month Int32
    ),
    PARTITIONED_BY = "['year', 'month']",
    `projection.enabled` : "true",

    `projection.year.type` : "integer",
    `projection.year.min` : "2010",
    `projection.year.max` : "2022",
    `projection.year.interval` : "1",

    `projection.month.type` : "integer",
    `projection.month.min` : "1",
    `projection.month.max` : "12",
    `projection.month.interval` : "1",
    `projection.month.digits` : "2",

    `storage.location.template` : "${year}/${month}"
)
```

The example above specifies that data exists for each year and each month from 2010 to 2022, with data placed in directories like `2022/12` within the bucket. If data for a certain period is absent within the bucket, this does not cause errors; the query will execute successfully, and the data will be skipped in the calculations.

In general, the advanced partitioning setup looks as follows:

```
SELECT
    *
FROM
    <connection>.<path>
WITH
(
    SCHEMA = (<fields>, <field1>, <field2>),
    PARTITIONED_BY = "'['field1', 'field2']",
    `projection.enabled` : <"true"|"false">,

    `projection.<field1_name>.type` : "<type>",
    `projection.<field1_name>....` : "<extended_properties>",

    `projection.<field2_name>.type` : "<type>",
    `projection.<field2_name>....` : "<extended_properties>",

    `storage.location.template` : ".../${field2}/${field1}/..."
)
```

Field Descriptions

Field name	Description	Allowed values
`projection.enabled`	Whether advanced partitioning is enabled or not	`true`, `false`
`projection.<field1_name>.type`	Data type of the field	`integer`, `enum`, `date`
`projection.<field1_name>.XXX`	Specific properties of the type	

Integer Field Type

It is used for columns whose values can be represented as integers ranging from 2^{-63} to 2^{63}-1.

Field name	Mandatory	Description	Example values
`projection.<field_name>.type`	Yes	Data type of the field	integer
`projection.<field_name>.min`	Yes	Specifies the minimum allowable value as an integer	-100 004
`projection.<field_name>.max`	Yes	Specifies the maximum allowable value as an integer	-10 5000
`projection.<field_name>.interval`	No, default is `1`	Specifies the step between elements within the value range. For example, a step of 3 within the range 2 to 10 will result in the values: 2, 5, 8	2 11
`projection.<field_name>.digits`	No, default is `0`	Specifies the number of digits in the number. If the number of significant digits in the number is less than the specified value, the value is padded with leading zeros up to the specified number of digits. For example, if .digits=3 is specified and the number 2 is passed, it will be converted to 002	2 4

Enum Field Type

It is used for columns whose values can be represented as a set of enumerated values.

Field name	Mandatory	Description	Example values
`projection.<field_name>.type`	Yes	Data type of the field	enum
`projection.<field_name>.values`	Yes	Specifies the allowable values, separated by commas. Spaces are not ignored	1, 2 A,B,C

Date Field Type

It is used for columns whose values can be represented as dates. The allowable date range is from 1970-01-01 to 2105-01-01.

Field name	Mandatory	Description	Example values
`projection.<field_name>.type`	Yes	Data type of the field	date
`projection.<field_name>.min`	Yes	Specifies the minimum allowable date. Allowed values in the format `YYYY-MM-DD` or as an expression containing the special macro substitution NOW	
`projection.<field_name>.max`	Yes	Specifies the maximum allowable date. Allowed values in the format `YYYY-MM-DD` or as an expression containing the special macro substitution NOW	2020-01-01 NOW-5DAYS NOW+3HOURS
`projection.<field_name>.format`	Yes	Date formatting string based on strptime	%Y-%m-%d %D
`projection.<field_name>.unit`	No, default is `DAYS`	Time interval units. Allowed values: `YEARS`, `MONTHS`, `WEEKS`, `DAYS`, `HOURS`, `MINUTES`, `SECONDS`, `MILLISECONDS`	SECONDS YEARS

`projection.<field_name>.interval`	No, default is `1`	Specifies the step between elements within the value range with the specified dimension in `projection.<field_name>.unit`. For example, for the range 2021-02-02 to 2021-03-05 with a step of 15 and the dimension DAYS, the values will be: 2021-02-17, 2021-03-04	2 6

Working with the NOW Macro Substitution

1. A number of arithmetic operations with the NOW macro substitution are supported: adding and subtracting time intervals. For example: `NOW-3DAYS`, `NOW+1MONTH`, `NOW-6YEARS`, `NOW+4HOURS`, `NOW-5MINUTES`, `NOW+6SECONDS`. The possible usage options for the macro substitution are described by the regular expression: `^\s*(NOW)\s*(([\+\-])\s*([0-9]+)\s*(YEARS?|MONTHS?|WEEKS?|DAYS?|HOURS?|MINUTES?|SECONDS?)\s*)?$`
2. Allowed interval dimensions: YEARS, MONTHS, WEEKS, DAYS, HOURS, MINUTES, SECONDS, MILLISECONDS.
3. Only one arithmetic operation is allowed in expressions; expressions like `NOW-5MINUTES+6SECONDS` are not supported.
4. Working with intervals always results in obtaining a valid date, but depending on the dimension, the final results may vary:
   - Adding `MONTHS` to a date adds a calendar month, not a fixed number of days. For example, if the current date is `2023-01-31`, adding `1 MONTHS` will result in the date `2023-02-28`.
   - Adding `30 DAYS` to a date adds a fixed number of days. For example, if the current date is `2023-01-31`, adding `30 DAYS` will result in the date `2023-03-02`.
   - The earliest possible date is `1970-01-01` (time 0 in Unix time). If the result of calculations is a date earlier than the minimum, the entire query fails with an error.
   - The latest possible date is `2105-12-31` (the maximum date in Unix time). If the result of calculations is a date later than the maximum, the entire query fails with an error.

Path Templates

Data in S3 (Yandex Object Storage) buckets can be placed in directories with arbitrary names. The `storage.location.template` setting allows you to specify the naming rules for the directories where the data is stored.

Field name	Description	Example values
`storage.location.template`	Path template for directory names. The path is specified as a text string with parameter macro substitutions `...${<field_name>}...${<field_name>}...`	`root/a/${year}/b/${month}/d${year}/${month}`

If the path contains the characters `$`, `\`, or the characters `{}`, they must be escaped with the `\` character. For example, to work with a directory named `my$folder`, it needs to be specified as `my\$folder`.

Import and export data using federated queries

> **Note**
>
> When importing/exporting data from/to S3 in Parquet format, you must consider the mapping of YQL and Apache Arrow types.

Data import

Federated queries allow you to import data from connected external sources into YDB database tables. To import data, you need to use a read query from an external data source or external table and write to a YDB table.

For columnar tables, massively parallel import from an external source is supported when using UPSERT and INSERT statements — multiple worker threads read data from the external source in parallel and write to the table. For row-based tables, this functionality is under development.

Operation	Write to row-based tables	Write to columnar tables
UPSERT	single-threaded	parallel
REPLACE	single-threaded	parallel
INSERT	single-threaded	parallel

> **Tip**
>
> The recommended import options using federated queries are the `UPSERT` and `REPLACE` operations — the data import scenario is significantly optimized for them.

Example of importing data from a PostgreSQL table into a YDB table:

```
UPSERT INTO target_table
SELECT * FROM postgresql_datasource.source_table
```

For more details on creating external data sources and external tables, as well as reading data from them, see the articles:

- S3

Experimental data sources

- ClickHouse
- Greenplum
- Microsoft SQL Server
- MySQL
- PostgreSQL
- YDB (federated queries between YDB databases)

Data export

Currently, data export using federated queries is supported only for S3-compatible storage; for more details, see the article Exporting data to S3 object storage.

Spilling

Spilling in general

Spilling is a memory management mechanism in which intermediate data generated during query execution that exceeds the available RAM of a node is temporarily offloaded to external storage. In YDB, disk is currently used for spilling. Spilling ensures the execution of user queries that require processing large volumes of data exceeding the available node memory.

In data processing systems, including YDB, spilling is important for:

- Processing queries with large volumes of data when intermediate results do not fit into memory.
- Executing complex analytical operations (aggregations, table joins) on large datasets
- Query performance optimization by intermediate materialization of some data in external memory, which in certain scenarios can speed up the overall execution time.

Spilling operates based on the principle of memory hierarchy:

1. **RAM (Random Access Memory)** is a fast but limited resource.
2. **External memory** — slower, but more capacious.

When memory usage approaches the limit, the system:

- Serializes part of the data.
- Saves them in external memory.
- frees the corresponding memory
- continues processing the query, using data in memory.
- if necessary, loads data back into memory to continue computations.

Spilling in YDB

YDB implements the spilling mechanism via **Spilling Service** — an actor service that provides temporary storage for data blobs. Spilling is performed only on database nodes. Detailed technical information about Spilling Service is available in the Spilling Service section.

Types of spilling in YDB

YDB implements two main types of spilling, operating at different levels of the computing process:

- Spilling in computations
- Spilling in transport

These types operate independently of each other and can be activated simultaneously within a single query, providing comprehensive memory management.

Spilling in computations

Compute cores YDB automatically spill intermediate data to disk when executing operations that require significant memory. This type of spilling is implemented at the level of individual compute operations and is activated when memory limits are reached.

Main use cases:

- **Aggregations** — when grouping large volumes of data, the system offloads intermediate hash tables to disk
- **Join operations** — when joining large tables, the Grace Hash Join algorithm partitions data and spills it to disk.

How it works

Compute nodes contain specialized objects for monitoring memory usage. When the data volume approaches the set limit:

1. The system switches to spilling mode
2. The data is serialized and split into blocks (buckets)
3. Some blocks are transferred to the Spilling Service for saving to disk
4. Metadata about data location is stored in memory
5. The system continues processing the data remaining in memory, which allows freeing up additional space
6. If necessary, the data is loaded back and processed

Spilling in transport

This type of spilling operates at the data transfer level between different query execution stages. The data transfer subsystem automatically buffers and spills data when buffers overflow. This helps avoid blocking operations that generate data, even in situations where the receiving side is temporarily unable to receive data.

How it works

The data transfer subsystem constantly monitors its state:

1. **Buffering**: Incoming data accumulates in the internal buffers of the subsystem
2. **Fill control**: The system monitors the fill level of buffers
3. **Automatic spilling**: When limits are reached, data is automatically serialized and transferred to the Spilling Service
4. **Continued operation**: The subsystem continues to accept new data after freeing up memory space
5. **Recovery**: When the next stage is ready, data is read from external storage and passed on.

Interaction with the memory controller

When executing queries, YDB tries to stay within the specified memory limit set by the memory controller. To continue fitting within this limit even as intermediate computations grow, spilling is used.

At the Resource Manager level, the threshold for transitioning to spilling is set by the `resource_manager.spilling_percent` parameter: when the Query Processor memory pool on a node is filled to the specified percentage, compute operations start preferring offloading data to disk over further growth of RAM consumption. The pool size is set by the `query_execution_limit_percent` / `query_execution_limit_bytes` parameters.

For more details on spilling settings and related memory limits, see the Memory management and Query execution memory limits sections.

Scan queries in YDB

Warning

Using `ScanQuery` is not recommended for new scenarios. Use standard mechanisms to execute queries.

For more details, see the Executing queries section.

The exception is executing long-running (over 5 minutes) queries against row tables. In this case, we still recommend using `ScanQuery`, as standard query execution mechanisms do not yet fully support this scenario.

Scan queries are a separate data access interface primarily intended for running analytical ad-hoc queries against a database.

This execution mode has the following distinctive properties:

- It is *read-only*.
- In *SERIALIZABLE_RW* mode, a data snapshot is taken, and all further work happens on top of that snapshot. As a result, the impact on the OLTP transaction stream is minimal (only snapshot acquisition).
- The query result is a data stream (gRPC stream). Therefore, scan queries do not have a limit on the number of rows in the result.
- Due to high overhead, it is suitable only for ad-hoc queries.

Note

You can query system views through the *Scan Queries* interface.

Scan queries are not considered a full-fledged way to run OLAP workloads because they currently have a number of technical limitations (which will be lifted over time):

- Query duration is limited to 10 minutes.
- Many operations (including sorting) are executed entirely in memory, so complex queries may fail with an out-of-resources error.
- For joins, only one strategy is currently supported — *MapJoin* (aka *Broadcast Join*), where the "right" table is converted into a map, so it must be no more than a few gigabytes in size.
- Prepared statements are not supported, i.e. the query is compiled on every call.
- There are no optimizations for point reads or small-range reads.
- Automatic retries are not supported in SDKs.

For OLAP workloads, YDB provides a specialized table type — column-oriented tables. They store each column's data separately from other columns, so only the columns directly involved in the query are read during execution.

Note

Even though *Scan Queries* do not directly interfere with OLTP transactions, they still consume shared database resources: CPU, memory, disk, and network. Therefore, running heavy queries **may cause resource starvation**, which will affect the performance of the entire database.

How to use

Like other query types, *Scan Queries* are available through CLI and SDK.

C++ SDK

To run a query via *Scan Queries*, `Ydb::TTableClient` provides two methods:

```
class TTableClient {
 ...
 TAsyncScanQueryPartIterator StreamExecuteScanQuery(const TString& query,
 const TStreamExecScanQuerySettings& settings = TStreamExecScanQuerySettings());

 TAsyncScanQueryPartIterator StreamExecuteScanQuery(const TString& query, const TParams& params,
 const TStreamExecScanQuerySettings& settings = TStreamExecScanQuerySettings());
 ...
};
```

YQL queries to topics

For reading and writing messages to topics, the familiar YQL constructs are used: SELECT for reading and INSERT for writing.

Local and external topics

YQL queries to topics work the same regardless of whether the topic is in the current database or in another database YDB. The source and destination of messages can be either a topic **in the same database** where the query is executed, or a topic **in another database**.

Local topics

Local topics are topics created in the **same database** YDB as the query being executed.

In the query text, they are referred to **by a short name** — just like a table in the current database:

```
SELECT * FROM input_topic WITH (FORMAT = json_each_row, SCHEMA = (...));
```

```
INSERT INTO output_topic SELECT ...;
```

External topics

External topics are topics located **in another database** YDB.

Access to them is performed only through a pre-created external data source with the YDB source type.

After creating a source, for example named `ext_source`, access to topic `input_topic` in the external database is written as follows:

```
SELECT * FROM ext_source.input_topic WITH (FORMAT = json_each_row, SCHEMA = (...));
```

The name `ext_source` in the documentation is **conventional** — in your database, the source may be named differently; it is important that it matches in `CREATE EXTERNAL DATA SOURCE` and in the prefix before the topic name.

Reading from a topic

Reading from a topic can be limited to only the topic's current data, or it can wait for new written messages.

Reading current data

In this mode, reading is performed from the first to the last offset stored in the topic at the time the query is started. If data continues to be written to the topic, the query will stop after reaching the last offset known at startup. Specifying filters by service fields speeds up reading, as reading is performed only over the specified ranges.

```
SELECT
    Data    -- message body
FROM
    input_topic  -- local topic; for external: ext_source.input_topic
LIMIT 10;
```

Reading with data waiting

To wait for new messages, use the `WITH (STREAMING = "TRUE")` option. Reading starts from the current moment and continues until the number of messages specified in the `LIMIT` expression is read. The `LIMIT` parameter is required, without it the query will not finish, as it will wait for new messages indefinitely.

```
SELECT
    Data
FROM
    ext_source.input_topic  -- external topic; for local: input_topic
WITH (STREAMING = "TRUE")
LIMIT 10;
```

For continuous processing of incoming data, use streaming queries.

Message format and schema

When reading from a topic, the message body can be obtained in two ways: raw data and formatted data.

Raw data

Use it when the message content does not need to be parsed; it is enough to read the body as is.

```
SELECT
    Data
FROM
    input_topic  -- local topic; for external: ext_source.input_topic
WITH (
    FORMAT = raw,
    SCHEMA = (
        Data String
    )
)
LIMIT 10;
```

As a result, only the `Data` column is available: the message body in its original form.

The same result can be obtained without the `WITH` block: see table reading.

Formatted data

Use it when messages are serialized in a known format (JSON, CSV, etc.). The `FORMAT` parameter sets the parsing method, and `SCHEMA` sets the names and types of fields that will appear in the `SELECT` result:

```
SELECT
    Id,
    Name
FROM
    input_topic  -- local topic; for external: ext_source.input_topic
WITH (
    FORMAT = json_each_row,
    SCHEMA = (
        Id Uint64 NOT NULL,
        Name Utf8 NOT NULL
    )
);
```

Fields from `SCHEMA` are available in `SELECT` by name, like table columns.

For more details about supported formats: Data formats for reading/writing from topics.

Using the reader

A consumer is a named subscription to a topic that stores the current read position.

A consumer is created via the CLI or when creating a topic using CREATE TOPIC. The consumer name is specified in the query text with a pragma:

```
PRAGMA pq.Consumer="my_consumer";
```

If a consumer is not specified, reading from the topic is performed without one. Specifying a consumer allows tracking the read position and lag from the topic side, for example via the CLI.

Moving data from a topic to a table via UPSERT

Data from a topic can be moved to a table via UPSERT INTO:

```
UPSERT INTO
    table_name
SELECT
    Data            -- you can use any transformations
FROM
    ext_source.input_topic;  -- external topic; for local: input_topic
```

Service fields

When reading, you can request service fields and user-defined message attributes:

Field	Type	Description
`__ydb_create_time`	`Timestamp`	Message creation time
`__ydb_write_time`	`Timestamp`	Time the message was written to the topic
`__ydb_offset`	`Uint64`	Message offset in the partition
`__ydb_partition_id`	`Uint64`	Partition number
`__ydb_message_group_id`	`String`	Message group identifier
`__ydb_seq_no`	`Uint64`	Message sequence number within the group
`__ydb_user_attributes`	`Dict<String,String>`	User-defined message attributes

Example of using service fields:

```
SELECT
    Data,                                               -- message body
    __ydb_create_time AS CreateTime,                    -- message creation time
    __ydb_write_time AS WriteTime,                      -- message write time
    __ydb_offset AS Offset,                             -- message offset in topic
    __ydb_partition_id AS Partition,                    -- partition number
    __ydb_message_group_id AS MessageGroupId,           -- message group identifier
    __ydb_seq_no AS SeqNo                               -- sequence number within partition
FROM
    input_topic  -- local topic; for external: ext_source.input_topic
LIMIT 10;
```

Filters on service fields are evaluated before reading data from the topic and significantly reduce the volume of messages read. Comparison operators (`=` , `<>` , `<` , `<=` , `>` , `>=` , `IN`), logical conditions (`AND` , `OR`), and fields `partition_id` , `write_time` , `offset` are supported. Predicates on other service fields do not limit the read volume.

```
SELECT
    Data
FROM
    ext_source.input_topic  -- external topic; for local: input_topic
WHERE
    __ydb_partition_id = 42
        AND __ydb_offset >= 1000
        AND __ydb_offset <= 1100
        AND __ydb_write_time > CurrentUtcTimestamp() - Interval("PT2H");
```

Example of using user attributes:

```
SELECT
    COUNT(*) AS ErrorCount
FROM
    input_topic  -- local topic; for external: ext_source.input_topic
WHERE
    __ydb_user_attributes["type"] = "log"
        AND __ydb_user_attributes["level"] = "error";
```

Writing to a topic

Writing a single message

```
INSERT INTO
    output_topic  -- local topic; for external: ext_source.output_topic
SELECT
    "my_message";       -- message body
```

Writing data from a table

To write a table row with multiple columns to a topic, create a JSON object. The `TableRow` function creates a structure from all columns, `Yson::From` converts it to Yson, `Yson::SerializeJson` serializes it to a JSON string, and `ToBytes` converts the result to the `String` type required for writing to the topic:

```
INSERT INTO
    ext_source.output_topic  -- external topic; for local: output_topic
SELECT
    ToBytes(Unwrap(Yson::SerializeJson(Yson::From(TableRow()))))
FROM
    table_name;
```

Limitations

Warning

Writing user attributes via YQL is not supported.

Warning

Transactional writing via YQL/`INSERT INTO` is not supported — partial query results may appear in the topic.

Transactions and queries to YDB

This section describes the specifics of YQL implementation for YDB transactions.

Query language

The main tool for creating, modifying, and managing data in YDB is the declarative query language YQL. YQL is a SQL dialect that can be considered a standard for communicating with databases. In addition, YDB supports a set of special RPCs, for example, for working with a tree schema or for managing a cluster.

Transaction modes

YDB supports several transaction execution modes. By default, transactions are executed in *Serializable* mode, which provides the strictest isolation level for user transactions. The transaction execution mode is set in the settings when it is created. Examples for YDB SDK see in Setting up the transaction execution mode. In YDB UI the transaction mode can also be selected in the settings.

Supported **read-write modes**: *Serializable* (default) and *Snapshot Read-Write*; **read-only modes**: *Snapshot Read-Only* and *Stale Read-Only*. The *Online Read-Only* mode is left for compatibility with old code (**legacy**); in new scenarios, use *Snapshot Read-Only* instead.

Serializable

Essence. Serializable execution of user transactions (Serializable isolation level).

Features. The Optimistic Concurrency Control mechanism is used. Optimistic locks are placed on rows read during the transaction. When the transaction completes, it is checked that the locks have not been invalidated. The optimistic nature of locks results in an important property for the user — in case of a conflict, the transaction that completes first wins. Competing transactions will fail with an error `Transaction locks invalidated`.

Guarantees.

- The result of successfully executed parallel transactions is equivalent to some serial order of their execution;
- For successful transactions, there are no read anomalies;
- A transaction sees all changes that were committed before its first read (the time the snapshot was taken), plus its own changes made earlier in the same transaction (read-your-own-writes);
- Linearizability **by key** is guaranteed: if transaction T1, affecting a certain key, completed before transaction T2, affecting **the same key**, began, then in the execution order T1 will be before T2. For transactions working with different keys, such an order is not guaranteed — the observed order of their commit may differ from the real order of their completion in time.

Snapshot Read-Write

Essence. It is Snapshot Isolation (analogous to Repeatable Read in PostgreSQL).
Reads are performed from a consistent data snapshot committed before the first read. A transaction will successfully commit only if, from the moment the data snapshot was taken until the transaction commit, the rows it modified were not modified by other transactions.

Features. The Optimistic Concurrency Control mechanism is used. Unlike Serializable, transactions do not take locks on read rows — this allows them to commit successfully even if the data they read was modified by other transactions. Locks are taken on modified rows: with parallel transactions changing the same keys, only the transaction that completes first will succeed. Competing transactions will be rejected with a write-write conflict at the commit stage with an error `Transaction locks invalidated`.

Guarantees.

- All reads in a transaction see the same data state on the snapshot obtained before the first read, plus its own changes made earlier in the same transaction (read-your-own-writes);
- If there is a write-write conflict, the transaction will not be able to commit;
- The write skew anomaly may be observed.

Snapshot Read-Only

Essence. The transaction works with a consistent database snapshot committed before the first read. The guarantees for data reads are the same as Snapshot Read-Write. Writes are prohibited in this mode, which makes it more efficient than Snapshot Read-Write when only data reading is needed.

Features. Provides maximum data freshness at the start of the transaction, but may have higher response latency due to the need to form a snapshot.

Guarantees. All reads in a transaction see the same data state on the snapshot; commits after the snapshot is taken are not visible.

Stale Read-Only

Essence. Reads are performed on tablet (shard) replicas with possible lag behind the tablet (shard) leader (usually fractions of a second). The mode is well suited for key-based read scenarios when minimal latency is needed. The user reads committed but possibly stale data.

Features. Low latency and high throughput due to reading from replicas. The read replica is usually selected in the same availability zone, but the exact location is not guaranteed.

Guarantees. Data consistency at the key level within **one** `SELECT` expression; between **different** `SELECT` expressions in the same transaction, consistency is **not** guaranteed.

Limitations. There is no single snapshot for the entire transaction; there may be a delay relative to the data on the leader (the data may not be the freshest). Using replicas for reads is possible only if all read rows are in one shard. If the read spans multiple shards, the read will be performed from leaders with a snapshot taken similarly to Snapshot Read-Only. Reading from column-oriented tables in this mode is not supported (see the warning below). Interactive transactions are not supported. For additional limitations and nuances on query types, see the SDK documentation for the selected language.

Online Read-Only

A deprecated (**legacy**) mode retained for compatibility. For new applications, when reading without writing, use *Snapshot Read-Only*. Details and examples of calling in the SDK can still be found in Online Read-Only.

Limitation for Online Read-Only and Stale Read-Only

These modes do not support reading from column-oriented tables. An attempt to read will cause an error of the following form:

```
Read from column tables is not supported in Online Read-Only or Stale Read-Only transaction modes. Use Serializable or Snapshot Read-Only mode instead.
```

For transactions that read from column-oriented tables, use:

- Serializable — the default mode;
- Snapshot Read-Only — a mode for reading from a consistent snapshot.

Implicit transactions

The logic of implicit transactions is applied when sending a single YQL script to the server without explicitly selecting a transaction mode. Typical entry points:

- YDB UI — the **Query** tab on the database page (query execution form), when run without selecting a transaction mode in the settings.
- YDB CLI — one-off script submission via the `ydb sql` command.
- Applications on YDB SDK — mode ImplicitTx.

If a transaction mode is not set for a query, YDB automatically manages its behavior. This mode is called an **implicit transaction**.

In this mode, YDB determines based on the query whether to execute it outside a transaction or wrap it in a transaction with *Serializable* mode. The implicit transaction mode is universal for query execution, as it supports statements of any kind with the specific behavior described below.

Behavior for different types of statements

- **Data Definition Language (DDL) statements**
  DDL statements (such as `CREATE TABLE`, `DROP TABLE`, etc.) are executed outside a transaction. A query can consist only of DDL statements. If an error occurs, changes made by previous statements in the query are not rolled back.
- **Data Manipulation Language (DML) statements**
  DML statements (such as `UPSERT`, `SELECT`, `UPDATE`, etc.) are wrapped in a transaction with *Serializable* mode. A query can consist only of DML statements. On successful execution, changes are committed, and if an error occurs, they are rolled back.
- **Batch modification statements**
  Batch modification statements (such as `BATCH UPDATE` and `BATCH DELETE FROM`) are executed outside a transaction. A query can consist only of one batch modification statement. If an error occurs, the statement's changes are not rolled back.

Summary table

Statement type	Implicit transaction handling	Support for multiple statements	Rollback on error
DDL	Outside a transaction	Yes (DDL only)	No
DML	Automatic transaction (Serializable)	Yes (DML only)	Yes
Batch modification statements	Outside a transaction	No	No

To explicitly set a transaction mode, use the appropriate settings at each entry point:

- YDB UI — select a transaction mode in the execution settings on the **Query** tab.
- YDB CLI — for the subcommand `table query execute` for queries of type `data` set the parameter `--tx-mode` (default `serializable-rw`, which corresponds to *Serializable* mode).
- YDB SDK — see setting the mode in the YDB SDK.

YQL language

Implemented YQL constructs can be divided into two classes: data definition language (DDL) and data manipulation language (DML).

For more information about supported YQL constructs, see the YQL documentation.

Below are the features and limitations of YQL support in YDB that are worth paying attention to:

- Multistatement transactions are allowed, that is, transactions consisting of a sequence of YQL expressions. During transaction execution, interaction with the client program is allowed; in other words, client interaction with the database may look like this: `begin a transaction and execute SELECT; analyze the SELECT results on the client; ...; execute UPDATE and commit the transaction`. Each of the queries within a transaction can also contain multiple YQL expressions. It is worth noting that if the transaction body is fully formed before accessing the database, the transaction can be processed more efficiently;
- In YDB it is not supported to mix DDL and DML queries in one transaction. The traditional concept of an ACID transaction applies specifically to DML queries, that is, queries that change data. DDL queries must be idempotent, that is, repeatable in case of an error. If you need to perform an action with a schema, each action will be transactional, but a set of actions will not;
- Any errors invalidate the entire transaction as a whole, not an individual query, so after a transaction completes with an error reporting a temporary failure, the transaction must be retried from the very beginning;
- Reads in a transaction see all data changes that were made earlier in the same transaction;
- All changes made within a transaction accumulate in the memory of the database server. They are not visible to other transactions until the current one completes successfully and are applied atomically at commit. The described scheme imposes a limitation: the volume of changes within a single transaction must fit in RAM. **Implementation detail:** if a transaction reads data from a table that it previously modified, the accumulated changes are written to shards prematurely — this affects efficiency (see the recommendation below). Prematurely written data is not visible to other transactions and is rolled back when the transaction is canceled;
- For transaction efficiency, avoid reading from tables previously modified in the same transaction (read-after-write), as this leads to premature data writes to shards. For each table, perform all reads before modifications.

For more information about YQL support in YDB see the YQL documentation.

Distributed transactions

A table in YDB can be sharded by ranges of primary key values. Different table shards can be served by different servers of the distributed database (including those located in different locations), and can also move independently between servers for rebalancing or maintaining shard operability during server or network equipment failures.

A topic in YDB can be sharded into multiple partitions. Different topic partitions, like table shards, can be served by different servers of the distributed database.

In YDB distributed transactions are supported. Distributed transactions are transactions that affect more than one shard of one or more tables and topics. They require more resources and take longer. While point reads and writes can be performed in up to 10 ms at the 99th percentile, distributed transactions typically take from 20 to 500 ms.

Transactions involving topics and tables

> **Warning**
>
> Supported only for row-oriented tables. Support for column-oriented tables is currently under development.

YDB supports transactions involving row-oriented tables and/or topics. Thus, you can transactionally move data from tables to topics and in the reverse direction, as well as between topics, so that data is not lost or duplicated even in unforeseen circumstances.

For more information about transactional operations when working with topics, see Transactions involving topics and Working with topics.

Transactions involving row-oriented and column-oriented tables

Currently, mixing column-oriented tables and row-oriented tables in a single transaction is supported only if the transaction performs read operations; no writes are allowed. Support for read-write transactions involving both table types is under development.

If a write transaction includes both types of tables, it fails with the following error: `Write transactions that use both row-oriented and column-oriented tables are disabled at current time`.

Change Data Capture (CDC)

Warning

Supported only for row-oriented tables. Support for column-oriented tables is currently under development.

Change Data Capture (CDC) captures changes to YDB table rows, uses these changes to generate a *changefeed*, writes them to distributed storage, and provides access to these records for further processing. It uses a topic as distributed storage to efficiently store the table change log.

When adding, updating, or deleting a table row, CDC generates a change record by specifying the primary key of the row and writes it to the topic partition corresponding to this key.

Guarantees

- Change records are sharded across topic partitions by primary key.
- Each change is only delivered once (exactly-once delivery).
- Changes by the same primary key are delivered to the same topic partition in the order they took place in the table.
- Change records are delivered to the topic partition only after the corresponding transaction in the table has been committed.

Limitations

- Changefeeds support records of the following types of operations:
  - Updates: overwriting the values of the specified columns. Query example: UPDATE.
  - Replacements: overwriting the values of the specified columns, the values of the unspecified columns are replaced by their default values. Query example: REPLACE INTO.
  - Erases. Query example: DELETE FROM.

Adding rows is a special update or replace case, and a record of adding a row in a changefeed will look similar to an update or replace record, depending on the original request that led to the change.

Virtual Timestamps

All changes in YDB tables are arranged according to the order in which transactions are performed. Each change is marked with a virtual timestamp which consists of two elements:

1. Global coordinator time.
2. Unique transaction ID.

Using these timestamps, you can arrange records from different partitions of the topic relative to each other or use them for filtering (for example, to exclude old change records).

For single-shard transactions, the timestamp of an existing distributed transaction in the execution queue can be used, which allows the timestamp to be non-unique. If there are no distributed transactions in the execution queue, the first element of the timestamp will be the time obtained from the coordinator, and the unique transaction ID will take the maximum possible value `18446744073709551615` (2^{64}-1, the maximum value of `Uint64`).

Note

By default, virtual timestamps are not emitted to the changefeed. To enable them, use the appropriate parameter when creating a changefeed.

Barriers

Barriers are service records without data about modification or deletion with virtual timestamps that appear in each partition of a topic at a specified interval. A barrier guarantees that any change with a virtual timestamp earlier than the barrier's has been written to this topic partition.

Barriers can be used to ensure strict ordering and global data consistency by buffering data between them.

Note

By default, barriers are not emitted to the changefeed. To set the frequency at which barriers are emitted, use the appropriate parameter when creating a changefeed.

Initial Table Scan

By default, a changefeed only includes records about those table rows that changed after the changefeed was created. Initial table scan enables you to export, to the changefeed, the values of all the rows that existed at the time of changefeed creation.

The scan runs in the background mode on top of the table snapshot. The following situations are possible:

- A non-scanned row changes in the table. The changefeed will receive, one after another: a record with the source value and a record about the update. When the same record is changed again, only the update record is exported.
- A changed row is found during scanning. Nothing is exported to the changefeed because the source value has already been exported at the time of change (see the previous paragraph).
- A scanned row changes in the table. Only an update record exports to the changefeed.

This ensures that, for the same row (the same primary key), the source value is exported first, and then the updated value is exported.

Note

The record with the source row value is labeled as an update record. When using virtual timestamps, records are marked by the snapshot's timestamp.

During the scanning process, depending on the table update frequency, you might see too many `OVERLOADED` errors. This is because, besides the update records, you also need to deliver records with the source row values. When the scan is complete, the changefeed switches to normal operation.

> **Warning**
>
> Automatic partitioning processes are suspended in the table and barriers are not emitted to the changefeed during the initial scan.

Record Structure

Depending on the changefeed parameters, the structure of a record may differ.

JSON Format

A JSON record has the following structure:

```
{
    "key": [<key components>],
    "update": {<columns>},
    "reset": {<columns>},
    "erase": {},
    "newImage": {<columns>},
    "oldImage": {<columns>},
    "ts": [<step>, <txId>],
    "user": "<user SID>",
    "traceId": "<Trace ID>"
}
```

- `key`: An array of primary key component values. Always present. The order of elements matches the order of the columns listed in the primary key of the table.
- `update`: Update flag. Present if a record matches the update operation. In `UPDATES` mode, it also contains the names and values of updated columns.
- `reset`: Replacement flag. Present if a record matches the replacement operation. In `UPDATES` mode, it also contains the names and values of the columns for which a value is set.
- `erase`: Erase flag. Present if a record matches the erase operation.
- `newImage`: Row snapshot that results from its being changed. Present in `NEW_IMAGE` and `NEW_AND_OLD_IMAGES` modes. Contains column names and values.
- `oldImage`: Row snapshot before the change. Present in `OLD_IMAGE` and `NEW_AND_OLD_IMAGES` modes. Contains column names and values.
- `ts`: Virtual timestamp. Present if the `VIRTUAL_TIMESTAMPS` setting is enabled. Contains the value of the global coordinator time (`step`) and the unique transaction ID (`txId`).
- `user`: User identifier. Present if the `USER_SIDS` setting is enabled. Contains the user's SID and is set to `ttl@system` if the record is deleted by the TTL process.
- `traceId`: OpenTelemetry trace identifier. Present if the `TRACE_IDS` setting is enabled.

Sample record of an update in `UPDATES` mode:

```
{
   "key": [1, "one"],
   "update": {
       "payload": "lorem ipsum",
       "date": "2022-02-22"
   }
}
```

Record of an erase:

```
{
   "key": [2, "two"],
   "erase": {}
}
```

Record with row snapshots:

```
{
   "key": [1, 2, 3],
   "update": {},
   "newImage": {
       "textColumn": "value1",
       "intColumn": 101,
       "boolColumn": true
   },
   "oldImage": {
       "textColumn": null,
       "intColumn": 100,
       "boolColumn": false
   }
}
```

Record with virtual timestamps:

```
{
   "key": [1],
   "update": {
       "created": "2022-12-12T00:00:00.000000Z",
       "customer": "Name123"
   },
   "ts": [1670792400890, 562949953607163]
}
```

A barrier record contains a single field `resolved` with a virtual timestamp:

```
{
    "resolved": [1670792500000, 0]
}
```

Note

- The same record may not contain the `update`, `reset` and `erase` fields simultaneously, since these fields are operation flags (you can't update and erase a table row at the same time). However, each record contains one of these fields (any operation is either an update, a replacement, or an erase).
- In `UPDATES` mode, the `update` or `reset` field for update or replacement operations is an operation flag and contains the names and values of updated columns.
- JSON object fields containing column names and values (`newImage`, `oldImage`, and `update` & `reset` in `UPDATES` mode), *do not include* the columns that are primary key components.
- If a record contains the `erase` field (indicating that the record matches the erase operation), this is always an empty JSON object (`{}`).

Debezium-Compatible JSON Format

A Debezium-compatible JSON record structure has the following format:

```
{
    "payload": {
        "op": <op>,
        "before": {<columns>},
        "after": {<columns>},
        "source": {
            "connector": <connector>,
            "version": <version>,
            "ts_ms": <ts_ms>,
            "step": <step>,
            "txId": <txId>,
            "snapshot": <bool>,
            "user": <user SID>,
            "traceId": <Trace ID>
        }
    }
}
```

- `op`: Operation that was performed on a row:
  - `c` — create. Applicable only in `NEW_AND_OLD_IMAGES` mode.
  - `u` — update.
  - `d` — delete.
  - `r` — read from snapshot.
- `before`: Row snapshot before the change. Present in `OLD_IMAGE` and `NEW_AND_OLD_IMAGES` modes. Contains column names and values.
- `after`: Row snapshot after the change. Present in `NEW_IMAGE` and `NEW_AND_OLD_IMAGES` modes. Contains column names and values.
- `source`: Source metadata for the event.
  - `connector`: Connector name. Current name is `ydb`.
  - `version`: Connector version that was used to generate the record. Current version is `1.0.0`.
  - `ts_ms`: Approximate time when the change was applied, in milliseconds.
  - `step`: Global coordinator time. Part of the virtual timestamp.
  - `txId`: Unique transaction ID. Part of the virtual timestamp.
  - `snapshot`: Whether the event is part of a snapshot.
  - `user`: User identifier. Present if the `USER_SIDS` setting is enabled. Contains the user's SID and equals `ttl@system` if the record is deleted by the TTL process.
  - `traceId`: OpenTelemetry trace identifier. Present if the `TRACE_IDS` setting is enabled.

When reading using Kafka API, the Debezium-compatible primary key of the modified row is specified as the message key:

```
{
    "payload": {<columns>}
}
```

- `payload`: Key of a row that was changed. Contains names and values of the columns that are components of the primary key.

Record Retention Period

By default, records are stored in the changefeed for 24 hours from the time they are sent. Depending on usage scenarios, the retention period can be reduced or increased up to 30 days.

> **Warning**
>
> Records whose retention time has expired are deleted, regardless of whether they were processed (read) or not.

Deleting records before they are processed by the client will cause offset skips, which means that the offsets of the last record read from the partition and the earliest available record will differ by more than one.

To set up the record retention period, specify the RETENTION_PERIOD parameter when creating a changefeed.

Topic Partitions

By default, the initial number of topic partitions is equal to the number of table partitions. You can redefine the initial number of topic partitions by specifying the TOPIC_MIN_ACTIVE_PARTITIONS parameter when creating a changefeed. To create a changefeed with a dynamically changing number of partitions, set the TOPIC_AUTO_PARTITIONING parameter when creating the changefeed.

> **Note**
>
> Currently, the ability to explicitly specify the number of topic partitions is available only for tables whose first primary key component is of type `Uint64` or `Uint32`.

Creating and Deleting a Changefeed

You can add a changefeed to an existing table or erase it using the ADD CHANGEFEED and DROP CHANGEFEED directives of the YQL `ALTER TABLE` statement. When erasing a table, the changefeed added to it is also deleted.

Getting and Updating Topic Settings

You can get the settings using an SDK or the YDB CLI by passing the path to the changefeed in the arguments, which has the following format:

```
path/to/table/changefeed_name
```

For example, if a table named `table` contains a changefeed named `updates_feed` in the `my` directory, its path looks as follows:

```
my/table/updates_feed
```

The topic settings can be updated using the expression ALTER TOPIC. Supported actions:

- updating settings:
  - `retention_period`;
  - `retention_storage_mb`;
  - `partition_write_burst_bytes`;
  - `partition_write_speed_bytes_per_second`.
- updating consumers.

CDC Purpose and Use

For information about using CDC when developing apps, see best practices.

Time to Live (TTL) and Eviction to External Storage

This section describes how the TTL mechanism works and what its limits are.

How It Works

The table's TTL is a sequence of storage tiers. Each tier contains an expression (TTL expression) and an action. When the expression is triggered, that tier is assigned to the row. When a tier is assigned to a row, the specified action is automatically performed: moving the row to external storage or deleting it. External storage is represented by the external data source object.

YDB allows you to specify a column (TTL column) whose values are used in TTL expressions. The expression is triggered when the specified number of seconds has passed since the time recorded in the TTL column. For rows with `NULL` value in TTL column, the expression is not triggered.

The timestamp for deleting a table item is determined by the formula:

```
eviction_time = valueof(ttl_column) + evict_after_seconds
```

> **Note**
>
> TTL doesn't guarantee that the item will be deleted exactly at `eviction_time`, it might happen later. If it's important to exclude logically obsolete but not yet physically deleted items from the selection, use query-level filtering.

Data is deleted by the *Background Removal Operation* (*BRO*), consisting of two stages:

1. Checking the values in the TTL column.
2. Deleting expired data.

The *BRO* has the following properties:

- The concurrency unit is a table partition.
- For tables with secondary indexes, the delete stage is a distributed transaction.

Guarantees

- For the same partition *BRO* is run at the intervals set in the TTL settings. The default run interval is 1 hour, the minimum allowable value is 15 minutes.
- Data consistency is guaranteed. The TTL column value is re-checked during the delete stage. This means that if the TTL column value is updated between stages 1 and 2 (for example, with `UPDATE`) and ceases to meet the delete criteria, the row will not be deleted.

Limitations

- The TTL column must be of one of the following types:
  - `Date`.
  - `Datetime`.
  - `Timestamp`.
  - `Uint32`.
  - `Uint64`.
  - `DyNumber`.
- The value in the TTL column with a numeric type (`Uint32`, `Uint64`, or `DyNumber`) is interpreted as a Unix time value. The following units are supported (set in the TTL settings):
  - Seconds.
  - Milliseconds.
  - Microseconds.
  - Nanoseconds.
- You can't specify multiple TTL columns.
- You can't delete the TTL column. However, if this is required, you should first disable TTL for the table.
- Only Object Storage is supported as external storage.
- The delete action can only be specified for the last tier.

Setup

Currently, you can manage TTL settings using:

- YQL.
- YDB console client.
- YDB C++, Go and Python SDK.

Database Limits

This section describes the parameters of limits set in YDB.

Schema Object Limits

The table below shows the limits that apply to schema objects: tables, databases, and columns. The "Object" column specifies the type of schema object that the limit applies to.
The "Error type" column shows the status that the query ends with if an error occurs. For more information about statuses, see Error handling in the API.

Objects	Limit	Value	Explanation	Internal name	Error type	Error message
Database	Maximum path depth	32	Maximum number of nested path elements (directories, tables).	MaxDepth	SCHEME_ERROR	Paths depth limit exceeded
Database	Maximum number of paths (schema objects)	10,000	Maximum number of path elements (directories, tables) in a database.	MaxPaths	PRECONDITION_FAILED	Paths count limit exceeded
Database	Maximum number of tablets	200,000	Maximum number of tablets (table shards and system tablets) that can run in the database. An error is returned if a query to create, copy, or update a table exceeds this limit. When a database reaches the maximum number of tablets, no automatic table sharding takes place.	MaxShards	PRECONDITION_FAILED	Shards count limit exceeded (in subdomain)
Database	Maximum object name length	255	Limits the number of characters in the name of a schema object, such as a directory or a table.	MaxPathElementLength	SCHEME_ERROR	Path part is too long
Database	Maximum ACL size	10 KB	Maximum total size of all access control rules that can be saved for the schema object in question.	MaxAclBytesSize	BAD_REQUEST	ACL size limit exceeded
Directory	Maximum number of objects	100,000	Maximum number of tables and child directories created in a directory.	MaxChildrenInDir	PRECONDITION_FAILED	Children count limit exceeded

Table	Maximum number of table shards	35,000	Maximum number of table shards.	MaxShardsInPath	PRECONDITION_FAILED	Shards count limit exceeded (in dir)
Table	Maximum number of columns	200	Limits the total number of columns in a table.	MaxTableColumns	SCHEME_ERROR on CREATE / BAD_REQUEST on ALTER	Too many columns
Table	Maximum column name length	255	Limits the number of characters in a column name.	MaxTableColumnNameLength	SCHEME_ERROR	Column name too long
Table	Maximum number of columns in a primary key	20	Each table must have a primary key. The number of columns in the primary key may not exceed this limit.	MaxTableKeyColumns	SCHEME_ERROR	Too many key columns
Table	Maximum number of indexes	20	Maximum number of indexes other than the primary key index that can be created in a table.	MaxTableIndices	PRECONDITION_FAILED	Indexes count has reached maximum value in the table
Table	Maximum number of followers	3	Maximum number of read-only replicas that can be specified when creating a table with followers.	MaxFollowersCount	BAD_REQUEST	Too much followers
Table	Maximum number of tables to copy	10,000	Limit on the size of the table list for persistent table copy operations.	MaxConsistentCopyTargets	BAD_REQUEST	Consistent copy object count limit exceeded

Size Limits for Stored Data

Parameter	Value	Error type
Maximum total size of all columns in a primary key	1 MB	GENERIC_ERROR
Maximum size of a string column value	16 MB	GENERIC_ERROR

Analytical Table Limits

Parameter	Value
Maximum row size	8 MB
Maximum size of an inserted data block	8 MB

Limits on Query Execution

The table below lists the limits that apply to query execution.

Parameter	Default	Explanation	Effect in case of a violation of the limit
Query duration	2 hours	The maximum amount of time allowed for a single query to execute.	Returns status code `TIMEOUT`
Maximum number of sessions per cluster node	1,000	The limit on the number of sessions that clients can create with each YDB node.	Returns status code `OVERLOADED`
Maximum query text length	10 KB	The maximum allowable length of YQL query text.	Returns status code `BAD_REQUEST`

Maximum size of parameter values	50 MB	The maximum total size of parameters passed when executing a parameterized query.	Returns status code `BAD_REQUEST`
Maximum size of a row	50 MB	The maximum total size of all fields of a single row returned or produced by the query.	Returns status code `PRECONDITION_FAILED`
Maximum number of locks per DataShard	10,000	The number of lock ranges per DataShard	Converts some locks to whole-shard locks, which use less memory but lock the entire shard instead of just a part.

Legacy Limits

In previous versions of YDB, queries were typically executed using an API called "Table Service". This API had the following limitations, which have been addressed by replacing it with a new API called "Query Service".

Parameter	Default	Explanation	Status in case of a violation of the limit
Maximum number of rows in query results	1,000	The complete results of some queries executed using the `ExecuteDataQuery` method may contain more rows than allowed. In such cases, the query will return the maximum number of rows allowed, and the result will have the `truncated` flag set.	SUCCESS
Maximum query result size	50 MB	The complete results of some queries may exceed the set limit. If this occurs, the query will fail and return no data.	PRECONDITION_FAILED

Resource pool limits

Parameter	Value
Maximum number of resource pool classifiers	1000

Limits on resource counts are also constrained by schema object limits. See above.

Backup concepts

YDB ensures data safety during hardware failures through replication and fault tolerance. However, replication does not protect against **logical errors**: an accidental `DROP TABLE`, an erroneous mass `UPDATE`, or `DELETE` will be replicated to all replicas. To protect against such scenarios, **backup** is required — a separate copy of data that can be restored from.

Full backup

A full backup is a snapshot of table data at a specific point in time. YDB provides several ways to create full backups, from simple to more functional.

Copying tables within a cluster

The simplest way is to create a copy of a table (or several tables) within the same cluster using the `ydb tools copy` command. The copy is created atomically from a consistent snapshot and uses a copy-on-write mechanism, so the operation is fast.

Suitable for:

- Quickly creating a safety copy before a dangerous operation.
- Cloning data for testing.

> **Warning**
>
> The copy is stored in the same cluster as the original data. It protects against logical errors but not against cluster loss.

Dump to file system

The `ydb tools dump` and `ydb tools restore` commands allow you to dump data to a local file system and restore it back.

Suitable for:

- Local development and testing.
- Small databases.
- Creating a copy on a separate medium.

Export to S3-compatible storage

The `ydb export s3` and `ydb import s3` commands allow you to export and import data to an external S3-compatible storage.

Suitable for:

- Disaster recovery (data is stored outside the cluster).
- Data migration between clusters.
- Long-term archiving.

Export to NFS

The `ydb export nfs` and `ydb import nfs` commands allow you to export and import data to a network file system (NFS) mounted on all hosts of the YDB cluster. Unlike dump to file system, the export is performed on the server side and does not require data transfer via CLI.

Suitable for:

- Disaster recovery (data is stored outside the cluster).
- Data migration between clusters.
- Long-term archiving.

For more details on configuring NFS for backup and recovery, see the recipe Backup and recovery via NFS.

Incremental backup

When working with large tables, repeatedly creating full backups can be too costly. Incremental backup solves this problem: after an initial full copy, each subsequent increment captures only the changes (inserts, updates, deletes) that occurred since the previous backup.

Incremental backups are organized into a **chain**:

```
Full backup → Increment₁ → Increment₂ → ... → Incrementₙ
```

To restore, the entire chain is needed: first the full copy is applied, then all increments sequentially. Restoration is performed to the state at the time of the last increment in the chain.

Incremental backup is implemented using backup collections.

> **Note**
>
> Currently, only row tables are supported.

Backup of system tablets

> **Note**
>
> Currently, only backup of cluster system tablets is supported. Backup of database system tablets is not supported.

The system tablet backup mechanism provides incremental copying of cluster metadata — such as Hive, BSController, and SchemeShard — to the local file system of cluster hosts.

This mechanism is used to restore cluster metadata when restoring from database backups is technically possible but not suitable in terms of time or effort. A typical scenario is when the total volume of databases in the cluster is large due to their number, the size of individual databases, or a combination of both; a full `import/restore` of all data into a new cluster in such a case leads to prolonged downtime. In this scenario, you can restore system tablets and bring the cluster back to a working state without performing a bulk restore of user data on the new cluster.

If the volume of databases allows for a standard restore, use export/import or dump/restore first. System tablet backup should be used as a special mechanism for situations where you need to restore cluster metadata and reduce the volume of restore operations.

Note

For practical instructions on enabling and restoring, see recipes for system tablet backup.

Warning

Backups of different system tablets are created independently of each other and are not consistent with each other. After restoration, the state of tablets may be inconsistent, which may negatively affect cluster operation.

How it works

Backup consists of two components:

- **State snapshot** — at each start, the tablet scans all its tables and writes its full state to a backup, including the data schema. The scan is based on a state snapshot and does not block tablet operation.
- **Change log** — with each change to data or schema, the tablet asynchronously writes the change to the log in parallel with writing to the distributed storage. When the log size exceeds the snapshot size, the tablet automatically creates a new snapshot.

Warning

Due to asynchronous writing, the latest changes that did not make it into the backup before the failure may be lost.

Backups are created **locally on the host where the tablet is currently running**. Therefore, the most recent copy is on the host where the tablet was running just before the failure.

The number of stored backups on a host is limited in the configuration. After a successful snapshot, the oldest copy is automatically deleted when the limit is exceeded. Incomplete copies (without a fully written snapshot) are deleted when a new backup is created.

Comparison of approaches

Method	Storage location	Incremental	Use cases
Copying tables within a cluster	Within the cluster	No	Quick copy before a dangerous operation
Dump to file system	File system	No	Development, testing, small databases
Export to S3-compatible storage	S3-compatible storage	No	Disaster recovery, migration, archiving
Export to NFS	Network File System (NFS)	No	Disaster recovery, migration, archiving
Incremental backup	Within the cluster (exported to S3 or file system)	Yes	Regular backups of large production databases
System tablet backup	Local file system of cluster hosts	Yes	Restoring cluster metadata in emergency situations

Asynchronous Replication

Asynchronous replication allows for synchronizing data between YDB databases in near real time. It can also be used for data migration between databases with minimal downtime for applications interacting with these databases. Such databases can be located in the same YDB cluster as well as in different clusters.

Overview

Asynchronous replication is based on Change Data Capture and operates on logical data. The following diagram illustrates the replication process:

As shown in the diagram above, asynchronous replication involves two databases:

1. **Source**. A database with replicated objects.
2. **Target**. A database where an asynchronous replication instance and replica objects will be created.

Asynchronous replication consists of the following stages:

- Initialization
- Initial table scan
- Change data replication

Initialization

Initialization of asynchronous replication includes the following steps:

- Creating an asynchronous replication instance on the target database using the CREATE ASYNC REPLICATION YQL expression.
- Establishing a connection with the source database. The target database connects to the source using the connection parameters specified during the creation of the asynchronous replication instance.

> **Note**
>
> The user account that is used to connect to the source database must have the following permissions:
>
> - Read permissions for schema objects and directory objects
> - Create, update, delete, and read permissions for changefeeds

- The following objects are created for replicated objects on the source:
  - changefeeds on the source
  - replica objects on the target

> **Note**
>
> Replicas are created under the user account that was used to create the asynchronous replication instance.

Initial Table Scan

During the initial table scan the source data is exported to changefeeds. The target runs consumers that read the source data from the changefeeds and write it to replicas.

You can get the progress of the initial table scan from the description of the asynchronous replication instance.

Synchronization Using Backup and Restore

With `INITIAL_SCAN = FALSE`, the initial data is transferred using server-side backup to S3 and restore from S3 operations. This method uses the backup mechanism to transfer large datasets.

Replication is created in the `PAUSED` state and prepares changefeeds without an initial scan. After all changefeeds are ready, the user creates a backup of the source tables and restores them on the target. Changes on the source accumulate in the changefeeds during the transfer. The target tables are not attached to replication at this stage.

After the restore is complete, the user switches replication to `STANDBY` using ALTER ASYNC REPLICATION. The target checks the restored table schemas, attaches the tables as replica objects, and starts applying accumulated changes. Attached tables become read-only.

To ensure data completeness, changefeeds must be ready before the backup is created, and accumulated records must remain available until their processing is acknowledged. The availability period is set with the AVAILABILITY_PERIOD parameter. For the procedure and checks, see the guide to initial synchronization using backup and restore.

Choosing an Initial Synchronization Method

Both methods require reading the source data and writing it to the target. Their additional costs differ:

Cost	Initial scan	Backup and restore
Data processing	Each source row is serialized into a CDC message, written to a changefeed, read, and applied on the target	Data is exported and imported by server-side operations; only changes pass through CDC
Temporary storage	Initial data and changes are stored in changefeeds according to the availability period	A consistent copy of the tables in the source and a backup in S3 are required; changefeeds store changes according to the availability period
Network transfer	Initial data is transferred from the source changefeeds to the target	Data is transferred from the source to S3 and then from S3 to the target; export compression can reduce the transfer volume
Setup and operation	Synchronization starts automatically when replication is created	Requires S3 storage, separate backup and restore operations, checking their completion, and starting replication

An initial scan is simpler to set up and suits small datasets. For large datasets, backup and restore can reduce the cost of processing the initial data through CDC, but require additional storage and S3 operations. Actual costs and duration depend on data volume, the rate of changes, cluster resources, compression, and the terms of S3 usage.

Change Data Replication

After the initial table scan is completed, the consumers read the change data and write it to replicas.

Each change data block has its *creation time* (). Consumers track the *reception time* of the change data (). Thus, you can use the following formula to calculate the *replication lag*:

You can also get the replication lag from the description of the asynchronous replication instance with the `--stats` option. If a consumer stops, loses its session, or does not report fresh statistics for 60 seconds, the lag value becomes unavailable. A missing value means that the lag is unknown, not zero.

Storing Changes in the Source

The AVAILABILITY_PERIOD parameter determines how long changefeeds retain messages whose processing has not yet been acknowledged by replication. It is set when replication is created and cannot be changed using `ALTER ASYNC REPLICATION`.

The default value is `'UNLIMITED'`: unacknowledged messages are retained until their processing is acknowledged. To limit the availability period, specify a positive interval, for example, `Interval('PT48H')`.

Regardless of the selected availability period, messages in the topic are deleted almost immediately after the consumer acknowledges their processing, freeing up space in the source and reducing the cost of storing changes that have already been processed. The `AVAILABILITY_PERIOD` parameter protects only unacknowledged messages from deletion.

Condition	Unlimited: `'UNLIMITED'`	Finite period: for example, `Interval('PT48H')`
Extended downtime or lag	Unacknowledged messages are retained regardless of their age	Unacknowledged messages may be deleted after the specified period expires
Storage usage in the source	Accumulated messages can keep growing in volume as long as replication does not acknowledge processing	The age of messages retained for replication is limited by the specified period
Initial transfer using a backup	No age limit for accumulated changes; enough storage space must be provided	Export, import, and processing of accumulated changes must fit within the selected period
What to monitor	Free space in the source and replication lag	Replication lag and the time remaining before the availability period expires

The availability period applies to the age of messages, not the duration of the current downtime. The `PAUSED` state does not suspend this period. If required messages have already been deleted, initial synchronization must be repeated to restore data completeness.

With `'UNLIMITED'`, replication uses an important consumer. With a finite period, it uses a consumer with a specified message availability period. This allows unacknowledged messages to be retained longer than the topic message retention period.

Restrictions

- The set of replicated objects is immutable and is generated when YDB creates an asynchronous replication instance.
- YDB supports the following types of replicated objects:
  - row-based tables, including those with synchronous secondary indexes (unique indexes are supported; vector indexes are excluded)
  - directories

YDB will replicate all row-based tables that are located in the given directories and subdirectories at the time the asynchronous replication instance is created.

- During asynchronous replication, you cannot add or delete columns in the source tables.
- During asynchronous replication, replicas are available only for reading.

Error Handling During Asynchronous Replication

Possible errors during asynchronous replication can be grouped into the following classes:

- **Temporary failures**, such as transport errors, system overload, etc. Requests will be resent until they are processed successfully.
- **Critical errors**, such as access violation errors, schema errors, etc. Replication will be aborted, and the description of the asynchronous replication instance will include the text of the error.

Warning

After fixing the cause of a critical error, you can resume asynchronous replication without dropping the instance. First pause it, then set its state to `STANDBY`:

```
ALTER ASYNC REPLICATION my_replication SET (STATE = 'PAUSED');
ALTER ASYNC REPLICATION my_replication SET (STATE = 'STANDBY');
```

Make sure the pause and processing of accumulated changes fit within the record retention period. For details, see ALTER ASYNC REPLICATION.

For more information about error classes and how to address them, refer to Error Handling.

Consistency Levels of Replicated Data

Row-Level Data Consistency

The Change Data Capture used for asynchronous replication guarantees that changes to the same primary key are delivered in the exact order in which they occurred at the source. This ensures row-level data consistency.

Data written to replica objects in this mode becomes available for reading immediately.

Global Data Consistency

When transactions are performed at the source, several rows in a table or even rows in different table partitions may be atomically modified. Global data consistency at the target implies preserving atomicity: changes "appear" (become available for reading) in a consistent manner.

To ensure global data consistency, changefeeds must be created with barriers enabled. Data is buffered directly in the partitions of replica objects between barriers. When the next set of barriers from all topics is received, the changes are committed and become available for reading. As a result, the data at the target is consistent as of the timestamp specified in the barrier. If we assume that barriers are created every 10 seconds at the source (the default value), then under normal conditions the target also commits and publishes the set of changes from the source every 10 seconds.

Change Commit Interval

By default changes are committed no more than once every 10 seconds. You can override the change commit interval by specifying the COMMIT_INTERVAL option when creating an asynchronous replication instance.

Note

The change commit interval directly affects the barrier emission interval in the changefeed — the parameter values are synchronized. Thus, changes are usually committed at the same frequency as barriers appear in the changefeeds. However, in some cases, for example, if there is an uneven load across tables, barriers in changefeeds may appear at significantly different times, which can increase the change commit interval. You can find information about the lag in the description of the asynchronous replication instance.

Asynchronous Replication Completion

Completion of asynchronous replication might be an end goal of data migration from one database to another. In this case the client stops writing data to the source, waits for the zero replication lag, and completes replication. After the replication process is completed, replicas become available both for reading and writing. Then you can switch the load from the source database to the target database and complete data migration.

Before completing replication, get an up-to-date lag value using `scheme describe --stats`. If the value is unavailable, wait for reporting to resume: a missing value or a previously displayed zero does not confirm that all changes have been transferred.

Note

You cannot resume completed asynchronous replication.

Warning

YDB currently supports only **forced** completion of asynchronous replication, when no additional checks are performed for data consistency, replication lag, etc.

To complete asynchronous replication, use the ALTER ASYNC REPLICATION YQL expression.

Dropping an Asynchronous Replication Instance

When you drop an asynchronous replication instance:

- Changefeeds are deleted in the source tables.
- The source tables are unlocked, and you can add and delete columns again.
- Optionally, all replicas are deleted.
- Asynchronous replication instance is deleted.

Warning

If asynchronous replication is dropped without prior completion and replica objects are not deleted, they will remain available only for reading.

To drop an asynchronous replication instance, use the DROP ASYNC REPLICATION YQL expression.

Bridge cluster operation mode

> **Feature of Yandex Enterprise Database**
>
> This functionality is available only in the Yandex Enterprise Database. In the open-source version of YDB it is absent.

This article describes a special operating mode of the YDB cluster in which data is stored with synchronous replication between multiple parts of the cluster called pile.

The bridge mode is an extension on top of the basic distributed storage modes: each pile is built using one of the YDB operating modes (for example, `mirror-3-dc` or `block-4-2`) and is fault-tolerant on its own; bridge adds synchronous replication between piles on top of that, plus managed failover/switchover of load between them. This provides an extra layer of fault tolerance on top of the chosen topologies. Bridge mode requires more hardware and is more complex to operate; it is especially useful for clusters deployed across two data centers and for systems with higher availability requirements — for example, when you need to remain available if three out of four data centers fail.

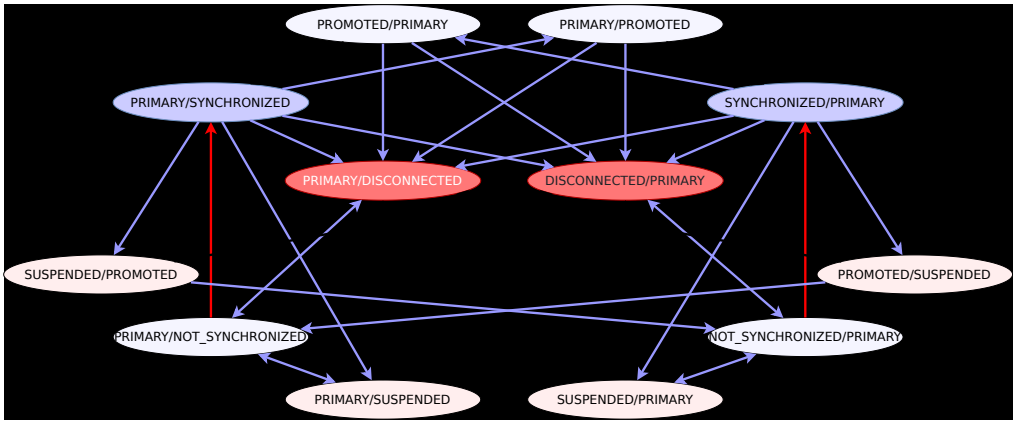
Description of the mode

In bridge mode, cluster nodes are split into several piles (typically one pile per datacenter). If one of the piles fails, the cluster becomes unavailable until the command to disable that pile is executed. After it is disabled, the cluster resumes operation.

YDB supports an arbitrary number of piles; however, for simplicity, the following discussion considers the case of two piles.

At the distributed storage level, bridge mode implements synchronous Active/Active replication between piles. At the database node level, Active/Passive redundancy is possible.

Data is stored in pairs of storage groups from different piles. Within each pile, any YDB operating mode supported for data storage may be used.



Bridge mode can achieve zero-downtime switchover. On failover, the cluster requires explicit disabling of replication to the failed pile before it can resume. When any pile is disabled, request processing is suspended until the command to disable replication to that pile is executed.

Piles are not standalone YDB clusters; they are parts of a single cluster with a complex topology:

- Tablets in bridge mode run as a single instance;
- each pile runs its own static group and set of independent storage groups with regular VDisks. Storage groups are accessed via DS-proxy-proxy, which exposes the DS-proxy interface to tablets and performs operations using two DS-proxy instances — one for the groups in each pile;
- each pile runs its own set of replicas of StateStorage, SchemeBoard, and Board. Access to StateStorage, SchemeBoard, and Board is through similar proxy-proxy components.

Pile states

Cluster operation is determined by the states of all its piles. For example, for a cluster of pile A and pile B, the pile states are written as (A, B), where order matters.

Each pile can be in one of the following states:

- `PRIMARY`. The main pile where tablets run. Only one pile can be in the `PRIMARY` state.
- `SYNCHRONIZED`. A follower pile whose storage groups are fully synchronized with `PRIMARY`.
- `DISCONNECTED`. Disconnected from `PRIMARY`; does not participate in operations.
- `NOT_SYNCHRONIZED`. A pile whose storage groups are not yet synchronized with `PRIMARY`. When synchronization completes, YDB automatically transitions the pile to `SYNCHRONIZED`.
- `PROMOTED`. A pile being smoothly transitioned from `SYNCHRONIZED` to `PRIMARY`. The pile remains in this state until the transition completes, after which YDB automatically transitions it to `PRIMARY`.
- `SUSPENDED`. A pile being smoothly transitioned to `DISCONNECTED`. When the transition completes, YDB automatically moves the pile to `DISCONNECTED`.

Normally, a pair of piles operates in `PRIMARY/SYNCHRONIZED` or `SYNCHRONIZED/PRIMARY`. That is, one pile is `PRIMARY` (tablets run there) and the other is `SYNCHRONIZED` (all its storage groups are synchronized with `PRIMARY`). In this configuration, a write is considered committed only after it has been successfully written to the storage groups of each pile with the required redundancy.

Transitions between states

From state	To state	How	Description
`PRIMARY`	`SYNCHRONIZED`	Automatically	Planned switchover complete.

PRIMARY	DISCONNECTED	Manually — failover	Emergency disable of unavailable PRIMARY and selection of new PRIMARY.
PRIMARY	SUSPENDED	Manually — takedown	Planned disable of current PRIMARY and selection of new PRIMARY.
SYNCHRONIZED	PRIMARY	Manually — failover	Emergency disable of unavailable PRIMARY and selection of new PRIMARY.
SYNCHRONIZED	DISCONNECTED	Manually — failover	Emergency disable of unavailable SYNCHRONIZED.
SYNCHRONIZED	PROMOTED	Manually — switchover	Start planned change of PRIMARY.
SYNCHRONIZED	SUSPENDED	Manually — takedown	Start planned disable of SYNCHRONIZED pile.
DISCONNECTED	NOT_SYNCHRONIZED	Manually — rejoin	Return pile to cluster after maintenance or recovery.
NOT_SYNCHRONIZED	SYNCHRONIZED	Automatically	Data synchronization complete.
NOT_SYNCHRONIZED	DISCONNECTED	Manually — failover	Emergency disable of unavailable NOT_SYNCHRONIZED.
PROMOTED	PRIMARY	Automatically	Planned switchover complete.
PROMOTED	PRIMARY	Manually — failover	Emergency disable of unavailable PRIMARY and selection of new PRIMARY.
PROMOTED	DISCONNECTED	Manually — failover	Emergency disable of unavailable PROMOTED.
SUSPENDED	NOT_SYNCHRONIZED	Manually — rejoin	Cancel planned disable of pile.
SUSPENDED	DISCONNECTED	Automatically	Planned disable complete.
SUSPENDED	DISCONNECTED	Manually — failover	Emergency disable of unavailable SUSPENDED.

State change scenarios

Pile failure

When a pile fails, the cluster becomes unavailable. To resume cluster operation, the failed pile must be disabled by moving it to the DISCONNECTED state.

The administrator can issue a transition from PRIMARY/SYNCHRONIZED or SYNCHRONIZED/PRIMARY to either PRIMARY/DISCONNECTED or DISCONNECTED/PRIMARY. The command updates the storage group configuration and changes how data is written to those groups. Interconnect tears down sessions with all nodes of the pile in DISCONNECTED; data exchange sessions are not established (TCP connections for exchanging pile state metadata may remain active). Subsequent read and write operations run without the pile in DISCONNECTED. If the PRIMARY pile has changed, tablets are restarted on it.

The same kind of transition applies when the failed pile was in any state and the pile being designated PRIMARY is in one of the allowed states: PRIMARY, SYNCHRONIZED, or PROMOTED.

If the pile being designated PRIMARY was in DISCONNECTED, NOT_SYNCHRONIZED, or SUSPENDED, a normal transition is not possible, because that pile may not hold a complete, up-to-date replica of the data.

Pile recovery

After the nodes of the failed pile are back up, the pile must be reattached to the cluster by moving it to NOT_SYNCHRONIZED.

The administrator can issue a transition from PRIMARY/DISCONNECTED to PRIMARY/NOT_SYNCHRONIZED or from DISCONNECTED/PRIMARY to NOT_SYNCHRONIZED/PRIMARY. Configuration is exchanged between nodes; interconnect sessions are established only between nodes with the same configuration. The command starts storage group synchronization. When synchronization finishes, an automatic transition occurs from PRIMARY/NOT_SYNCHRONIZED to PRIMARY/SYNCHRONIZED or from NOT_SYNCHRONIZED/PRIMARY to SYNCHRONIZED/PRIMARY.

Planned PRIMARY pile switchover

To change the PRIMARY pile in a planned way, the pile that will become the new PRIMARY must be moved to the PROMOTED state.

The administrator can issue a transition from PRIMARY/SYNCHRONIZED to PRIMARY/PROMOTED or from SYNCHRONIZED/PRIMARY to PROMOTED/PRIMARY. The command does not change how data is written to storage groups but updates their configuration and initiates the change of PRIMARY pile with a smooth migration of tablets to the new PRIMARY. When the transition completes, the former PRIMARY becomes SYNCHRONIZED and PROMOTED becomes PRIMARY.

Planned pile disable

To disable a pile in a planned way, it must be moved to the SUSPENDED state.

The administrator can issue a transition from PRIMARY/SYNCHRONIZED to PRIMARY/SUSPENDED or from SYNCHRONIZED/PRIMARY to SUSPENDED/PRIMARY. A planned disable of the nodes of the pile moved to SUSPENDED is performed, and they are moved to DISCONNECTED. The system aims to minimize the impact of this process on cluster operation. After the pile has been moved to DISCONNECTED, its nodes can be shut down for maintenance.

Then perform normal pile recovery by moving it to NOT_SYNCHRONIZED.

Recovery from cluster split with incompatible configuration (split brain)

A situation can occur where the administrator has put the cluster in a state where pile A and pile B are isolated from each other, and then pile A was reconfigured so that it became PRIMARY and pile B became SYNCHRONIZED, while at the same time pile B was reconfigured so that it became PRIMARY and pile A became SYNCHRONIZED. This results in a cluster split with incompatible configuration (split-brain). In this state, each part of the cluster may remain operational.

To restore a single cluster, choose which pile will be wiped. Then stop all nodes of that pile, wait for them to stop completely, wipe all disks on all nodes, and bring the nodes of the pile being wiped back up.
Then perform normal pile recovery by moving it to `NOT_SYNCHRONIZED`.

Non-standard pile recovery

In complex situations (for example, after sequential pile failures), the following scenario can occur: first pile A failed, was moved to `DISCONNECTED`, and the cluster continued operating; then pile B failed irreversibly; after that, pile A was recovered. In such cases, the cluster can be recovered based on pile A.

If the cluster must be brought back up when only a pile in `DISCONNECTED`, `NOT_SYNCHRONIZED`, or `SUSPENDED` is available, the administrator can run a transition from `PRIMARY/DISCONNECTED` to `DISCONNECTED/PRIMARY` (or similarly for `NOT_SYNCHRONIZED` or `SUSPENDED`) with the special `force` parameter. This causes a cluster split with incompatible configuration. Depending on the actual state of data in the pile being moved to `PRIMARY`, the cluster may be restored to a correct or internally inconsistent state. Correct operation of such a cluster is not guaranteed.

If the cluster turns out to be operational, you can proceed to restore it to normal state. Before recovering the disabled pile, fully wipe data and metadata on all its nodes, then move the pile to `NOT_SYNCHRONIZED`.

Bridge mode implementation details

For more on how bridge mode works, see Bridge mode.

Data transfer

Transfer in YDB is an asynchronous mechanism for moving data from a topic to a table. Creating a transfer instance, modifying it, and deleting it is done using YQL. The transfer runs inside the database and works in the background. Transfer is used to solve the task of delivering data from a topic to a table.

In practice, it's often more convenient to write data not directly to a table, but to a topic, and then asynchronously rewrite it from the topic to the table. This approach allows for even load distribution and handling spikes, since writing to a message queue is a lighter operation. Depending on the number of messages written to the topic, the delay in data availability for reading from the table after adding to the topic can range from several seconds to several minutes.

The transfer reads messages from the specified topic, transforms them into a format suitable for writing to the table, and then writes them to the target table. If the table already contains a row with the specified primary key, the row will be updated. Data transformation is performed using a lambda function that takes a message as a parameter and returns a list of structures, each corresponding to a row to be added or replaced in the table. For example, if the table contains a column `example_column` of type `Int32`, the structure must include a named field `example_column` of the same type.
If the lambda function returns an empty list, no rows in the table will be changed. The lambda function is not allowed to access tables and other YDB objects.
The lambda function being used can be obtained from the description of the transfer instance.

Transfer consumes additional server resources, primarily CPU. CPU consumption depends on the complexity of transforming the data written to the topic.

Transfer can read data from topics located both in the database where it's created and in another YDB database or cluster. To read a topic from another database when creating a transfer, you must specify the connection parameters to that database. The target table must be located in the same database where the transfer is created.

Reading from a topic is performed using a consumer. The transfer automatically adds a consumer with a unique name to the topic for reading messages. When the transfer is deleted, the created consumer is automatically deleted. It's also possible to create a consumer manually and specify its name when creating the transfer. A manually created consumer is not automatically deleted when the transfer is deleted. The name of the automatically created consumer can be obtained from the description of the transfer instance.

If data needs to be transferred from one topic to multiple tables, a separate transfer must be created for each table. Similarly, data from multiple topics can be directed to one table, for which each topic must be associated with a separate transfer. If the consumer name is set manually, then when there are multiple transfers reading from one topic, each transfer must be assigned a unique consumer, otherwise the data will be processed by only one of them.

> **Note**
>
> When updating a row in the table, all row values are overwritten with the data from the structure returned by the lambda function. If the structure doesn't contain a named field corresponding to a table column, the value of that column will be set to `NULL`. Named fields that don't have a correspondence in the table are ignored.
>
> When attempting to write a `NULL` value to a `NOT NULL` table column, the transfer ends with a critical error.

Guarantees

- Table writes are guaranteed to follow the write order in the topic partition. It's recommended to group messages related to one table row into one topic partition.
- Writing to the table is performed using bulk upsert without atomicity guarantees. Data writing is split into several independent transactions, each affecting a single table partition, with parallel execution.

Transfer startup

If a transfer is created without explicitly specifying a consumer name, a new consumer will be added to the topic. In this case processing of topic messages will start from the first message in the topic.
If a transfer is created with a previously created consumer specified, processing of topic messages will start from the first message not processed by that consumer.

Required permissions for transfer operation

To create and execute a transfer, the user must have write permissions to the target table and read permissions from the source topic. If the topic is located in another YDB database and the consumer is created automatically, additional permission to modify the topic is required, which allows the transfer to automatically create the consumer and delete it when the transfer is deleted.

Diagnostics

Current transfer parameters, including the lambda function text, can be viewed in the YDB UI and in the description of the transfer instance.

Data processing speed and delays can be monitored using consumer metrics that are used for reading from the topic.

Temporary transfer suspension

Transfer operation can be temporarily paused and then resumed. After resuming transfer operation, messages following the last processed message in the topic will start being processed.

To pause the transfer, you should change the transfer status to `PAUSED`. To resume the transfer, change the status to `ACTIVE`.

> **Warning**
>
> The topic has a message retention time, after which messages are deleted. If the transfer is paused longer than the retention time, the messages are deleted and won't be processed when the transfer is resumed.
>
> To guarantee that unprocessed messages are not deleted, you should make the consumer important.

Error handling during transfer

Different types of errors can occur during the transfer process:

- **Temporary failures**. Transport errors, system overload, and other temporary problems. Requests will be retried until successful execution.

- **Critical errors**. Errors related to access rights, data schema, and other critical aspects. When such errors occur, the transfer will be stopped, and the error text will be displayed on the transfer page in the YDB UI user interface. The error text can also be obtained from the description of the transfer instance.

To resume a transfer operation, eliminate the cause of the error and execute the `ALTER TRANSFER` command. For example, if the error was in the lambda function, change the lambda function. If the error is not related to the transfer configuration, for example, missing read permissions, then after eliminating the cause of the error, the transfer must be restarted by temporarily stopping and then resuming its operation.

YDB for DevOps Engineers

This section of YDB documentation covers everything you need to know to work with YDB clusters.

Before getting started, it is recommended to familiarize yourself with YDB system requirements.

Main subsections:

- Concepts for DevOps engineers — additions to the general concepts section, relevant for DevOps engineers.
- YDB Cluster Configuration — YDB cluster configuration management.
- YDB Deployment Options — YDB cluster deployment options.
  - **Ansible**: for deployments on bare metal and virtual machines.
  - **Kubernetes**: for containerized deployments.
  - **Manual**: manual cluster deployment.
- Observability overview — tools for observing YDB clusters.
- Backup and recovery — backup and recovery of YDB clusters.

Concepts for DevOps engineers

This section supplements the general section Concepts YDB with theoretical materials that are primarily relevant for DevOps engineers.

Main topics:

- YDB System Requirements and Recommendations
- CPU settings for production
- Storage capacity planning
- YDB Versioning
- Maintenance without downtime
- SelfHeal

See also:

- YDB Deployment Options
- YDB Cluster Configuration
- Observability overview
- Backup and recovery

YDB System Requirements and Recommendations

This section provides recommendations for deploying YDB clusters that are relevant regardless of the chosen deployment method (Ansible, Kubernetes, or manual).

Hardware Configuration

The fault-tolerance requirements determine the necessary number of servers and disks. For more information, see YDB Cluster Topology.

Processor (CPU)

A YDB server can only run on x86-64 processors with AVX2 instruction support: Intel Haswell (4th generation) and later, AMD EPYC and later.

The ARM architecture is currently not supported for production YDB server deployments. For local development on Apple Silicon Macs, you can run YDB in Docker with x86_64 instruction emulation (Rosetta); see the Docker tab in YDB Quick Start.

> **Note**
>
> CPU power-saving modes (C-states, P-states, and the cpufreq scaling governor) can increase latency due to delays when leaving idle states.
>
> For production workloads, use the **performance** cpufreq governor (and equivalent BIOS settings).
>
> See CPU settings for production for details.

RAM

We recommend using error-correcting code (ECC) memory to protect against hardware failures.

Disk Subsystem

A YDB server can run on servers with any disk type (HDD/SSD/NVMe). However, we recommend using SSD/NVMe disks for better performance.

For YDB to work efficiently, we recommend using physical (not virtual) disks larger than 800 GB as block devices.

The minimum disk size is 80 GB, otherwise the YDB node won't be able to use the device. Correct and uninterrupted operation with minimum-size disks is not guaranteed. We recommend using such disks exclusively for informational purposes.

> **Warning**
>
> Configurations with disks less than 800 GB or any types of storage system virtualization cannot be used for production services or system performance testing.
>
> We don't recommend storing YDB data on disks shared with other processes (for example, the operating system).

YDB works with disk drives directly and does not use any filesystem to store data. Don't mount a file system or perform other operations with partitions used by YDB. Also, avoid sharing the YDB's block device with the operating system and different processes, which can lead to significant performance degradation.

Prefer to use physical local disk drives for YDB instead of virtual or network storage devices.

Remember that YDB uses some disk space for internal needs when planning disk capacity. For example, on a medium-sized cluster of 8 nodes, you can expect approximately 100 GB to be consumed for a static group on the whole cluster. On a large cluster with more than 1500 nodes, this will be about 200 GB. There are also 25.6 GB of logs on each Pdisk and a system area on each Pdisk. Its size depends on the size of the Pdisk, but is no less than 0.2 GB.

The disk is also used for spilling, a memory management mechanism that temporarily saves intermediate query execution results to disk when RAM is insufficient. This is important to consider when planning disk capacity. Detailed spilling configuration is described in the Spilling Configuration section.

Software Configuration

A YDB server can be run on servers with a Linux operating system, kernel 4.19 and higher, and libc 2.30. For example, Ubuntu 20.04, Debian 11, Fedora 34, or newer releases. For optimal performance, we recommend using more recent Linux kernel versions (6.6 or newer), as they include significant improvements in I/O subsystems, scheduling, and memory management that positively impact database workloads.

YDB uses the TCMalloc memory allocator. To make it efficient, enable Transparent Huge Pages and Memory overcommitment.

To improve disk and network I/O performance in a trusted environment, you can disable IOMMU by setting the Linux boot parameter `intel_iommu=off` or `amd_iommu=off`. In an untrusted environment, as well as under strict security requirements or with active virtualization use (for example, PCI passthrough and device isolation), disabling IOMMU is not recommended. In such cases, use `intel_iommu=on iommu=pt` or `amd_iommu=on iommu=pt`.

The environment can be considered trusted if only YDB and user-controlled applications are running on the server. Configurations that run third-party applications or virtual machines should be considered untrusted.

If the server has more than 32 CPU cores, to increase YDB performance, run each dynamic node in a separate taskset/cpuset of 10 to 32 cores. For example, with 128 CPU cores, an optimal setup is to run 4 dynamic nodes, each in its own 32-core taskset. Cores within one taskset/cpuset should belong to the same NUMA node.

MacOS and Windows operating systems are currently unsupported for running production YDB servers. However, running YDB in a Docker container on them is acceptable for development and functional testing.

CPU settings for production

Problem

CPU power-saving modes (such as Intel SpeedStep, AMD Cool'n'Quiet, C-states, and P-states) can hurt YDB performance for several reasons:

1. **Unstable CPU frequency** — YDB expects stable CPU throughput for predictable operation.
2. **Core affinity issues** — changing per-core frequency can break load balancing across threads.
3. **Mode-switching latency** — transitions between power-saving states add extra delays.
4. **Unpredictable throughput** — operations may run at different speeds depending on the current CPU mode.

Typical symptoms:

- Unstable query latency.
- Unexplained performance drops.
- Uneven load across cluster nodes.
- Erratic behavior under heavy load.

Solution

Recommended BIOS/UEFI settings

For YDB servers, configure the following BIOS/UEFI settings:

1. **CPU Power Management** — set to **Performance** or **Max Performance**.
2. **Intel Turbo Boost** — enable for maximum performance.
3. **C-states** — disable or limit to C1/C1E.
4. **P-states** — use a fixed maximum frequency.
5. **Intel SpeedStep / AMD Cool'n'Quiet** — disable.
6. **Package C-State Limit** — set to C0 or C1.

Operating system settings

On Linux, for deployments **not** using the Ansible role (which configures this automatically), run the following commands as root:

```
# Force the performance cpufreq governor
echo 'performance' | sudo tee /sys/devices/system/cpu/cpu*/cpufreq/scaling_governor >/dev/null

# Pin minimum frequency to maximum
echo $(cat /sys/devices/system/cpu/cpu0/cpufreq/cpuinfo_max_freq) | \
sudo tee /sys/devices/system/cpu/cpu*/cpufreq/scaling_min_freq >/dev/null

# Reduce PCIe ASPM power saving
echo 'performance' | sudo tee /sys/module/pcie_aspm/parameters/policy >/dev/null
```

Verifying current settings

Useful checks (after applying settings, the first command should output `performance` for every CPU core):

```
# Current governor
cat /sys/devices/system/cpu/cpu*/cpufreq/scaling_governor

# Available frequencies
cat /sys/devices/system/cpu/cpu0/cpufreq/scaling_available_frequencies

# C-states
cat /sys/devices/system/cpu/cpu0/cpuidle/state*/name
```

Rationale

As a high-performance distributed database, YDB needs stable and predictable CPU performance. Client-style power-saving modes are a poor fit for server workloads that require sustained availability and low latency.

A stable CPU frequency helps with:

- Predictable operation latency.
- Correct behavior of load-balancing mechanisms.
- Steady throughput under load.
- Minimal delays for transaction processing.

Exceptions

Compromises may be acceptable when:

- **Test environments** — energy efficiency matters more than raw performance.
- **Standby nodes** — not serving active traffic.
- **Low-load deployments** — power savings are a priority.

For busy production clusters, follow the recommendations above.

Storage capacity planning

Storage capacity planning is the determination of the required number of physical disks to store a given volume of data, taking into account replication and overhead, as well as the inverse problem: estimating the useful data volume for a given amount of equipment.

Distributed storage model

At the hardware level, the YDB cluster includes a number of physical disks (HDD / SSD / NVMe). Other components (CPU, RAM, network) are not covered in this article.

Clusters YDB are multitenant, and one physical disk can be shared by multiple consumers — isolated databases. Each physical disk has one component running on top of it for working with it — PDisk. The resources of a single PDisk (IOPS, read and write bandwidth, capacity) are divided into equal shares called slots. Slots are reserved for creating logical (virtual) disks VDisk. Each VDisk is assigned one slot.

To manage resources, the user has access to the storage group entity. A storage group is a set of several VDisks on different servers that provide fault tolerance similar to RAID. The number of VDisks in a storage group is determined by the cluster's operating mode:

Mode	Data centers	Racks in the data center (minimum)	VDisk in storage group	Redundancy factor `RF`
`block-4-2`	1	8* (10+ recommended)	8	1.5
`mirror-3-dc`	3	3* (recommended 4+)	9	3 (up to 6**)
`mirror-3of4`	1	8* (10+ recommended)	8	4
`none`	1	1	1	1

- Values of 8 for `block-4-2` and `mirror-3of4`, and 3 for `mirror-3-dc` are the minimum number of racks required to ensure cluster operability. With this configuration, the cluster starts and operates, but has no margin for self-healing: if a rack fails, its VDisks have nowhere to migrate within the failure model, and any additional failure may lead to data unavailability. Additional racks are needed by the SelfHeal mechanism to move VDisks from a failed rack to the remaining equipment while preserving fault tolerance guarantees. Therefore, for practical operation, it is recommended to use at least 10 racks for `block-4-2` and `mirror-3of4`, and at least 4 racks for `mirror-3-dc`. For more details on storage modes and fault tolerance guarantees, see YDB Cluster Topology.

** For the `mirror-3-dc` mode in normal operation `RF = 3` (3 data copies). When one data center is unavailable, writing goes to 4 copies (2 in each remaining data center), and the load on the remaining DCs doubles. If a DC may be unavailable for a long time (or data centers are taken out for maintenance one by one), `RF = 6` must be provisioned. If only short-term failures are acceptable (recovery is faster than the system can overwrite a significant portion of data), `RF = 3` is sufficient. For more details on storage modes and fault tolerance guarantees, see YDB Cluster Topology.

From the user's perspective, a storage group can be viewed as a fixed set of resources: IOPS, read and write bandwidth, capacity. Each database owns one or more storage groups. Each storage group belongs to one specific database.

User tables consist of tablets. Each tablet manages a fragment of user or system data. Tablets store data in groups; each tablet can write data to multiple storage groups, and many tablets write to each storage group.

Quantities used

Tablet Storage is the total volume of data stored by the database tablets.

Database Storage is the total size allocated by the database VDisks. This size includes:

- the actual data written by tablets;
- redundancy from replication or error-correcting encoding;
- service metadata and logs;
- allocated but not actually used space.

For existing databases, the Tablet Storage and Database Storage values can be viewed in the YDB UI on the database page under the Info → Storage tab.

The distributed storage implements complex deferred garbage collection, so at any given time, part of the occupied space is taken up by outdated data that has not yet been removed by the collector.

Other overheads can vary significantly depending on the nature of the stored data and the workload. For a rough estimate, `Overhead = 2` can be considered — this is the median value obtained empirically from a sample of production databases in `mirror-3-dc` mode. Depending on the mode, data structure, and workload nature, overheads may differ substantially. For a more accurate estimate, a pilot experiment is recommended.

These quantities can be approximately related by the ratio:

```
Database Storage = Tablet Storage × RF × Overhead
```

Estimating Required Equipment

The task boils down to selecting a cluster configuration such that the data reliably fits into storage groups and the cluster retains a working reserve of empty slots to ensure fault tolerance.

Input parameters:

- `Tablet Storage` — the useful volume of data to be placed.
- `DriveSize` — the capacity of the disks used.

Desired parameters (cluster configuration):

- `NumRacks` — the number of racks / servers (failure domains)
- `DisksPerRack` — the number of disks in each failure domain.

Reference values:

- `RF` — the redundancy factor, determined by the cluster operating mode (see table above).
- `Overhead` — storage overhead (see section above); for a rough estimate, assume `2`.
- `ExpectedSlotCount` — the number of slots per PDisk; determined by disk characteristics — IOPS and read/write bandwidth. Typical values: `8` for HDD, `16` for SSD/NVMe.
- `VDisksInGroup` — the number of VDisks in a storage group, determined by the cluster operating mode (see table above).

To estimate the required equipment, perform the following steps.

1. Estimate the required Database Storage volume:

   ```
   Database Storage = Tablet Storage × RF × Overhead
   ```

2. Determine the slot size:

   ```
   SlotSize = (DriveSize - 27.65 GB) / ExpectedSlotCount
   ```

   About 27.65 GB of PDisk capacity is reserved for system needs; the remaining space is evenly distributed among slots.

   This formula is applicable for disks with a capacity of 800 GB or more. Using smaller disks is not recommended if optimal performance is required. For more details on disk subsystem requirements, see the YDB System Requirements and Recommendations section.

3. Estimate the number of storage groups:

   ```
   TotalGroups = ceil( Database Storage / (SlotSize × VDisksInGroup × 0.85) )
   ```

   The coefficient 0.85 reflects the recommended VDisk fill percentage (VDisk Raw Usage = 85%).

   When monitoring, it is recommended to focus on the VDisk Slot Usage and Capacity Alert values. For existing groups, the VDisk Raw Usage, VDisk Slot Usage, and Capacity Alert values can be viewed in the YDB UI on the **Info** → **Storage** tab of the database page.

   The threshold at which a group is considered full corresponds to the values VDisk Slot Usage = 100%, Capacity Alert = LightYellow, VDisk Raw Usage ≈ 90% — whereas the formula above leaves a margin up to this threshold.

4. Estimate the number of occupied slots:

   ```
   UsedSlots = TotalGroups × VDisksInGroup
   ```

5. Obtain a lower estimate of the required number of physical disks (without considering the fault tolerance reserve):

   ```
   TotalPDisks ≥ ceil( UsedSlots / ExpectedSlotCount )
   ```

6. Select the cluster configuration — parameters `NumRacks`, `DisksPerRack`, and determine the minimum required total reserve of empty slots in the cluster:

   ```
   TotalSlots    = NumRacks × DisksPerRack × ExpectedSlotCount
   MinEmptySlots = ceil( MaxSlotsInRack + 0.027 × TotalSlots )
   ```

   The reserve of empty slots is necessary for the normal operation of the SelfHeal mechanism, which performs automatic reconfiguration of storage groups to replace failed or long-unavailable disks.

   The first term `MaxSlotsInRack` is the maximum number of slots in one failure domain. For a homogeneous cluster `MaxSlotsInRack = DisksPerRack × ExpectedSlotCount`, for a heterogeneous one — `MaxSlotsInRack = max_i(DisksPerRack_i × ExpectedSlotCount)`. This reserve is necessary so that when the most capacious domain fails, its VDisks can fit on the remaining equipment.

   The second term `0.027 × TotalSlots` is an empirically selected operational reserve (~1 disk per 37), covering unscheduled replacement of individual disks.

7. Evaluate the configuration's compliance with the minimum requirements:

   ```
   EmptySlots = TotalSlots - UsedSlots
   ```

   The condition `EmptySlots ≥ MinEmptySlots` must be met. If the condition is not met, increase `NumRacks` or `DisksPerRack` and return to step 6. See Calculation Example.

Estimating Useful Storage Capacity

The inverse problem is to estimate how much useful data can be placed on a given amount of equipment.

Suppose there are `TotalPDisks` physical disks with a capacity of `DriveSize` each. Then:

1. Total number of slots:

   ```
   TotalSlots = TotalPDisks × ExpectedSlotCount
   ```

2. Some slots remain empty for the SelfHeal reserve, the rest are available for storage groups:

   ```
   MinEmptySlots = ceil( MaxSlotsInRack + 0.027 × TotalSlots )
   UsableSlots = TotalSlots - MinEmptySlots
   ```

   Here `MaxSlotsInRack` is the maximum number of slots in one failure domain (rack or server): for a homogeneous cluster `DisksPerRack × ExpectedSlotCount`, for a heterogeneous one — `max_i(DisksPerRack_i × ExpectedSlotCount)`.

3. Number of storage groups:

```
TotalGroups = floor( UsableSlots / VDisksInGroup )
```

4. Useful capacity of the distributed storage considering the 85% fill threshold:

```
Database Storage = TotalGroups × VDisksInGroup × SlotSize × 0.85
```

5. Estimation of useful data volume:

```
Tablet Storage = Database Storage / (RF × Overhead)
```

Calculation Example

Suppose you need to place 100 TB of data (Tablet Storage) in a cluster with fault tolerance mode `block-4-2`, using SSD disks with a capacity of 3.2 TB.

Initial parameters:

Parameter	Value
Tablet Storage	100 000 GB
Mode	`block-4-2`
RF	1.5
Overhead	2
DriveSize	3 200 GB
ExpectedSlotCount	16
VDisksInGroup	8

Calculation:

1. Database Storage = 100 000 × 1.5 × 2 = **300 000 GB**
2. SlotSize = (3 200 − 27.65) / 16 ≈ **198.27 GB**
3. TotalGroups = ⌈300 000 / (198.27 × 8 × 0.85)⌉ = **223 storage groups**
4. UsedSlots = 223 × 8 = **1 784 slots**
5. TotalPDisks (without reserve) = ⌈1 784 / 16⌉ = **112 disks**
6. Next, we will select a specific cluster configuration, providing a reserve of empty slots to ensure fault tolerance. To do this, we will consider various equipment options and evaluate compliance with the minimum requirements, taking into account that for mode `block-4-2` at least 8 failure domains (servers or racks) are required, and for stable practical operation 10 or more are recommended:
   - Let's take 10 racks with 12 disks each. In one rack, 12 × 16 = 192 slots, TotalSlots = 1 920. MinEmptySlots = ⌈192 + 0.027 × 1 920⌉ = 244. EmptySlots = 1 920 − 1 784 = 136. 136 < 244 — the minimum requirements are not met. It is easy to verify that 10 racks with 14 disks each are sufficient: TotalSlots = 2 240, MinEmptySlots = ⌈224 + 0.027 × 2 240⌉ = 285, EmptySlots = 2 240 − 1 784 = 456 > 285.
   - You can choose a server as the failure domain and consider 30 servers with 4 disks each. In one failure domain, 4 × 16 = 64 slots, TotalSlots = 1 920. MinEmptySlots = ⌈64 + 0.027 × 1 920⌉ = 116. EmptySlots = 1 920 − 1 784 = 136 > 116 — the minimum requirements are met.

Thus, to store 100 TB of data in mode `block-4-2` on SSD disks with a capacity of 3.2 TB, you will need 10 racks with 14 disks each (140 disks) or 30 servers with 4 disks each (120 disks).

Reverse calculation:

Next, let's take the configuration from the previous example — 30 servers with 4 SSD disks each with a capacity of 3.2 TB, and estimate how much useful data will fit in such a cluster.

1. TotalSlots = 120 × 16 = **1,920 slots**
2. MinEmptySlots = ⌈MaxSlotsInRack + 0.027 × TotalSlots⌉ = ⌈4 × 16 + 0.027 × 1,920⌉ = ⌈115.84⌉ = **116 slots**
3. UsableSlots = 1,920 − 116 = **1,804 slots**
4. TotalGroups = ⌊1,804 / 8⌋ = **225 storage groups**
5. SlotSize = (3,200 − 27.65) / 16 ≈ **198.27 GB**
6. Database Storage = 225 × 8 × 198.27 × 0.85 ≈ **303,353 GB**
7. Tablet Storage = 303,353 / (1.5 × 2) ≈ **101,118 GB**

Thus, a cluster of 30 servers and 120 SSD disks of 3.2 TB each in `block-4-2` mode can store about 101.1 TB of data (Tablet Storage).

- YDB System Requirements and Recommendations
- Storage SelfHeal

YDB Versioning

YDB releases are named with a version that is a string consisting of several components. Depending on the context, some of the rightmost components may be omitted. The ordered list of components:

1. Last two digits of the release year
2. Major version number within the year
3. Minor version number within the major version
4. Patch number within the minor version
5. Release type

Major releases are usually identified by two components, for example, `24.3` is the third major release in 2024. Minor releases are identified by three components, for example, `24.3.14` is the fourteenth minor release within the third major version of 2024.

The list of available YDB releases is published on the download page. The YDB release policy is described in detail in the Manage YDB Releases article in the documentation section for YDB developers.

Version Compatibility

> **Note**
>
> Previously, the YDB server version consisted of three numbers (for example, `v24.3.3`), starting with major version `25.1`. The fourth number was added to specify the patch number (for example, `v25.1.1.3`). For more details about changes in version naming, see Manage YDB Releases.

You can update YDB to a new version in the following cases:

- If the major version numbers are the same, the minor versions can differ.
- If the major version numbers differ by one, first update to the latest available minor release of the current major version before updating to the next major version.

For example:

- `X.Y.*.* → X.Y.*.*` — update is possible, all minor versions within the same major version are compatible.
- `X.Y.Z.*` (last available `X.Y.*.*`) → `X.Y+1.*.*` - update is possible, major versions are sequential.
- `X.Y.*.*` → `X.Y+2.*.*` — update is not possible, major versions are non-sequential.
- `X.Y.*.* → X.Y-2.*.*` — update is not possible, major versions are non-sequential.

> **Warning**
>
> Also, you cannot downgrade YDB by more than two major versions because the older version might not support newer data formats stored on disk.

Version Compatibility Examples

- `v.25.1.3.2` → `v.25.1.5.5` - update is possible
- `v.25.1.5.5` → `v.25.2.3.1` - update is possible (where `v25.1.5.*` is the last available minor version in `v.25.1`)
- `v.25.1.4.1` → `v.25.2.3.1` - update is not possible, you must first update to the last minor version (`v.25.1.5.*`)
- `v.25.1.5.5` → `v.25.3.5.3` - update is not possible, you must first update to the next major version (`v.25.2.*.*`).

Formal Description of Possible Versions

```
<valid-version> ::= <version-core> "-" <version-type>
                  | <version-core>

<version-core> ::= <year> "." <major>
                 | <year> "." <major> "." <minor>
                 | <year> "." <major> "." <minor> "." <patch>

<year> ::= <digit> <digit>

<major> ::= <digits>

<minor> ::= <digits>

<patch> ::= <digits>

<version-type> ::= "testing"
                 | "stable"
                 | "lts"

<digit> ::= "0" | "1" | "2" | "3" | "4" | "5" | "6" | "7" | "8" | "9"

<digits> ::= <digit> | <digit> <digits>
```

Examples of Full Versions

- Testing version: `24.3.13.6-testing`
- Stable version: `24.3.14.2-stable`
- LTS version: `24.3.14.2-lts`

Maintenance without downtime

A YDB cluster periodically needs maintenance, such as upgrading its version or replacing broken disks. Maintenance can cause a cluster or its databases to become unavailable due to:

- Going beyond the expectations of the affected storage groups failure model.
- Going beyond the expectations of the State Storage failure model.
- Lack of computational resources due to stopping too many dynamic nodes.

To avoid such situations, YDB has a system tablet that monitors the state of the cluster - the *Cluster Management System (CMS)*. The CMS allows you to answer the question of whether a YDB node or host running YDB nodes can be safely taken out for maintenance. To do this, create a maintenance task in the CMS and specify in it to acquire exclusive locks on the nodes or hosts that will be involved in the maintenance. The cluster components on which the locks are acquired are considered unavailable from the CMS perspective and can be safely engaged in maintenance. The CMS will check the current state of the cluster and acquire locks only if the maintenance complies with the availability mode and unavailable node limits.

Failures during maintenance

During maintenance activities whose safety is guaranteed by the CMS, failures unrelated to those activities may occur in the cluster. If the failures threaten the cluster's availability, urgently aborting the maintenance can help mitigate the risk of cluster downtime.

Maintenance task

A *maintenance task* is a set of *actions* that the user asks the CMS to perform for safe maintenance.

Supported actions:

- Acquiring an exclusive lock on a cluster component (node, host, or disk).

Actions in a task are divided into groups. Actions from the same group are performed atomically. Currently, groups can consist of only one action.

If an action cannot be performed at the time of the request, the CMS informs you of the reason and time it is worth *refreshing* the task and sets the action status to *pending*. When the task is refreshed, the CMS attempts to perform the pending actions again.

Performed actions have a deadline after which they are considered *completed* and stop affecting the cluster. For example, an exclusive lock is released. An action can be completed early.

Protracted maintenance

If maintenance continues after the actions performed to make it safe have been completed, this is considered a failure in the cluster.

Completed actions are automatically removed from the task.

Availability mode

In a maintenance task, you need to specify the cluster's availability mode to comply with when checking whether actions can be performed. The following modes are supported:

- **Strong**: a mode that minimizes the risk of availability loss.
  - No more than one unavailable VDisk is allowed in each affected storage group.
  - No more than one unavailable State Storage ring is allowed.
- **Weak**: a mode that does not allow exceeding the failure model.
  - For affected storage groups with the block-4-2 scheme, no more than two unavailable VDisks are allowed.
  - For affected storage groups with the mirror-3-dc scheme, up to four unavailable VDisks are allowed, three of which must be in the same data center.
  - No more than `(nto_select - 1) / 2` unavailable State Storage rings are allowed.
- **Force**: a forced mode, the failure model is ignored. *Not recommended for use.*

Priority

You can specify the priority of a maintenance task. A lower value means a higher priority.

The task's actions cannot be performed until all conflicting actions from tasks with a higher priority are completed. Tasks with the same priority have no advantage over each other.

Unavailable node limits

In the CMS configuration, you can configure limits on the number of unavailable nodes for a database (tenant) or the cluster as a whole. Relative and absolute limits are supported.

By default, each database and the cluster as a whole are allowed to have no more than 13% unavailable nodes.

Checking algorithm

To check if the actions of a maintenance task can be performed, the CMS sequentially goes through each action group in the task and checks the action from the group:

- If the action's object is a host, the CMS checks whether the action can be performed with all nodes running on the host.
- If the action's object is a node, the CMS checks:
  - Whether there is a lock on the node.
  - Whether it's possible to lock the node according to the limits of unavailable nodes.
  - Whether it's possible to lock all VDisks of the node according to the availability mode.
  - Whether it's possible to lock the State Storage ring of the node according to the availability mode.
  - Whether it's possible to lock the node according to the limit of unavailable nodes on which cluster system tablets can run.
- If the action's object is a disk, the CMS checks:

- Whether there is a lock on the disk.
- Whether it's possible to lock all VDisks of the disk according to the availability mode.

The action can be performed if the checks are successful, and temporary locks are acquired on the checked nodes, hosts, or disks. The CMS then considers the next group of actions. Temporary locks help to understand whether the actions requested in different groups conflict with each other. Once the check is complete, the temporary locks are released.

Suspending maintenance

See the `disable_maintenance` flag in CMS configuration.

Bridge mode

If the cluster runs in bridge mode, unavailable-node limits and availability checks are applied independently for each pile.

Examples

The ydbops utility tool uses CMS for cluster maintenance without downtime. You can also use the CMS directly through the gRPC API.

Rolling restart

To perform a rolling restart of the entire cluster, you can use the command:

```
$ ydbops restart
```

The default availability mode is `strong`. This mode minimizes the risk of availability loss. Use the `--availability-mode` parameter to override the default availability mode.

The `ydbops` utility will automatically create a maintenance task to restart the entire cluster using the given availability mode. As it progresses, the `ydbops` will refresh the maintenance task and acquire exclusive locks on the nodes in the CMS until all nodes are restarted.

Take out a host for maintenance

To take out a host for maintenance, follow these steps:

1. Create a maintenance task using the command:

   ```
   $ ydbops maintenance create --hosts=<fqdn> --duration=<seconds>
   ```

   This command creates a maintenance task that will acquire an exclusive lock for `<seconds>` seconds on the host with the fully qualified domain name `<fqdn>`.
2. After creating a task, refresh its state until the lock is taken, using the command:

   ```
   $ ydbops maintenance refresh --task-id=<id>
   ```

   This command refreshes the task with identifier `<id>` and attempts to acquire the required lock. When a `PERFORMED` response is received, proceed to the next step.
3. Perform host maintenance while the lock is acquired.
4. After the maintenance is complete, release the lock using the command:

   ```
   $ ydbops maintenance complete --task-id=<id> --hosts=<fqdn>
   ```

SelfHeal

SelfHeal automatically restores the fault tolerance of five types of YDB cluster objects:

1. Dynamic storage groups.
2. The static storage group.
3. State Storage replicas.
4. Board replicas.
5. SchemeBoard replicas.

These objects are handled by three mechanisms: SelfHeal for dynamic storage groups, a separate SelfHeal for the static storage group, and a shared SelfHeal for State Storage, Board, and SchemeBoard. The documentation groups these mechanisms into two sections: Storage SelfHeal (dynamic and static groups) and Metadata Distribution SelfHeal (State Storage, Board, and SchemeBoard).

When a node or disk fails, SelfHeal waits for the failure to persist before starting relocation. If the node or disk recovers before the mechanism is triggered, relocation does not start. For disks, the default waiting time is about one hour.

> **Note**
>
> SelfHeal for dynamic storage groups does not depend on the configuration version. SelfHeal for the static group and metadata distribution subsystems is available only with configuration V2 and distributed configuration enabled. Automatic static group management must also be allowed with the `automatic_static_group_management` parameter.

For more details about the mechanisms:

- Storage SelfHeal
- Metadata Distribution SelfHeal

Storage SelfHeal

Storage SelfHeal is a mechanism for automatically restoring YDB storage fault tolerance.

For an overview of the mechanisms and their operating conditions, see SelfHeal. Recovery of State Storage, Board, and SchemeBoard replicas is described in Metadata Distribution SelfHeal.

How storage SelfHeal works

Sentinel, a component of CMS, continuously monitors the state of PDisks and nodes. If a fault persists long enough (about one hour by default), Sentinel initiates relocation of the affected VDisks to healthy hardware so that the failure model is satisfied again.

The Blob Storage Controller executes the command: data is replicated in the background. The relocation itself can take from minutes to a day, depending on the data volume and the hardware. Once the command has been accepted, CMS treats the task as issued; distributed storage is responsible for completing replication.

Storage SelfHeal is enabled by default for dynamic groups. On clusters with configuration V2, you can also enable static group SelfHeal. With configuration V1, static group SelfHeal cannot be enabled.

Enabling and disabling SelfHeal

You can enable and disable SelfHeal using the YDB DSTool utility.

To enable SelfHeal, run the command:

```
ydb-dstool -e <bs_endpoint> cluster set --enable-self-heal
```

`<bs_endpoint>` is the endpoint of any storage node in the cluster.

To disable SelfHeal, run the command:

```
ydb-dstool -e <bs_endpoint> cluster set --disable-self-heal
```

SelfHeal settings

You can configure SelfHeal in **Viewer** → **Cluster Management System** → **CmsConfigItems**.

To create settings for the first time, click **Create**. If you need to change existing settings, click the ✎ button.

The following settings are available:

Parameter	Description
Status	Enabling and disabling SelfHeal in CMS.
Dry run	Enabling and disabling the mode in which CMS does not change the BSC setting.
Config update interval (sec.)	Period of configuration updates from BSC.
Retry interval (sec.)	Period of retries for configuration updates.
State update interval (sec.)	Period of PDisk state updates.
Timeout (sec.)	Timeout for PDisk state updates.
Change status retries	Number of retries to change the PDisk status in BSC (`ACTIVE` , `FAULTY` , `BROKEN` , etc.).
Change status retry interval (sec.)	Delay between attempts to change the PDisk status in BSC. CMS monitors the disk state at an interval of **State update interval**. If the disk remains in one state for several **Status update interval** cycles, CMS changes its status in BSC. Next are the settings for the number of update cycles after which CMS will change the disk status. If the disk state is `Normal` , the disk is moved to status `ACTIVE` ; in other states, the disk is moved to status `FAULTY` . The value `0` disables status change for the state (as implemented for `Unknown` by default). For example, with default settings, if CMS observes disk state `Initial` for 5 `Status update interval` cycles of 60 seconds each, the disk status will be changed to `FAULTY` .
Default state limit	For states for which no setting is specified, this "default" value can be used. For unknown PDisk states for which there is no setting, this value is also used. This value is used if the value is not set for states `Initial` , `InitialFormatRead` , `InitialSysLogRead` , `InitialCommonLogRead` , `Normal` .
Initial	PDisk starts initialization. Transitions to `FAULTY` .
InitialFormatRead	PDisk reads its format record. Transitions to `FAULTY` .
InitialFormatReadError	PDisk received an error while reading its format record. Transitions to `FAULTY` .
InitialSysLogRead	PDisk reads the system log. Transitions to `FAULTY` .
InitialSysLogReadError	PDisk received an error while reading the system log. Transitions to `FAULTY` .
InitialSysLogParseError	PDisk received an error while parsing or checking the consistency of the system log. Transitions to `FAULTY` .
InitialCommonLogRead	PDisk reads the common log of VDisks. Transitions to `FAULTY` .
InitialCommonLogReadError	PDisk received an error while reading the common log of VDisks. Transitions to `FAULTY` .
InitialCommonLogParseError	PDisk received an error while parsing or checking the consistency of the common log. Transitions to `FAULTY` .

CommonLoggerInitError	PDisk received an error while initializing internal structures intended for writing to the common log. Transitions to `FAULTY`.
Normal	PDisk has completed initialization and is operating normally. Transition to `ACTIVE` will occur after the specified number of cycles (for example, if `Normal` persists for 5 minutes, the disk transitions to state `ACTIVE`).
OpenFileError	PDisk received an error while opening the disk file. Transitions to `FAULTY`.
Missing	The node responds, but this PDisk is not in its list. Transitions to `FAULTY`.
Timeout	The node did not respond within the allotted timeout. Transitions to `FAULTY`.
NodeDisconnected	Node disconnection. Transitions to `FAULTY`.
Stopped	PDisk is stopped. Transitions to `FAULTY`.
Unknown	Unexpected response, for example, response `TEvUndelivered` to a state request. Transitions to `FAULTY`.

Working with donor disks

A donor disk is a previous VDisk after data migration that continues to store its data and only responds to read requests from the new VDisk. When migrating with donor disks enabled, previous VDisks continue to function until the data is fully migrated to new disks. To prevent data loss during VDisk migration, enable the use of donor disks:

```
ydb-dstool -e <bs_endpoint> cluster set --enable-donor-mode
```

To disable donor disks, enter the command:

```
ydb-dstool -e <bs_endpoint> cluster set --disable-donor-mode
```

Metadata Distribution SelfHeal

Metadata Distribution SelfHeal automatically manages the replica configurations of State Storage, Board, and SchemeBoard.

The configuration uses the historical name `state_storage_self_heal_config` for this mechanism. It applies to all three subsystems.

> **Warning**
>
> These instructions apply only to YDB clusters with **V2 configuration** and **distributed configuration**. On clusters with **V1 configuration**, these steps and commands (including obtaining configuration via `ydb admin cluster config fetch`) are unavailable or will not produce the expected result. Alternatives for V1 are not provided here — see Migration to V2 configuration.

The mechanism detects node failures and, if the nodes cannot recover quickly, relocates the affected replicas to other nodes. As the cluster grows, it can also automatically increase replica counts based on the configuration and available nodes.

The Sentinel component of the CMS cluster management system triggers the mechanism.

Enabling and disabling Metadata Distribution SelfHeal

You can enable and disable Metadata Distribution SelfHeal by changing the configuration:

1. Get the current cluster configuration using the ydb admin cluster config fetch command:

   ```
   ydb [global options...] admin cluster config fetch > config.yaml
   ```

2. Modify the configuration file `config.yaml` by changing the value of parameter `state_storage_self_heal_config.enable` to `true` or `false`:

   ```
   config:
       self_management_config:
           enabled: true # Enabling distributed configuration
       cms_config:
           sentinel_config:
               enable: true # Enabling Sentinel
               state_storage_self_heal_config:
                   enable: true # Enabling Metadata Distribution SelfHeal
   ```

   > **Note**
   >
   > For the mechanism to work, both CMS Sentinel and distributed configuration must be activated. Make sure they are enabled.
   >
   > See also: Migration to V2 configuration and enabling distributed configuration.

   When the `state_storage_self_heal_config.enable` parameter is set to `true`, the mechanism for maintaining the operability and fault tolerance of State Storage, Board, and SchemeBoard is enabled.

3. Update the cluster configuration taking into account the changes made using ydb admin cluster config replace:

   ```
   ydb [global options...] admin cluster config replace -f config.yaml
   ```

Managing automatic configuration changes

In addition to globally enabling or disabling Metadata Distribution SelfHeal with the `state_storage_self_heal_config.enable` parameter, you can use the `self_management_config` section of `config.yaml` to manage automatic configuration changes separately for each metadata distribution subsystem and restrict the nodes to which SelfHeal can relocate replicas.

```
config:
    self_management_config:
        enabled: true
        automatic_state_storage_management: true
        automatic_state_storage_board_management: true
        automatic_scheme_board_management: true
        state_storage_self_heal_allowed_nodes: [1, 2, 3, 4, 5, 6, 7, 8]
        state_storage_board_self_heal_allowed_nodes: [1, 2, 3, 4, 5, 6, 7, 8]
        scheme_board_self_heal_allowed_nodes: [1, 2, 3, 4, 5, 6, 7, 8]
```

Parameter	Default value	Description
`automatic_state_storage_management`	`true`	Allows SelfHeal to automatically change the State Storage configuration. When set to `false`, SelfHeal does not change the current State Storage configuration.
`automatic_state_storage_board_management`	`true`	Same for Board: allows or disallows SelfHeal to automatically change its configuration.
`automatic_scheme_board_management`	`true`	Same for SchemeBoard: allows or disallows SelfHeal to automatically change its configuration.
`state_storage_self_heal_allowed_nodes`	`[]` (no restrictions)	List of node IDs to which SelfHeal can move or on which it can add State Storage replicas. An empty list means there are no restrictions and any cluster nodes can be used.

`state_storage_board_self_heal_allowed_nodes`	`[]` (no restrictions)	Same for Board replicas.
`scheme_board_self_heal_allowed_nodes`	`[]` (no restrictions)	Same for SchemeBoard replicas.

Additional Metadata Distribution SelfHeal parameters

In the `cms_config.sentinel_config.state_storage_self_heal_config` section of the `config.yaml` configuration file, you can configure additional Metadata Distribution SelfHeal parameters. They affect how quickly the mechanism responds to changes and how many metadata distribution subsystem replicas are created. The example below shows all parameters with their default values:

```
config:
    cms_config:
        sentinel_config:
            enable: true
            state_storage_self_heal_config:
                enable: true
                wait_for_config_step: 60000000
                relax_time: 600000000
                pileup_replicas: false
                override_replicas_in_ring_count: 0
                override_rings_count: 0
                replicas_specific_volume: 200
```

Parameter	Default value	Description
`wait_for_config_step`	`60000000` (microseconds, 60 seconds)	Wait time between intermediate steps of applying a new configuration of the metadata distribution subsystems (adding/removing ring groups, clearing the `WriteOnly` flag, see Configuring State Storage). The value is specified in microseconds.
`relax_time`	`600000000` (microseconds, 600 seconds)	Minimum interval between two consecutive Metadata Distribution SelfHeal activations. Until the specified time has elapsed since the previous activation, a repeated configuration change is not started, even if faulty nodes are detected. The value is specified in microseconds.
`pileup_replicas`	`false`	Allows placing replicas of different subsystems (State Storage, Board, SchemeBoard) on the same set of nodes. When set to `false`, SelfHeal tries to use different nodes for replicas of different subsystems where possible; when set to `true`, nodes already occupied by one subsystem can be reused for the others.
`override_replicas_in_ring_count`	`0` (calculated automatically)	Forcibly sets the number of replicas in one ring. If the value is `0`, the number of replicas in the ring is calculated automatically based on `replicas_specific_volume` and the number of available nodes.
`override_rings_count`	`0` (calculated automatically)	Forcibly sets the number of rings in the configuration. If the value is `0`, the number of rings is calculated automatically based on the number of available nodes and the cluster topology.
`replicas_specific_volume`	`200`	Determines how many cluster nodes should correspond to one additional replica in the ring: one additional replica is added for every `replicas_specific_volume` nodes in the cluster. Used in automatic calculation of the number of replicas if `override_replicas_in_ring_count` is not set (equals `0`).

Checking the result

You can check that the changes have been applied in the `CMS` section of the cluster YDB UI (available on port 8765): go to the `Sentinel` tab to view the status of Sentinel and Metadata Distribution SelfHeal.

YDB Cluster Configuration

This section presents materials on YDB cluster configuration management. You will learn about two versions of the configuration mechanism (V1 and V2), their differences, and how to check which version is used in your cluster.

Main subsections:

- Configuration V1 — section about configuration V1, used in YDB.
- Configuration V2 — section about configuration V2, experimental functionality for YDB versions 25.1 and above.
- Cluster Configuration Migration — migration between configurations V1 and V2.
- Checking Configuration Version — checking which configuration version is used on the cluster.
- Comparing YDB Cluster Configurations: V1 and V2 — detailed comparison of configurations V1 and V2.

Tip

New YDB clusters are recommended to be deployed using configuration V2. If a cluster was deployed using configuration V1, it will still use it after updating to YDB version 25.1 or higher. After such an update, it is recommended to plan and perform migration to V2, because support for V1 will be discontinued in future versions of YDB. For the instructions on how to determine the configuration version of the cluster, see Checking Configuration Version.

Configuration V1

This section of the YDB documentation describes Configuration V1, which is the main way to configure YDB clusters deployed using YDB.

Configuration V1 is a two-level YDB cluster configuration system consisting of static configuration and dynamic configuration:

1. **Static configuration**: a YAML format file that is located locally on each static node and used when starting the `ydbd server` process. This configuration contains, among other things, static group and State Storage settings.
2. **Dynamic configuration**: a YAML format file that is an extended version of static configuration. It is loaded via CLI and reliably stored in the Console tablet, which then distributes the configuration to all dynamic cluster nodes. Using dynamic configuration is optional.

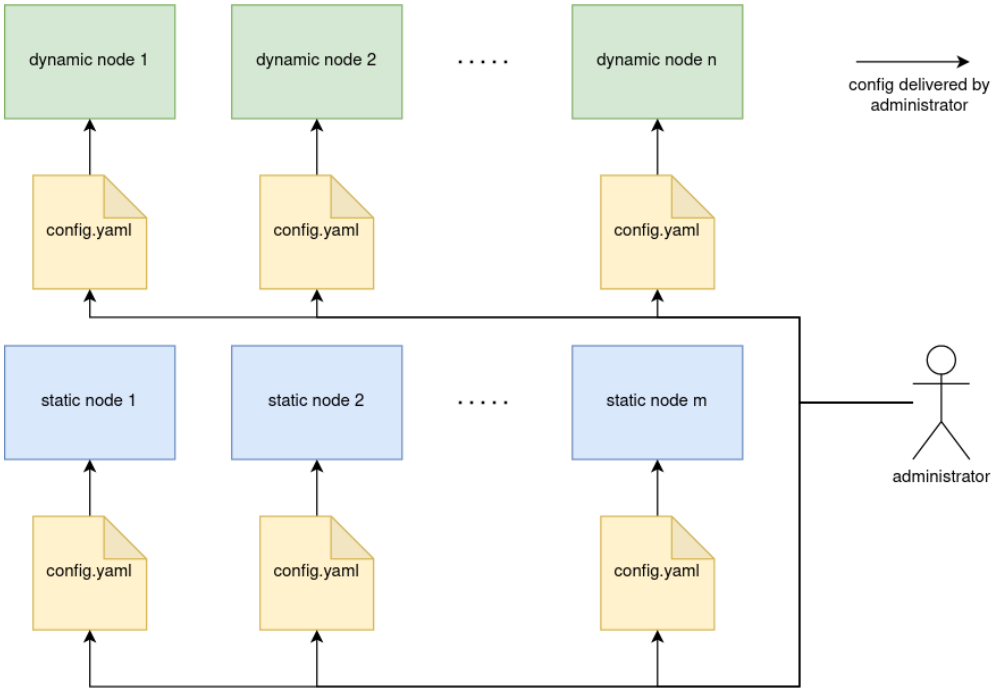
You can learn more about Configuration V1 in the Configuration V1 Overview section.

Starting from version v25.1, YDB supports Configuration V2, a unified approach to configuration in a single file format. When using Configuration V2, automatic configuration of static group and State Storage becomes possible. When deploying new clusters on YDB version v25.1 and above, it is recommended to use Configuration V2.

Main materials:

- Configuration V1 Overview
- YDB Cluster Configuration
- Dynamic Cluster Configuration
- Volatile Configurations
- Cluster Configuration Domain-Specific Language (DSL)
- Changing Configurations via CMS
- Changing Actor System Configuration
- Expanding a Cluster
- Configuring metadata distribution subsystems State Storage, Board, and Scheme Board
- State Storage Move
- Static Group Move
- Replacing Node FQDN
- Database Node Authentication and Authorization

Configuration V1 Overview



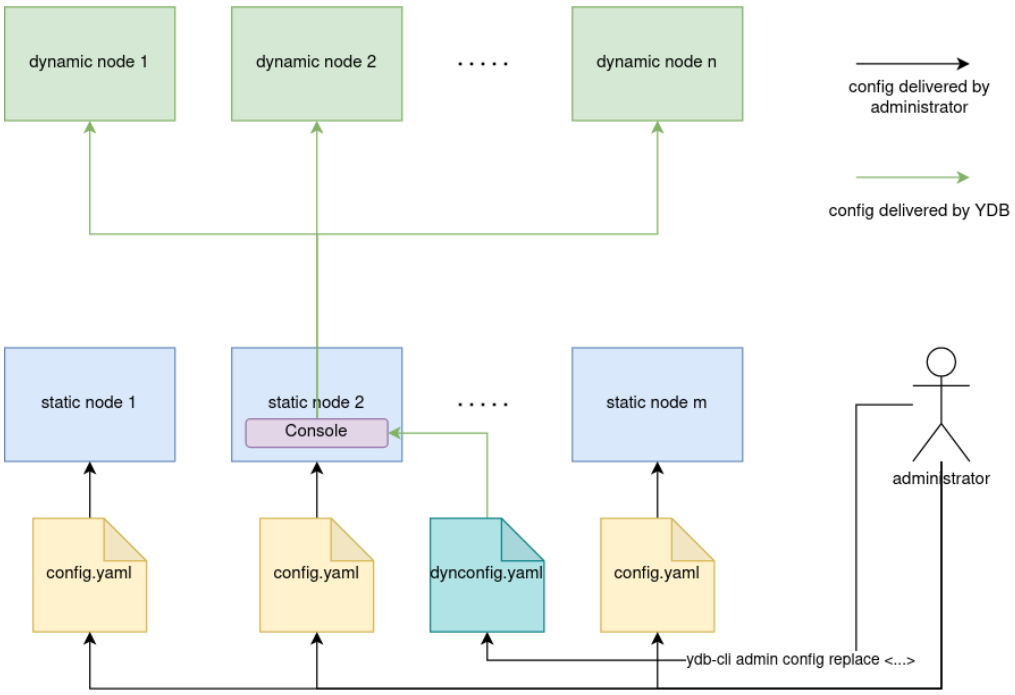
To start a YDB node, configuration is required. There are two types of configuration:

- **Static** — a YAML format file stored on the node's local disk.
- **Dynamic** — a YAML format document stored in the YDB configuration storage.

Static cluster nodes use static configuration. Dynamic nodes can use static configuration, dynamic configuration, or their combination.

Static Configuration

Static configuration is a YAML file stored on cluster nodes. This file lists all system settings. The path to the file is passed to the `ydbd` process at startup through a command line parameter. Distribution of static configuration across the cluster and maintaining it in a consistent state on all nodes is the responsibility of the cluster administrator. Details on using static configuration can be found in the YDB Cluster Configuration section. This configuration is **required** to start static nodes.



Basic Usage Scenario

1. Copy standard configuration from GitHub.
2. Modify the configuration according to your requirements.
3. Place identical configuration files on all cluster nodes.
4. Start all cluster nodes, explicitly specifying the path to the configuration file using the `--yaml-config` command line argument.

Dynamic Configuration

Dynamic configuration is a YAML document reliably stored in the cluster in the Console tablet. Unlike static configuration, it is sufficient to load it into the cluster, as YDB will be responsible for its distribution and maintaining it in a consistent state. At the same time, dynamic configuration using selectors allows handling complex scenarios while remaining within a single configuration file. A description of dynamic configuration is presented in the Dynamic Cluster Configuration section.

Basic Usage Scenario

1. Copy standard configuration from GitHub.
2. Modify the configuration according to your requirements.
3. Place identical configuration files on all static cluster nodes.
4. Start all static cluster nodes, explicitly specifying the path to the configuration file using the `--yaml-config` command line argument.
5. Supplement the configuration file to dynamic configuration format.
6. Load the resulting configuration to the cluster using `ydb admin config replace -f dynconfig.yaml`.

YDB Cluster Configuration

The cluster configuration is specified in the YAML file passed in the `--yaml-config` parameter when the cluster nodes are run. This article provides an overview of the main configuration sections and links to detailed documentation for each section.

Each configuration section serves a specific purpose in defining how the YDB cluster operates, from hardware resource allocation to security settings and feature flags. The configuration is organized into logical groups that correspond to different aspects of cluster management and operation.

Configuration Sections

The following top-level configuration sections are available, listed in alphabetical order:

Section	Required	Description
actor_system_config	Yes	CPU resource allocation across actor system pools
auth_config	No	Authentication and authorization settings
aws_client_config	No	AWS client default settings
blob_storage_config	No	Static cluster group configuration for system tablets
bridge_config	No	Cluster piles for bridge mode
client_certificate_authorization	No	Client certificate authentication
cms_config	No	Cluster Management System configuration
domains_config	No	Cluster domain configuration including Blob Storage and State Storage
feature_flags	No	Feature flags to enable or disable specific YDB features
healthcheck_config	No	Health check service thresholds and timeout settings
hive_config	No	Hive component configuration for tablet management
host_configs	No	Typical host configurations for cluster nodes
hosts	Yes	Static cluster nodes configuration
immediate_controls_config	No	Configuration of dynamic cluster settings
kafka_proxy_config	No	Kafka Proxy configuration
log_config	No	Logging configuration and parameters
memory_controller_config	No	Memory allocation and limits for database components
node_broker_config	No	Stable node names configuration
query_service_config	No	Federated query connector configuration
resource_broker_config	No	Resource broker for controlling CPU and memory consumption
security_config	No	Security configuration settings
table_service_config	No	Query processing configuration
tli_config	No	Transaction lock invalidation (TLI) diagnostics parameters
tls	No	TLS configuration for secure connections

Practical Guidelines

While this documentation section focuses on complete reference documentation for available settings, practical recommendations on what to tune and when can be found in the following places:

- As part of the initial YDB cluster deployment:
  - Ansible
  - Kubernetes
  - Manual
- As part of troubleshooting
- As part of security hardening

Sample Cluster Configurations

You can find model cluster configurations for deployment in the repository. Check them out before deploying a cluster.

Dynamic Cluster Configuration

Dynamic configuration allows running dynamic nodes by configuring them centrally, without the need to manually distribute files across nodes. YDB acts as a configuration management system, providing tools for reliable storage, versioning, and configuration delivery, as well as a DSL (Domain Specific Language) for overriding parts of it for specific node groups. The configuration is a YAML document. It is an extended version of static configuration:

- configuration description is moved to the `config` field
- a `metadata` field is added, necessary for validation and versioning
- `allowed_labels` and `selector_config` fields are added for granular setting overrides

This configuration is loaded into the cluster, where it is reliably stored and delivered to each dynamic node at startup. Some settings are updated on the fly, without restarting nodes. Using dynamic configuration, you can centrally solve the following tasks:

- switch component logging settings for both the entire cluster and individual databases or node groups
- enable experimental functionality (feature flags) on individual databases
- change actor system settings on a specific database, individual node, or group of nodes

Preparing to Use Dynamic Configuration

Before starting to use dynamic configuration in the cluster, it is necessary to perform preparatory work:

1. Enable database node authentication and authorization in the cluster.
2. If configuration management via CMS was previously used in the cluster, export existing settings in YAML format. To do this, run the following command:

   ```
   ./ydbd -s grpcs://<node1.ydb.tech>:2135 --ca-file ca.crt --token-file ydbd-token \
        admin console configs dump-yaml > dynconfig.yaml
   ```

   You must first obtain an authentication token using the `ydb auth get-token` command, similar to the cluster initialization procedure.
3. Create the initial dynamic configuration file:
   - If settings were previously made in CMS (exported in the previous step), use the resulting file as a basis and:
     - add a `metadata` section following the pattern from the configuration example
     - add the `yaml_config_enabled: true` parameter to the `config` section
   - If no settings were previously made via CMS, use the minimal content of the dynamic configuration file.
   - If the cluster uses actor system interconnect encryption, add the corresponding TLS settings for interconnect to the `config` section.
4. Apply the created dynamic configuration file to the cluster:

   ```
   # Apply configuration file dynconfig.yaml to the cluster
   ydb admin config replace -f dynconfig.yaml
   ```

> **Note**
>
> After enabling dynamic configuration support in the YDB cluster, the legacy configuration management function via CMS will become unavailable.

Configuration examples

Example of minimal dynamic configuration for a single-datacenter cluster:

```
# Configuration metadata.
# Field managed by server
metadata:
  # Cluster name from cluster_uuid parameter set during cluster installation, or "" if parameter is not set
  cluster: ""
  # Configuration file identifier, always increases by 1 and starts from 0.
  # Automatically increased when loading new configuration to server.
  version: 0
# Main cluster configuration, all values from it are applied by default until overridden by selectors.
# Content is similar to static cluster configuration
config:
  # must always be set to true to use yaml configuration
  yaml_config_enabled: true
  # actor system configuration - since by default this section is used
  # only by DB nodes, configuration is set specifically for them
  actor_system_config:
    # automatic configuration selection for node based on type and number of available cores
    use_auto_config: true
    # HYBRID || COMPUTE || STORAGE — node type, always COMPUTE for database nodes
    node_type: COMPUTE
    # number of allocated cores
    cpu_count: 14
allowed_labels: {}
selector_config: []
```

Configuration parameters are described in more detail on the YDB Cluster Configuration page.

The initially installed cluster dynamic configuration gets version number 1. When applying a new configuration, the version of the stored configuration is compared with that specified in the YAML document and automatically increased by one.

Example of more complex dynamic configuration with typical global parameters and special parameters for one of the databases:

```
---
metadata:
  kind: MainConfig
  cluster: ""
  version: 1
config:
  yaml_config_enabled: true
  table_profiles_config:
    table_profiles:
    - name: default
      compaction_policy: default
      execution_policy: default
      partitioning_policy: default
      storage_policy: default
      replication_policy: default
      caching_policy: default
    compaction_policies:
    - name: default
    execution_policies:
    - name: default
    partitioning_policies:
    - name: default
      auto_split: true
      auto_merge: true
      size_to_split: 2147483648
    storage_policies:
    - name: default
      column_families:
      - storage_config:
          sys_log:
            preferred_pool_kind: ssd
          log:
            preferred_pool_kind: ssd
          data:
            preferred_pool_kind: ssd
    replication_policies:
    - name: default
    caching_policies:
    - name: default
  interconnect_config:
    encryption_mode: REQUIRED
    path_to_certificate_file: "/opt/ydb/certs/node.crt"
    path_to_private_key_file: "/opt/ydb/certs/node.key"
    path_to_ca_file: "/opt/ydb/certs/ca.crt"
allowed_labels:
  node_id:
    type: string
  host:
    type: string
  tenant:
    type: string
selector_config:
- description: Custom settings for testdb
  selector:
    tenant: /cluster1/testdb
  config:
    shared_cache_config:
      memory_limit: 34359738368
    feature_flags: !inherit
      enable_views: true
    actor_system_config:
      use_auto_config: true
      node_type: COMPUTE
      cpu_count: 14
```

Updating Dynamic Configuration

```
# Get cluster configuration
ydb admin config fetch > dynconfig.yaml
# Edit using any text editor
vim dynconfig.yaml
# Apply configuration file dynconfig.yaml to cluster
ydb admin config replace -f dynconfig.yaml
```

Additional configuration capabilities are described on the selectors and volatile configuration pages.
All commands for working with configuration are described in the Fetch the cluster configuration section.

Implementation

Configuration Update from Administrator Perspective

1. The configuration file is loaded by the user using a grpc call or YDB CLI into the cluster.
2. The file is checked for validity, basic constraints are checked, version correctness, cluster name correctness, correctness of configurations obtained after DSL transformation.
3. The configuration version in the file is increased by one.
4. The file is reliably stored in the cluster by the Console tablet.
5. File updates are distributed across cluster nodes.

Configuration Update from Cluster Node Perspective

1. Each node requests full configuration at startup.
2. Upon receiving configuration, the node generates final configuration for its set of labels.
3. The node subscribes to configuration updates by registering with the Console tablet.
4. In case of configuration update, the local service receives it and transforms it for the node's labels.
5. All local services subscribed to updates receive the updated configuration.

Points 1,2 are performed only for dynamic cluster nodes.

Configuration Versioning

This mechanism allows avoiding concurrent configuration modification and making its update idempotent. When receiving a configuration modification request, the server compares the version of the received modification with the saved one. If the version is one less, then configurations are compared — if they are identical, it means the user is trying to load the configuration again, the user gets OK, and the configuration on the cluster is not updated. If the version equals the current one on the cluster, then the configuration is replaced with the new one, while the version field is increased by one. In all other cases, the user gets an error.

Dynamically Updatable Settings

Part of the system settings are updated without restarting nodes. To change them, it is sufficient to load a new configuration and wait for its distribution across the cluster.

List of dynamically updatable settings:

- `immediate_controls_config`
- `log_config`
- `memory_controller_config`
- `monitoring_config`
- `table_service_config`
- `tracing_config.external_throttling`
- `tracing_config.sampling`

The list may be expanded in the future.

Limitations

- Using more than 30 different labels in selectors can lead to delays of tens of seconds during configuration validation, as YDB needs to check the validity of each possible final configuration. At the same time, the number of values of one label has much less impact.
- Using large files (more than 500KiB for a 1000-node cluster) configuration can lead to increased network traffic in the cluster when updating configuration. Traffic volume is directly proportional to the number of nodes and configuration volume.

Volatile Configurations

Volatile configurations are a special type of configurations that complement dynamic ones and are not persistent. That is, these configurations are reset when the Console tablet moves or restarts, as well as when the main configuration is updated.

Main usage scenarios:

- temporary configuration changes for debugging or testing;
- trial enabling of potentially dangerous settings. In case of cluster crash or restart, these settings will be automatically disabled.

These configurations are added to the end of the selector set, the description syntax is identical to selector syntax.

```
# Get all volatile configurations loaded on the cluster
ydb admin volatile-config fetch --all --output-directory <dir>
# Get volatile configuration with id=1
ydb admin volatile-config fetch --id 1
# Apply volatile configuration volatile.yaml to the cluster
ydb admin volatile-config add -f volatile.yaml
# Remove volatile configurations with id=1 and id=3 on the cluster
ydb admin volatile-config drop --id 1 --id 3
# Remove all volatile configurations on the cluster
ydb admin volatile-config drop --all
```

Example of Working with Volatile Configuration

Temporarily enabling `blobstorage` component logging settings to `DEBUG` on node `host1.example.com`:

```
# Request current metadata to form correct volatile configuration header
$ ydb admin config fetch --all
---
kind: MainConfig
cluster: "example-cluster-name"
version: 2
config:
  # ...
---
kind: VolatileConfig
cluster: "example-cluster-name"
version: 2
id: 1
selector_config:
  # ...
# Load configuration with version 2, cluster name example-cluster-name and identifier 2
$ ydb admin volatile-config add -f - <<<EOF
metadata:
  kind: VolatileConfig
  cluster: "example-cluster-name"
  version: 2
  id: 2
selector_config:
- description: Set blobstorage logging level to DEBUG
  selector:
    node_host: host1.example.com
  config:
    log_config: !inherit
      entry: !inherit_key:component
      - component: BLOBSTORAGE
        level: 8
EOF
# ...
# log analysis
# ...
# Remove configuration
$ ydb admin volatile-config drop --id 2
```

Cluster Configuration Domain-Specific Language (DSL)

Cluster Configuration DSL

Selectors

The main entity of the DSL is **selectors**. They allow the overriding of parts of the configuration or the entire configuration for specific nodes or groups of nodes. For example, they can be used to enable experimental functionality for nodes of a particular database. Each selector is an array of overrides and extensions to the main configuration. Each selector has a `description` field, which can be used to store an arbitrary description string. The `selector` field represents a set of rules that determine whether the selector should be applied to a specific node based on a set of labels. The `config` field describes the override rules. Selectors are applied in the order they are defined.

Labels

Labels are special tags used to mark nodes or groups of nodes. Each node has a set of automatically assigned labels:

- `node_id` — the internal identifier of the node in the system
- `node_host` — the node's `hostname` obtained at startup
- `tenant` — the database served by this node
- `dynamic` — whether this node is dynamic (true/false)

Additionally, the user can explicitly define any additional labels when starting the `ydbd` process on the node using command-line arguments, such as `--label example=test`.

Example of Using Selectors

The example below defines the actor system's general configuration and the tenant `large_tenant` configuration. By default, with such a configuration, the actor system assumes that each node has 4 cores, while nodes of the `large_tenant` have 16 cores. The actor system's node type is overridden to `COMPUTE`.

```
metadata:
  cluster: ""
  version: 8
config:
  actor_system_config:
    use_auto_config: true
    node_type: STORAGE
    cpu_count: 4

# This section is used as a hint when generating possible configurations using the resolve command
allowed_labels:
  dynamic:
    type: string

selector_config:
- description: large_tenant has bigger nodes with 16 cpu # arbitrary description string
  selector: # selector for all nodes of the tenant large_tenant
    tenant: large_tenant
  config:
    actor_system_config: !inherit # reuse the original actor_system_config, the semantics of !inherit are des
cribed in the section below
      # in this case, !inherit allows managing the actor_system_config.use_auto_config parameter for the enti
re cluster by changing only the base setting
      cpu_count: 16
      node_type: COMPUTE
```

Permissive Labels

A mapping in which you can set the allowable values for labels. This section is used as a hint when generating possible configurations using the resolve command. Values are not validated at node startup.

There are two types of labels available:

- string;
- enum.

string

It can take any value or be unset.

Example:

```
dynamic:
  type: string
host_name:
  type: string
```

enum

It can take values from the `values` list or be unset.

Example:

```
flavour:
  type: enum
  values:
    ? small
    ? medium
    ? big
```

Selector Behavior

Selectors represent a simple predicate language. Selectors for each label are combined using the **AND** condition.

Simple Selector

The following selector will select nodes where the `label1` is equal to `value1` **and** the `label2` is equal to `value2`:

```
selector:
  label1: value1
  label2: value2
```

The following selector will select **ALL** nodes in the cluster, as no conditions are specified:

```
selector: {}
```

In

This operator allows for selecting nodes with label values from a list.

The following selector will select all nodes where `label1` is equal to `value1` **or** `value2`:

```
selector:
  label1:
    in:
    - value1
    - value2
```

NotIn

This operator allows selecting nodes where the chosen label does not match any value from a list.

The following selector will select all nodes where `label1` is equal to `value1` **and** `label2` is not equal to `value2` **and** `value3`:

```
selector:
  label1: value1
  label2:
    not_in:
    - value2
    - value3
```

Additional YAML Tags

Tags are necessary for partial or complete reuse of configurations from previous selectors. They allow you to merge, extend, delete, and override parameters set in previous selectors and the main configuration.

!inherit

Scope: YAML mapping
Action: similar to the merge tag in YAML, copy all child elements from the parent mapping and merge with the current ones, overwriting them.
Example:

Original configuration	Override	Resulting configuration

`config:`
`  some_config:`
`  first_entry: 1`
`  second_entry: 2`
`  third_entry: 3`
	`config:`
	`  some_config: !inherit`
	`  second_entry: 100`
		`config:`
		`  some_config:`
		`  first_entry: 1`
		`  second_entry: 100`
		`  third_entry: 3`

!inherit:<key>

Scope: YAML sequence
Action: copy elements from the parent array and overwrite, treating the `key` object in the elements as the key, appending new keys to the end.
Example:

Original configuration	Override	Resulting configuration

```
config:
  some_config:
    array:
    - abc: 2
      value: 10
    - abc: 1
      value: 20
      another_value: test
```

```
config:
  some_config: !inherit
    array: !inherit:abc
    - abc: 1
      value: 30
    - abc: 3
      value: 40
```

```
config:
  some_config:
    array:
    - abc: 2
      value: 10
    - abc: 1
      value: 30
    - abc: 3
      value: 40
```

!remove

Scope: YAML sequence element under `!inherit:<key>`
Action: remove the element with the corresponding key.
Example:

Original configuration	Override	Resulting configuration

`config:`
`  some_config:`
`  array:`
`  - abc: 2`
`  value: 10`
`  - abc: 1`
`  value: 20`
`  another_value: test`
	`config:`
	`  some_config: !inherit`
	`  array: !inherit:abc`
	`  - !remove`
	`  abc: 1`
		`config:`
		`  some_config:`
		`  array:`
		`  - abc: 2`
		`  value: 10`

!append

Scope: YAML sequence
Action: copy elements from the parent array and append new ones to the end.
Example:

Original configuration	Override	Resulting configuration

`config:`
`  some_config:`
`  array:`
`  - abc: 2`
`  value: 10`
`  - abc: 1`
`  value: 20`
`  another_value: test`
	`config:`
	`  some_config: !inherit`
	`  array: !append`
	`  - abc: 1`
	`  value: 30`
	`  - abc: 3`
	`  value: 40`
		`config:`
		`  some_config:`
		`  array:`
		`  - abc: 2`
		`  value: 10`
		`  - abc: 1`
		`  value: 20`
		`  another_value: test`
		`  - abc: 1`
		`  value: 30`
		`  - abc: 3`
		`  value: 40`

Generating Final Configurations

Configurations can contain complex sets of overrides. With the YDB CLI, you can view the final configurations for:

- specific nodes
- sets of labels
- all possible combinations for the current configuration

```
# Generate all possible final configurations for cluster.yaml
ydb admin config resolve --all -f cluster.yaml
# Generate the configuration for cluster.yaml with labels tenant=/Root/test and canary=true
ydb admin config resolve -f cluster.yaml --label tenant=/Root/test --label canary=true
# Generate the configuration for cluster.yaml with labels similar to those on node 1001
ydb admin config resolve -f cluster.yaml --node_id 1001
# Take the current cluster configuration and generate the final configuration for it with labels similar to t
hose on node 1001
ydb admin config resolve --from-cluster --node_id 1001
```

The configuration transformation command is described in more detail in the section Fetch the cluster configuration.

Example output of `ydb admin config resolve --all -f cluster.yaml` for the following configuration file:

```
metadata:
  cluster: ""
  version: 8
config:
  actor_system_config:
    use_auto_config: true
    node_type: STORAGE
    cpu_count: 4
allowed_labels:
  dynamic:
    type: string
selector_config:
- description: Actorsystem for dynnodes # arbitrary description string
  selector: # selector for all nodes with label dynamic = true
    dynamic: true
  config:
    actor_system_config: !inherit # reuse the original actor_system_config, the semantics of !inherit are des
cribed in the section below
      node_type: COMPUTE
      cpu_count: 8
```

Output:

```
---
label_sets: # sets of labels for which the configuration is generated
- dynamic:
    type: NOT_SET # one of three label types: NOT_SET | COMMON | EMPTY
config: # generated configuration
  invalid: 1
  actor_system_config:
    use_auto_config: true
    node_type: STORAGE
    cpu_count: 4
---
label_sets:
- dynamic:
    type: COMMON
    value: true # label value
config:
  invalid: 1
  actor_system_config:
    use_auto_config: true
    node_type: COMPUTE
    cpu_count: 8
```

Changing Configurations via CMS

> **Note**
>
> This method of changing configuration is deprecated. The recommended configuration method for V1 is described in the cluster dynamic configuration section.

Get Current Settings

The following command will get current settings for the cluster or tenant.

```
ydbd -s <endpoint> admin console configs load --out-dir <config-folder>
```

```
ydbd -s <endpoint> admin console configs load --out-dir <config-folder> --tenant <tenant-name>
```

Update Settings

First, you need to download the required config as indicated above, then you need to prepare a protobuf file with a change request.

```
Actions {
  AddConfigItem {
    ConfigItem {
      Cookie: "<cookie>"
      UsageScope {
        TenantAndNodeTypeFilter {
          Tenant: "<tenant-name>"
        }
      }
      Config {
          <config-name> {
              <full-config>
          }
      }
    }
  }
}
```

The UsageScope field is optional and is needed to apply settings for a specific tenant.

```
ydbd -s <endpoint> admin console configs update <protobuf-file>
```

Changing Actor System Configuration

An actor system is the basis of YDB. Each component of the system is represented by one or more actors.
Each actor is allocated to a specific ExecutorPool corresponding to the actor's task.
Changing the configuration lets you more accurately distribute the number of cores reserved for each type of task.

Actor System Config Description

The actor system configuration contains an enumeration of ExecutorPools, their mapping to task types, and the actor system scheduler configurations.

The following task types and their respective pools are currently supported:

- System: Designed to perform fast internal YDB operations.
- User: Includes the entire user load for handling and executing incoming requests.
- Batch: Tasks that have no strict limit on the execution time, mainly running background operations.
- IO: Responsible for performing any tasks with blocking operations (for example, writing logs to a file).
- IC: Interconnect, includes all the load associated with communication between nodes.

Each pool is described by the Executor field as shown in the example below.

```
Executor {
  Type: BASIC
  Threads: 9
  SpinThreshold: 1
  Name: "System"
}
```

A summary of the main fields:

- **Type**: Currently, two types are supported, such as **BASIC** and **IO**. All pools, except **IO**, are of the **BASIC** type.
- **Threads**: The number of threads (concurrently running actors) in this pool.
- **SpinThreshold**: The number of CPU cycles before going to sleep if there are no tasks, which a thread running as an actor will take (affects the CPU usage and request latency under low loads).
- **Name**: The pool name to be displayed for the node in Monitoring.

Mapping pools to task types is done by setting the pool sequence number in special fields. Pool numbering starts from 0. Multiple task types can be set for a single pool.

List of fields with their respective tasks:

- **SysExecutor**: System
- **UserExecutor**: User
- **BatchExecutor**: Batch
- **IoExecutor**: IO

Example:

```
SysExecutor: 0
UserExecutor: 1
BatchExecutor: 2
IoExecutor: 3
```

The IC pool is set in a different way, via ServiceExecutor, as shown in the example below.

```
ServiceExecutor {
  ServiceName: "Interconnect"
  ExecutorId: 4
}
```

The actor system scheduler is responsible for the delivery of deferred messages exchanged by actors and is set with the following parameters:

- **Resolution**: The minimum time offset step in microseconds.
- **SpinThreshold**: Similar to the pool parameter, the number of CPU cycles before going to sleep if there are no messages.
- **ProgressThreshold**: The maximum time offset step in microseconds.

If, for an unknown reason, the scheduler thread is stuck, it will send messages according to the lagging time, offsetting it by the **ProgressThreshold** value each time.

We do not recommend changing the scheduler config. You should only change the number of threads in the pool configs.

Example of the default actor system configuration:

```
Executor {
  Type: BASIC
  Threads: 9
  SpinThreshold: 1
  Name: "System"
}
Executor {
  Type: BASIC
  Threads: 16
  SpinThreshold: 1
  Name: "User"
}
Executor {
  Type: BASIC
  Threads: 7
  SpinThreshold: 1
  Name: "Batch"
}
Executor {
  Type: IO
  Threads: 1
  Name: "IO"
}
Executor {
  Type: BASIC
  Threads: 3
  SpinThreshold: 10
  Name: "IC"
  TimePerMailboxMicroSecs: 100
}
SysExecutor: 0
UserExecutor: 1
IoExecutor: 3
BatchExecutor: 2
ServiceExecutor {
  ServiceName: "Interconnect"
  ExecutorId: 4
}
```

On Static Nodes

Static nodes take the configuration of the actor system from the `/opt/ydb/cfg/config.yaml` file.

After changing the configuration, restart the node.

On Dynamic Nodes

Dynamic nodes take the configuration from the CMS. To change it, you can use the following command:

```
ConfigureRequest {
  Actions {
    AddConfigItem {
      ConfigItem {
        // UsageScope: { ... }
        Config {
          ActorSystemConfig {
            <actor system config>
          }
        }
        MergeStrategy: 3
      }
    }
  }
}
```

```
ydbd -s <endpoint> admin console execute --domain=<domain> --retry=10 actorsystem.txt
```

Expanding a Cluster

You can expand a YDB cluster by adding new nodes to its configuration. Below is the list of actions for expanding a YDB cluster installed manually on VM instances or physical servers. In the Kubernetes environment, clusters are expanded by adjusting the YDB controller settings for Kubernetes.

When expanding your YDB cluster, you do not have to pause user access to databases. When the cluster is expanded, its components are restarted to apply the updated configurations. This means that any transactions that were in progress at the time of expansion may need to be executed again on the cluster. The transactions are rerun automatically because the applications leverage the YDB SDK features for error control and transaction rerun.

Preparing New Servers

If you deploy new static or dynamic nodes of the cluster on new servers added to the expanded YDB cluster, on each new server, you need to install the YDB software according to the procedures described in the cluster deployment instructions. Among other things, you need to:

1. Create an account and a group in the operating system to enable YDB operation.
2. Install the YDB software.
3. Generate the appropriate TLS key and certificate for the software and add them to the server.
4. Copy the up-to-date configuration file for the YDB cluster to the server.

The TLS certificates used on the new servers must meet the requirements for filling out the fields and be signed by the same trusted certification authority that signed the certificates for the existing servers of the expanded YDB cluster.

Adding Dynamic Nodes

By adding dynamic nodes, you can expand the available computing resources (CPU cores and RAM) needed for your YDB cluster to process user queries.

To add a dynamic node to the cluster, run the process that serves this node, passing to it, in the command line options, the name of the served database and the addresses of any three static nodes of the YDB cluster, as shown in the cluster deployment instructions.

Once you have added the dynamic node to the cluster, the information about it becomes available on the cluster monitoring page in the YDB UI.

To remove a dynamic node from the cluster, stop the process on the dynamic node.

Adding Static Nodes

By adding static nodes, you can increase the throughput of your I/O operations and increase the available storage capacity in your YDB cluster.

To add static nodes to the cluster, perform the following steps:

1. Format the disks that will be used to store the YDB data by following the procedure for the cluster deployment step
2. Edit the cluster's configuration file:
   - Add the description of the added nodes (in the `hosts` section) and disks used by them (in the `host_configs` section) to the configuration.
   - Use the `storage_config_generation: K` option to set the ID of the configuration update at the top level, where `K` is the integer update ID (for the initial config, `K=0` or omitted; for the first expansion, `K=1`; for the second expansion, `K=2`; and so on).
3. Copy the updated cluster's configuration file to all the existing and added servers in the cluster, overwriting the old version of the configuration file.
4. Restart all the existing static nodes in the cluster one by one, waiting for each restarted node to initialize and become fully operational.
5. Restart all the existing static nodes in the cluster one by one.
6. Start the processes that serve the new static nodes in the cluster, on the appropriate servers.
7. Make sure that all the new static nodes now show up on the cluster monitoring page in the YDB UI.
8. Issue an authentication token using the YDB CLI, for example:

   ```
   ydb -e grpcs://<node1.ydb.tech>:2135 -d /Root --ca-file ca.crt \
         --user root auth get-token --force >token-file
   ```

   The command example above uses the following options:

   - `node1.ydb.tech`: The FQDN of any server hosting the cluster's static nodes.
   - `2135`: Port number of the gRPCs service for the static nodes.
   - `ca.crt`: Name of the file with the certificate authority certificate.
   - `root`: The name of a user who has administrative rights.
   - `token-file`: name of the file where the authentication token is saved for later use.

   When you run the above command, YDB CLI will request the password to authenticate the given user.
9. Allow the YDB cluster to use disks to store data on the new static nodes. For this, run the following command on any cluster node:

   ```
   export LD_LIBRARY_PATH=/opt/ydb/lib
   /opt/ydb/bin/ydbd -f ydbd-token-file --ca-file ca.crt -s grpcs://`hostname -f`:2135 \
       admin blobstorage config init --yaml-file  /opt/ydb/cfg/config.yaml
   echo $?
   ```

   The command example above uses the following options:

   - `ydbd-token-file`: File name of the previously issued authentication token.
   - `2135`: Port number of the gRPCs service for the static nodes.
   - `ca.crt`: Name of the file with the certificate authority certificate.

If the above command results in the error of the configuration ID mismatch, it means that you made an error editing the `storage_config_generation` field in the cluster configuration file. In the error text, you can find the expected configuration ID that can be used to edit the cluster configuration file. Sample error message for the configuration ID mismatch:

```
ErrorDescription: "ItemConfigGeneration mismatch ItemConfigGenerationProvided# 0 ItemConfigGenerationExp
ected# 1"
```

10. Add additional storage groups to one or more databases by running the following commands on any cluster node:

    ```
    export LD_LIBRARY_PATH=/opt/ydb/lib
    /opt/ydb/bin/ydbd -f ydbd-token-file --ca-file ca.crt -s grpcs://`hostname -f`:2135 \
        admin database /Root/testdb pools add ssd:1
    echo $?
    ```

    The command example above uses the following options:

    - `ydbd-token-file`: File name of the previously issued authentication token.
    - `2135`: Port number of the gRPCs service for the static nodes.
    - `ca.crt`: Name of the file with the certificate authority certificate.
    - `/Root/testdb`: Full path to the database.
    - `ssd:1`: Name of the storage pool and the number of storage groups allocated.
11. Make sure that all the new storage groups now show up on the cluster monitoring page in the YDB UI.

To remove a static node from the YDB cluster, use the documented decommissioning procedure.

If the server running the static cluster node is damaged or becomes irreparable, deploy the unavailable static node on a new server with the same or higher number of disks.

Configuring metadata distribution subsystems State Storage, Board, and Scheme Board

Applies if you need to change the metadata distribution subsystems configuration consisting of State Storage, Board, and Scheme Board on the YDB cluster.

> **Warning**
>
> Errors in metadata subsystem configuration (including the `domains_config` section) or an incorrect sequence of changes can lead to YDB cluster unavailability.

To change the metadata distribution subsystems configuration in the YDB cluster, perform the following steps.

1. Make the required changes to the `domains_config` section of the `config.yaml` configuration file on each node of the YDB cluster:
   For rules on changing the `domains_config` section, see Rules for configuring metadata distribution subsystems.
2. Using the rolling-restart procedure, sequentially restart all nodes of the YDB cluster — static and dynamic: metadata subsystem replicas are placed on static nodes, and tablets on dynamic nodes access them. For more on nodes, see Cluster topology.
   Before restarting the next host, wait for the restart on the previous host to complete and for the node to rejoin the cluster.

Rules for configuring metadata distribution subsystems

The rules listed below apply to `state_storage` and to the separate fields `explicit_state_storage_config`, `explicit_state_storage_board_config`, `explicit_scheme_board_config` in the `domains_config` section of the `config.yaml` file (see State Storage configuration). The `explicit_*` keys correspond individually to State Storage, Board, and Scheme Board.

A ring in the configuration refers to the `ring` block inside the `ring_groups` list element (see State Storage Configuration).

The configuration is changed in several steps. First, a new group of rings consisting of properly selected nodes (according to the failure model) is added, and then the old group of rings is removed.

To avoid cluster unavailability, perform the removal and addition of ring groups strictly in the sequence of steps described below.

1. To change the configuration of the metadata distribution subsystems without cluster unavailability, you must do this by adding and removing ring groups.
2. Only ring groups with the `WriteOnly: true` parameter can be added and removed.
3. The new configuration must always contain at least one ring group from the previous configuration without the `WriteOnly` parameter. Such a ring group must come first in the list.
4. If different ring groups use the same cluster nodes, add the `ring_group_actor_id_offset` parameter to the ring group with a unique value (for example, `1`, `2`, ...). The value must be unique among ring groups.

   This parameter will make the replica identifiers in this ring group unique; they will not match the identifiers from other groups, and this will allow placing several replicas of the same type on one cluster node.
5. The transition to the new configuration is performed in 4 sequential steps. At each step, a new configuration is prepared and applied to the cluster.

   Newly created or ready-to-remove ring groups are marked with the `WriteOnly: true` flag. This is necessary so that read requests are handled by the already deployed ring group while the new configuration spreads to the required number of nodes, new replicas are created, or old ones are removed.

   Therefore, you must pause for at least `1 minute` between steps.

   - Add a new ring group with the `WriteOnly: true` parameter corresponding to the target configuration.
   - Remove flag `WriteOnly`.
   - Set the `WriteOnly: true` flag on the ring group corresponding to the old configuration, and move the new ring group to the beginning of the list of ring groups.
   - Delete the old ring group.

Example

Consider the current configuration as an example:

```
config:
  domains_config:
    explicit_scheme_board_config:
      ring:
        nto_select: 5
        node: [1,2,3,4,5,6,7,8]
```

and the target configuration:

```
config:
  domains_config:
    explicit_scheme_board_config:
      ring:
        nto_select: 5
        node: [10,20,30,40,5,6,7,8]
```

We want to move some of the replicas to other cluster nodes.

Step 1
At the first step, prepare `ring_groups` following the configuration rules: the first ring group matches the **current** configuration from the listings above, the second matches the **target** one and is marked with `WriteOnly: true`. Specify the `ring_group_actor_id_offset` parameter as described in the same rules if the node sets of the groups match.

```
config:
  domains_config:
    explicit_scheme_board_config:
      ring_groups:
        - ring:
          nto_select: 5
          node: [1,2,3,4,5,6,7,8]
        - ring:
          nto_select: 5
          node: [10,20,30,40,5,6,7,8]
          write_only: true
          ring_group_actor_id_offset: 1
```

Step 2
Remove the `WriteOnly` flag.

```
config:
  domains_config:
    explicit_scheme_board_config:
      ring_groups:
        - ring:
          nto_select: 5
          node: [1,2,3,4,5,6,7,8]
        - ring:
          nto_select: 5
          node: [10,20,30,40,5,6,7,8]
          ring_group_actor_id_offset: 1
```

Step 3
Make the new ring group first in the list. Set the `WriteOnly: true` flag on the old configuration.

```
config:
  domains_config:
    explicit_scheme_board_config:
      ring_groups:
        - ring:
          nto_select: 5
          node: [10,20,30,40,5,6,7,8]
          ring_group_actor_id_offset: 1
        - ring:
          nto_select: 5
          node: [1,2,3,4,5,6,7,8]
          write_only: true
```

Step 4
Apply the target configuration to the cluster:

```
config:
  domains_config:
    explicit_scheme_board_config:
      ring_groups:
        - ring:
          nto_select: 5
          node: [10,20,30,40,5,6,7,8]
          ring_group_actor_id_offset: 1
```

Checking the result

You can verify that the changes have been applied in the `CMS` section of the cluster YDB UI (available on port 8765): go to the `Tablets` tab and check the replicas of the metadata subsystem tablets to make sure the configuration has been picked up.

State Storage Move

If you need to decommission a YDB cluster host that contains part of State Storage, you need to move it to another host.

> **Warning**
>
> Errors in metadata subsystem configuration (including the `domains_config` section) or an incorrect sequence of changes can lead to YDB cluster unavailability.

As an example, consider a YDB cluster with the following State Storage configuration:

```
...
domains_config:
  ...
  state_storage:
  - ring:
      node: [1, 2, 3, 4, 5, 6, 7, 8, 9]
      nto_select: 9
    ssid: 1
  ...
...
```

On the host with `node_id:1`, a cluster static node is configured and running, which serves part of State Storage. Suppose we need to decommission this host.

To replace `node_id:1`, we added a new host with `node_id:10` to the cluster and deployed a static node on it.

To move State Storage from host `node_id:1` to `node_id:10`:

1. Stop the cluster static nodes on hosts with `node_id:1` and `node_id:10`.

   > **Note**
   >
   > A YDB cluster is fault-tolerant. Temporary node shutdown does not lead to cluster unavailability. For more details, see YDB Cluster Topology.

2. In the configuration file `config.yaml`, change the `node` host list, replacing the identifier of the host being removed with the identifier of the host being added:

   ```
   domains_config:
   ...
     state_storage:
     - ring:
         node: [2, 3, 4, 5, 6, 7, 8, 9, 10]
         nto_select: 9
       ssid: 1
   ...
   ```

3. Update the configuration files `config.yaml` for all cluster nodes, including dynamic ones.
4. Using the rolling-restart procedure, restart all cluster nodes, including dynamic ones, except for static nodes on hosts with `node_id:1` and `node_id:10`. Note that a delay of at least 15 seconds is required between host restarts.
5. Start the cluster static nodes on hosts `node_id:1` and `node_id:10`.

Static Group Move

If you need to decommission a YDB cluster host that contains part of the static group, you need to move it to another host.

> **Warning**
>
> Errors in metadata subsystem configuration (including the `domains_config` section) or an incorrect sequence of changes can lead to YDB cluster unavailability.

As an example, consider a YDB cluster where a static node is configured and running on the host with `node_id:1`. This node serves part of the static group.

Static group configuration fragment:

```
...
blob_storage_config:
  ...
  service_set:
    ...
    groups:
      ...
      rings:
        ...
        fail_domains:
        - vdisk_locations:
          - node_id: 1
            path: /dev/vda
            pdisk_category: SSD
        ...
      ...
    ...
  ...
...
```

To replace `node_id:1`, we added a new host with `node_id:10` to the cluster and deployed a static node on it.

To move part of the static group from host `node_id:1` to `node_id:10`:

1. Stop the cluster static node on the host with `node_id:1`.

   > **Note**
   >
   > A YDB cluster is fault-tolerant. Temporary node shutdown does not lead to cluster unavailability. For more details, see YDB Cluster Topology.

2. In the configuration file `config.yaml`, change the `node_id` value, replacing the identifier of the host being removed with the identifier of the host being added:

   ```
   ...
   blob_storage_config:
     ...
     service_set:
       ...
       groups:
         ...
         rings:
           ...
           fail_domains:
           - vdisk_locations:
             - node_id: 10
               path: /dev/vda
               pdisk_category: SSD
           ...
         ...
       ...
     ...
   ...
   ```

   Change the `path` and disk `pdisk_category` if they differ on the host with `node_id: 10`.
3. Update the configuration files `config.yaml` for all cluster nodes, including dynamic ones.
4. Using the rolling-restart procedure, restart all static cluster nodes.
5. Go to the YDB UI monitoring page and ensure that the static group VDisk appeared on the target physical disk and is replicating. For more details, see Monitoring static groups.
6. Using the rolling-restart procedure, restart all dynamic cluster nodes.

Replacing Node FQDN

Replacing Node FQDN

This procedure describes how to replace the FQDN (Fully Qualified Domain Name) of a YDB cluster node without downtime.

Prerequisites

Note

A YDB cluster is fault-tolerant. Temporary node shutdown does not lead to cluster unavailability. For more details, see YDB Cluster Topology.

Warning

Errors in metadata subsystem configuration (including the `domains_config` section) or an incorrect sequence of changes can lead to YDB cluster unavailability.

Procedure Overview

The FQDN replacement process involves:

1. **Preparation**: Verify cluster health and prepare a new node configuration
2. **Node shutdown**: Gracefully stop the node to be replaced
3. **Configuration update**: Update the cluster configuration with a new FQDN
4. **Node restart**: Start the node with new FQDN
5. **Verification**: Confirm successful FQDN change

Step-by-Step Instructions

Step 1: Verify Cluster Health

Before starting the replacement, ensure the cluster is healthy:

```
ydb monitoring healthcheck
```

Step 2: Prepare New Node Configuration

1. Update DNS records to point the new FQDN to the same IP address
2. Update TLS certificates if they include hostname verification
3. Prepare updated configuration files with the new FQDN

Step 3: Stop the Target Node

Gracefully stop the node that needs FQDN replacement:

```
# For systemd-managed nodes
sudo systemctl stop ydbd-storage

# For manually started nodes
kill -TERM <ydbd_pid>
```

Step 4: Update Cluster Configuration

Update the cluster configuration to reflect the new FQDN:

```
# Example configuration update
hosts:
  - host: new-hostname.example.com  # Updated FQDN
    host_config_id: 1
    port: 19001
    location:
      unit: "1"
      data_center: "DC1"
      rack: "1"
```

Step 5: Apply Configuration Changes

Apply the updated configuration to the cluster:

```
ydb admin config replace --config-file updated-config.yaml
```

Step 6: Start Node with New FQDN

Start the node using the new FQDN:

```
# Update hostname if necessary
sudo hostnamectl set-hostname new-hostname.example.com

# Start the node
sudo systemctl start ydbd-storage
```

Step 7: Verify the Change

Confirm the FQDN change was successful:

```
# Check node status
ydb monitoring healthcheck

# Verify node registration
ydb admin config fetch | grep new-hostname
```

Troubleshooting

Common Issues

1. **DNS resolution problems**: Ensure new FQDN resolves correctly
2. **Certificate validation errors**: Update certificates if they include hostname verification
3. **Node registration failures**: Check network connectivity and firewall rules

Recovery Procedures

If the FQDN replacement fails:

1. Revert DNS changes to the original FQDN
2. Restore the original configuration
3. Restart the node with the original settings
4. Investigate and resolve the underlying issue

Best Practices

1. **Test in staging**: Always test FQDN replacement in a non-production environment first
2. **Backup configurations**: Keep backups of working configurations before making changes
3. **Monitor during change**: Watch cluster health metrics during the replacement process
4. **Document changes**: Maintain records of FQDN changes for future reference
5. **Coordinate with the team**: Ensure all team members are aware of the planned change

Database Node Authentication and Authorization

Database Node Authentication and Authorization

Database node authentication in a YDB cluster ensures verification of database node authenticity when making service calls to other nodes via the gRPC protocol. Node authorization ensures verification and provision of necessary permissions when processing service calls, including operations for registering starting nodes in the cluster and accessing configuration. Using database node authentication and authorization is recommended for all YDB clusters, as it helps avoid situations of unauthorized data access through the inclusion of attacker-controlled nodes in the cluster.

Database node authentication and authorization is performed in the following order:

1. The starting database node opens a gRPC connection to one of the cluster storage nodes specified in the `--node-broker` command-line option. The connection uses the TLS protocol, and the starting node's certificate is used as the client certificate in the connection settings.
2. The storage node and database node perform mutual authenticity verification using the TLS protocol: the certificate trust chain is verified and the hostname correspondence to the "Subject Name" field value of the certificate is checked.
3. The storage node verifies that the "Subject" field of the certificate meets the requirements established by settings in the static configuration.
4. Upon successful completion of the above checks, the connection from the database node is considered authenticated, and it is assigned an access subject identifier — SID, determined by the settings.
5. The database node uses the established gRPC connection to register as part of the cluster using the corresponding service call. During registration, the database node transmits its network address intended for interaction with other cluster nodes.
6. The storage node verifies that the SID assigned to the gRPC connection is in the list of allowed ones. Upon successful completion of this check, the storage node registers the database node in the cluster, mapping the received network address to the node identifier.
7. The database node joins the cluster by connecting through its network address and specifying the node identifier received during registration. Attempts to join the cluster by nodes with unknown network addresses or identifiers are blocked by other nodes.

The following describes the settings necessary to enable database node authentication and authorization.

Configuration Prerequisites

1. The deployed YDB cluster must have gRPC traffic encryption configured using the TLS protocol.
2. When preparing node certificates for a cluster where database node authentication and authorization is planned to be used, it is necessary to ensure uniform rules for filling the "Subject" field of certificates, allowing identification of certificates issued for cluster nodes. More information is provided in the certificate verification rules configuration documentation.

   > **Note**
   >
   > The proposed example script for generating self-signed YDB node certificates fills the "Subject" field with the value `O=YDB` for all node certificates. The configuration examples provided below are prepared for certificates with exactly this "Subject" field content.

3. The command-line parameters for starting database nodes must include options that specify paths to certificate files from trusted certificate authorities, a node certificate, and a node key. The list of additional options is provided in the table below.

Command-line Option	Description
`--grpc-ca`	Path to the certificate file `ca.crt` from a trusted certificate authority.
`--grpc-cert`	Path to the node certificate file `node.crt`.
`--grpc-key`	Path to the node private key file `node.key`.

   Example command for starting a database node with options specifying paths to TLS keys and certificates for the gRPC protocol:

   ```
   /opt/ydb/bin/ydbd server --config-dir /opt/ydb/cfg --tenant /Root/testdb \
       --grpcs-port 2136 --grpc-ca /opt/ydb/certs/ca.crt \
       --grpc-cert /opt/ydb/certs/node.crt --grpc-key /opt/ydb/certs/node.key \
       --ic-port 19002 --ca /opt/ydb/certs/ca.crt \
       --mon-port 8766 --mon-cert /opt/ydb/certs/web.pem \
       --node-broker grpcs://<ydb1>:2135 \
       --node-broker grpcs://<ydb2>:2135 \
       --node-broker grpcs://<ydb3>:2135
   ```

Enabling Database Node Authentication and Authorization

> **Note**
>
> Starting from version 25.2, properly configured database node authentication is mandatory.
>
> Node registration in the cluster is impossible without successful authentication.

To enable mandatory database node authorization, the following configuration blocks must be added to the cluster configuration file:

1. At the root level of the configuration, add a `client_certificate_authorization` block specifying requirements for filling the "Subject" field of trusted certificates of connecting nodes, for example:

```
client_certificate_authorization:
  request_client_certificate: true
  client_certificate_definitions:
    - member_groups: ["registerNode@cert"]
      subject_terms:
      - short_name: "O"
        values: ["YDB"]
```

If necessary, add other certificate checks according to the documentation.

After the certificate is verified and its "Subject" field is confirmed to comply with the requirements established in the `subject_terms` block, the connection will be assigned access subjects from the `member_groups` parameter. To distinguish such access subjects, the `@cert` suffix is added to their names.

2. In the `security_config` section of the cluster configuration, add the `register_dynamic_node_allowed_sids` element with a list of access subjects allowed to register database nodes. Example:

```
security_config:
  enforce_user_token_requirement: true
  ...
  register_dynamic_node_allowed_sids:
  - "registerNode@cert"
```

For more information on configuring cluster authentication parameters, see Configuring Administrative and Other Privileges.

3. In the `auth_config` section of the cluster configuration, add the `node_registration_token` as an empty string. Example:

```
auth_config:
  ...
  node_registration_token: ""
```

4. Update the static configuration files on all cluster nodes manually or using the Ansible playbook.
5. Perform a rolling restart of cluster storage nodes using ydbops or using the Ansible playbook.
6. Perform a rolling restart of cluster database nodes using ydbops or using the Ansible playbook.

Configuration V2

This section of the documentation describes the YDB clusters configuration method called V2, which is the experimental way to configure YDB clusters version v25.1 and above.

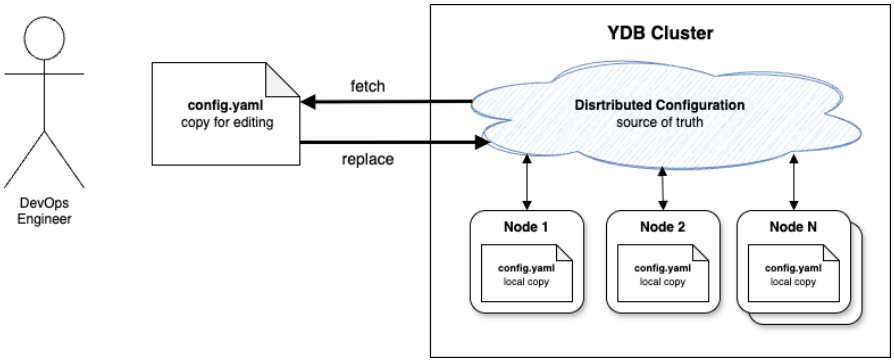
> **Warning**
>
> This article is dedicated to YDB clusters that use configuration V2. This configuration method is currently experimental and is only available for YDB versions starting from v25.1. For production use, we recommend choosing configuration V1 — it is the main method and is officially supported for all YDB clusters.

Main materials:

- Configuration V2 Overview
- Updating YDB Cluster Configuration
- Cluster configuration DSL
- Configuration parameters
- Cluster Expansion
- Removing a node from a cluster
- Configuring the State Storage, Board, and Scheme Board metadata distribution subsystems
- State Storage Move
- Static Group Move
- Replacing node FQDN
- Authentication and authorization of database nodes

Configuration V2 Overview

To deploy a new YDB cluster, to add new nodes to an existing cluster, or to change parameters, a configuration is required.



> **Warning**
>
> This article is dedicated to YDB clusters that use configuration V2. This configuration method is currently experimental and is only available for YDB versions starting from v25.1. For production use, we recommend choosing configuration V1 — it is the main method and is officially supported for all YDB clusters.

YDB cluster configuration V2 is a text file in YAML format. In its minimal form, it contains a `config` section with various parameters necessary for starting and configuring cluster nodes, as well as a section with `metadata`. Extended capabilities for flexible configuration are described in the article Cluster Configuration Domain-Specific Language (DSL). You can learn more about available parameters in the configuration reference.

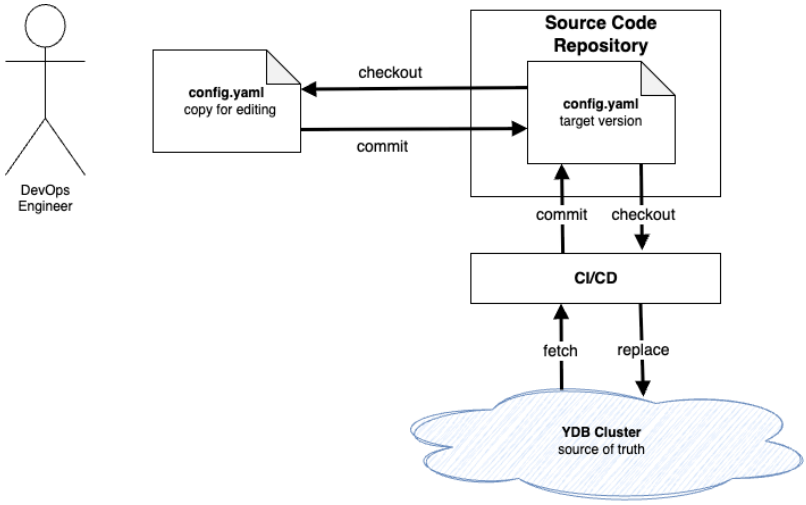
Example configuration V2 file

```
metadata:
  cluster: ""
  version: 0
config:
  hosts:
    - host: localhost
  drive:
    - type: RAM
  grpc_config:
    port: 2136
  monitoring_config:
    monitoring_port: 8765
```

Configuration Management

The YDB cluster itself is responsible for managing the state of the configuration file, and it is also the single source of truth about how it is currently configured. The distributed configuration mechanism is responsible for reliable storage of the current state. You can see the current state of the cluster configuration using the console command ydb admin cluster config fetch, and the state of each specific node through its YDB UI.

Changing the YDB cluster configuration is performed by the administrator as follows:



1. Save the current state of the cluster configuration to a local file via ydb admin cluster config fetch.
2. Edit the required parameters in the file in a text editor or any other convenient way.
3. Load changes back to the cluster by calling the ydb admin cluster config replace command.

Configuration change example

```
$ ydb -e grpc://<ydb.example.com>:2135 admin cluster config fetch > config.yaml     # 1
$ vim config.yaml                                                                   # 2
$ ydb -e grpc://<ydb.example.com>:2135 admin cluster config replace -f config.yaml  # 3
```

Loading changes back to the cluster is not always successful. In addition to basic validation of a configuration file, the system has protection against concurrent changes by multiple administrators. The system increments the `metadata.version` field with each configuration change and refuses to accept a new version if its number does not match the expected one, as this means that there was another change between `fetch` and `replace`, and `replace` would erase it. To minimize such conflicts, you can use the "Infrastructure as Code" approach: store a copy of the configuration file in a version control system repository (for example, Git) and run `fetch` and `replace` commands only from a continuous integration and delivery (CI/CD) system linked to this repository, reacting to changes in the YDB configuration file in the repository and ensuring sequential sending of all changes to the YDB cluster.

Infrastructure as Code approach diagram

Each YDB cluster node saves a local copy of the configuration to the directory specified in the `ydbd --config-dir` startup argument. This local copy is used in the following situations:

1. To apply settings that are needed at the very start of the node's operation, even before it has the ability to start communicating with other cluster nodes. Changing such settings may require restarting the node.
2. For initial deployment and expansion of the cluster.
3. In case of force majeure, if problems arose with the main configuration management mechanism that require manual intervention.

The above describes the main mechanism for managing YDB configuration V2. Depending on the preferred infrastructure management method, additional automation may be provided.

Basic Configuration Usage Scenarios

Initial YDB Cluster Deployment

For cluster configuration during initial deployment, it is recommended to use instructions for the selected infrastructure management method:

- Deploying a YDB cluster with Ansible;
- Getting Started with YDB in Kubernetes;
- Deploying YDB Cluster Manually.

Configuration Update

To update the configuration of an already deployed cluster, you need to use the appropriate commands depending on the deployment method:

- Updating Configuration of YDB Clusters Deployed with Ansible;
- Updating configuration of manually deployed YDB clusters.

If configuration changes affect parameters that require restarting cluster nodes, use the rolling restart procedure. More details about it depending on the deployment method:

- Restarting a cluster deployed with Ansible;
- Restarting a manually deployed cluster.

Cluster Expansion

When expanding the cluster, configuration is delivered to old and new nodes differently:

- To nodes that existed before expansion, changes are delivered automatically when calling ydb admin cluster config replace.
- Before the first start of new nodes, a local copy is delivered by the special command ydb admin node config init, not by the node itself.

Updating YDB Cluster Configuration

This article covers changing cluster configuration after initial deployment.

> **Warning**
>
> This article is dedicated to YDB clusters that use configuration V2. This configuration method is currently experimental and is only available for YDB versions starting from v25.1. For production use, we recommend choosing configuration V1 — it is the main method and is officially supported for all YDB clusters.

YDB cluster configuration management is performed using YDB CLI. The standard approach to updating a configuration is to get the current configuration from the cluster using YDB CLI, modify it locally, and then load the updated configuration back to the cluster.

To prevent accidental overwriting of changes when multiple administrators work simultaneously, YDB configuration contains metadata with a version number. With each successful configuration upload, this number is automatically incremented. If another administrator tries to upload a configuration based on a previous (outdated) version (i.e., with the same or lower version number in metadata), the system will reject this attempt. This ensures that changes by one administrator will not be silently overwritten by changes from another.

To update a configuration, you need to get the current configuration, modify it, and apply the updated configuration. During the configuration application process, it will be reliably saved by the cluster and distributed to all its nodes. As configuration is delivered to cluster nodes, the configuration begins to be applied by these nodes. Some configuration parameters change node behavior immediately after configuration delivery, while others only take effect when the node starts, and changing such parameters requires a cluster restart for them to take effect.

Basic Configuration Operations

Getting Current Configuration

To get the current cluster configuration, use the command:

```
ydb -e grpcs://<endpoint>:2135 admin cluster config fetch > config.yaml
```

Specify the address of any cluster node as `<endpoint>`.

Applying New Configuration

To load updated configuration to the cluster, use the following command:

```
ydb -e grpcs://<endpoint>:2135 admin cluster config replace -f config.yaml
```

Specify the address of any cluster node as `<endpoint>`.

Some configuration parameters are applied on the fly after executing the command, however some require performing the cluster restart procedure.

Cluster Configuration Domain-Specific Language (DSL)

Cluster Configuration DSL

Selectors

The main entity of the DSL is **selectors**. They allow the overriding of parts of the configuration or the entire configuration for specific nodes or groups of nodes. For example, they can be used to enable experimental functionality for nodes of a particular database. Each selector is an array of overrides and extensions to the main configuration. Each selector has a `description` field, which can be used to store an arbitrary description string. The `selector` field represents a set of rules that determine whether the selector should be applied to a specific node based on a set of labels. The `config` field describes the override rules. Selectors are applied in the order they are defined.

Labels

Labels are special tags used to mark nodes or groups of nodes. Each node has a set of automatically assigned labels:

- `node_id` — the internal identifier of the node in the system
- `node_host` — the node's `hostname` obtained at startup
- `tenant` — the database served by this node
- `dynamic` — whether this node is dynamic (true/false)

Additionally, the user can explicitly define any additional labels when starting the `ydbd` process on the node using command-line arguments, such as `--label example=test`.

Example of Using Selectors

The example below defines the actor system's general configuration and the tenant `large_tenant` configuration. By default, with such a configuration, the actor system assumes that each node has 4 cores, while nodes of the `large_tenant` have 16 cores. The actor system's node type is overridden to `COMPUTE`.

```
metadata:
  cluster: ""
  version: 8
config:
  actor_system_config:
    use_auto_config: true
    node_type: STORAGE
    cpu_count: 4

# This section is used as a hint when generating possible configurations using the resolve command
allowed_labels:
  dynamic:
    type: string

selector_config:
- description: large_tenant has bigger nodes with 16 cpu # arbitrary description string
  selector: # selector for all nodes of the tenant large_tenant
    tenant: large_tenant
  config:
    actor_system_config: !inherit # reuse the original actor_system_config, the semantics of !inherit are des
cribed in the section below
      # in this case, !inherit allows managing the actor_system_config.use_auto_config parameter for the enti
re cluster by changing only the base setting
      cpu_count: 16
      node_type: COMPUTE
```

Permissive Labels

A mapping in which you can set the allowable values for labels. This section is used as a hint when generating possible configurations using the resolve command. Values are not validated at node startup.

There are two types of labels available:

- string;
- enum.

string

It can take any value or be unset.

Example:

```
dynamic:
  type: string
host_name:
  type: string
```

enum

It can take values from the `values` list or be unset.

Example:

```
flavour:
  type: enum
  values:
    ? small
    ? medium
    ? big
```

Selector Behavior

Selectors represent a simple predicate language. Selectors for each label are combined using the **AND** condition.

Simple Selector

The following selector will select nodes where the `label1` is equal to `value1` **and** the `label2` is equal to `value2`:

```
selector:
  label1: value1
  label2: value2
```

The following selector will select **ALL** nodes in the cluster, as no conditions are specified:

```
selector: {}
```

In

This operator allows for selecting nodes with label values from a list.

The following selector will select all nodes where `label1` is equal to `value1` **or** `value2`:

```
selector:
  label1:
    in:
    - value1
    - value2
```

NotIn

This operator allows selecting nodes where the chosen label does not match any value from a list.

The following selector will select all nodes where `label1` is equal to `value1` **and** `label2` is not equal to `value2` **and** `value3`:

```
selector:
  label1: value1
  label2:
    not_in:
    - value2
    - value3
```

Additional YAML Tags

Tags are necessary for partial or complete reuse of configurations from previous selectors. They allow you to merge, extend, delete, and override parameters set in previous selectors and the main configuration.

!inherit

Scope: YAML mapping
Action: similar to the merge tag in YAML, copy all child elements from the parent mapping and merge with the current ones, overwriting them.
Example:

Original configuration	Override	Resulting configuration

`config:`
`  some_config:`
`  first_entry: 1`
`  second_entry: 2`
`  third_entry: 3`
	`config:`
	`  some_config: !inherit`
	`  second_entry: 100`
		`config:`
		`  some_config:`
		`  first_entry: 1`
		`  second_entry: 100`
		`  third_entry: 3`

!inherit:<key>

Scope: YAML sequence
Action: copy elements from the parent array and overwrite, treating the `key` object in the elements as the key, appending new keys to the end.
Example:

Original configuration	Override	Resulting configuration

```
config:
  some_config:
    array:
    - abc: 2
      value: 10
    - abc: 1
      value: 20
      another_value: test
```

```
config:
  some_config: !inherit
    array: !inherit:abc
    - abc: 1
      value: 30
    - abc: 3
      value: 40
```

```
config:
  some_config:
    array:
    - abc: 2
      value: 10
    - abc: 1
      value: 30
    - abc: 3
      value: 40
```

!remove

Scope: YAML sequence element under `!inherit:<key>`
Action: remove the element with the corresponding key.
Example:

Original configuration	Override	Resulting configuration

`config:`
`  some_config:`
`  array:`
`  - abc: 2`
`  value: 10`
`  - abc: 1`
`  value: 20`
`  another_value: test`
	`config:`
	`  some_config: !inherit`
	`  array: !inherit:abc`
	`  - !remove`
	`  abc: 1`
		`config:`
		`  some_config:`
		`  array:`
		`  - abc: 2`
		`  value: 10`

!append

Scope: YAML sequence
Action: copy elements from the parent array and append new ones to the end.
Example:

Original configuration	Override	Resulting configuration

`config:`
`  some_config:`
`  array:`
`  - abc: 2`
`  value: 10`
`  - abc: 1`
`  value: 20`
`  another_value: test`
	`config:`
	`  some_config: !inherit`
	`  array: !append`
	`  - abc: 1`
	`  value: 30`
	`  - abc: 3`
	`  value: 40`
		`config:`
		`  some_config:`
		`  array:`
		`  - abc: 2`
		`  value: 10`
		`  - abc: 1`
		`  value: 20`
		`  another_value: test`
		`  - abc: 1`
		`  value: 30`
		`  - abc: 3`
		`  value: 40`

Generating Final Configurations

Configurations can contain complex sets of overrides. With the YDB CLI, you can view the final configurations for:

- specific nodes
- sets of labels
- all possible combinations for the current configuration

```
# Generate all possible final configurations for cluster.yaml
ydb admin config resolve --all -f cluster.yaml
# Generate the configuration for cluster.yaml with labels tenant=/Root/test and canary=true
ydb admin config resolve -f cluster.yaml --label tenant=/Root/test --label canary=true
# Generate the configuration for cluster.yaml with labels similar to those on node 1001
ydb admin config resolve -f cluster.yaml --node_id 1001
# Take the current cluster configuration and generate the final configuration for it with labels similar to t
hose on node 1001
ydb admin config resolve --from-cluster --node_id 1001
```

The configuration transformation command is described in more detail in the section Fetch the cluster configuration.

Example output of `ydb admin config resolve --all -f cluster.yaml` for the following configuration file:

```
metadata:
  cluster: ""
  version: 8
config:
  actor_system_config:
    use_auto_config: true
    node_type: STORAGE
    cpu_count: 4
allowed_labels:
  dynamic:
    type: string
selector_config:
- description: Actorsystem for dynnodes # arbitrary description string
  selector: # selector for all nodes with label dynamic = true
    dynamic: true
  config:
    actor_system_config: !inherit # reuse the original actor_system_config, the semantics of !inherit are des
cribed in the section below
      node_type: COMPUTE
      cpu_count: 8
```

Output:

```
---
label_sets: # sets of labels for which the configuration is generated
- dynamic:
    type: NOT_SET # one of three label types: NOT_SET | COMMON | EMPTY
config: # generated configuration
  invalid: 1
  actor_system_config:
    use_auto_config: true
    node_type: STORAGE
    cpu_count: 4
---
label_sets:
- dynamic:
    type: COMMON
    value: true # label value
config:
  invalid: 1
  actor_system_config:
    use_auto_config: true
    node_type: COMPUTE
    cpu_count: 8
```

YDB Cluster Configuration

The cluster configuration is specified in the YAML file passed in the `--yaml-config` parameter when the cluster nodes are run. This article provides an overview of the main configuration sections and links to detailed documentation for each section.

Each configuration section serves a specific purpose in defining how the YDB cluster operates, from hardware resource allocation to security settings and feature flags. The configuration is organized into logical groups that correspond to different aspects of cluster management and operation.

Configuration Sections

The following top-level configuration sections are available, listed in alphabetical order:

Section	Required	Description
actor_system_config	Yes	CPU resource allocation across actor system pools
auth_config	No	Authentication and authorization settings
aws_client_config	No	AWS client default settings
blob_storage_config	No	Static cluster group configuration for system tablets
bridge_config	No	Cluster piles for bridge mode
client_certificate_authorization	No	Client certificate authentication
cms_config	No	Cluster Management System configuration
domains_config	No	Cluster domain configuration including Blob Storage and State Storage
feature_flags	No	Feature flags to enable or disable specific YDB features
healthcheck_config	No	Health check service thresholds and timeout settings
hive_config	No	Hive component configuration for tablet management
host_configs	No	Typical host configurations for cluster nodes
hosts	Yes	Static cluster nodes configuration
immediate_controls_config	No	Configuration of dynamic cluster settings
kafka_proxy_config	No	Kafka Proxy configuration
log_config	No	Logging configuration and parameters
memory_controller_config	No	Memory allocation and limits for database components
node_broker_config	No	Stable node names configuration
query_service_config	No	Federated query connector configuration
resource_broker_config	No	Resource broker for controlling CPU and memory consumption
security_config	No	Security configuration settings
table_service_config	No	Query processing configuration
tli_config	No	Transaction lock invalidation (TLI) diagnostics parameters
tls	No	TLS configuration for secure connections

Practical Guidelines

While this documentation section focuses on complete reference documentation for available settings, practical recommendations on what to tune and when can be found in the following places:

- As part of the initial YDB cluster deployment:
  - Ansible
  - Kubernetes
  - Manual
- As part of troubleshooting
- As part of security hardening

Sample Cluster Configurations

You can find model cluster configurations for deployment in the repository. Check them out before deploying a cluster.

Cluster Expansion

You can expand a YDB cluster by adding new nodes to the cluster configuration. Below are the necessary actions for expanding a YDB cluster installed manually on virtual machines or physical servers. Cluster expansion in a Kubernetes environment is performed by adjusting the YDB controller settings for Kubernetes.

Expanding a YDB cluster does not require suspending user access to databases. When expanding the cluster, its components are restarted to apply configuration changes, which in turn may lead to the need to retry transactions running on the cluster. Transaction retries are performed automatically by applications using YDB SDK capabilities for error control and operation retry.

Preparing New Servers

When placing new static or dynamic cluster nodes on new servers that were not previously part of the expanded YDB cluster, each new server must install YDB software according to the procedures described in the cluster deployment instructions. In particular, it is necessary to:

1. create an account and group in the operating system for the YDB service
2. install YDB software
3. prepare and place the corresponding TLS key and certificate on the server
4. copy the current YDB cluster configuration file to the server

TLS certificates used on new servers must comply with field filling requirements, and be signed by a trusted certificate authority used on existing servers of the expanded YDB cluster.

Adding Dynamic Nodes

Adding dynamic nodes allows increasing available computing resources (processor cores and RAM) for executing user queries by the YDB cluster.

To add a dynamic node to the cluster, it is sufficient to start the process serving this node, passing it the path to the cluster configuration folder, the name of the served database, and addresses of any three static cluster nodes in the command line parameters, as shown in the cluster deployment instructions.

After successfully adding a dynamic node to the cluster, information about it will be available on the cluster monitoring page in the YDB UI.

To remove a dynamic node from the cluster, it is sufficient to stop the dynamic node process.

Adding Static Nodes

Adding static nodes allows increasing throughput when performing input-output operations and increasing available capacity for data storage in the YDB cluster.

To add static nodes to the cluster, you need to perform the following sequence of actions:

1. Format disks that will be used for storing YDB data using the procedure described for the cluster deployment stage.
2. Obtain an authentication token for executing administrative commands using YDB CLI, for example:

   ```
   ydb -e grpcs://<node1.ydb.tech>:2135 -d /Root --ca-file ca.crt \
       --user root auth get-token --force > token-file
   ```

   The example command above uses the following parameters:

   - `node1.ydb.tech` — FQDN of any server hosting static cluster nodes
   - `2135` — grpcs service port number for static nodes
   - `ca.crt` — certificate authority certificate file name
   - `root` — username with administrative rights
   - `token-file` — name of the file where the authentication token is saved for subsequent use

   When executing the above command, YDB CLI will request a password for authenticating the specified user.
3. Get the current cluster configuration by executing the following command on any cluster node:

   ```
   ydb --token-file token-file --ca-file ca.crt -e grpcs://<node1.ydb.tech>:2135 \
       admin cluster config fetch > config.yaml
   ```

4. Correct the cluster configuration file, including in the configuration a description of the added nodes (in the `hosts` section) and disks used on them (in the `host_configs` section).
5. Allow the YDB cluster to use disks on new static nodes for data storage by executing the following command on any cluster node:

   ```
   export LD_LIBRARY_PATH=/opt/ydb/lib
   ydb --token-file ydbd-token-file --ca-file ca.crt -e grpcs://<node1.ydb.tech>:2135 \
       admin cluster config replace -f config.yaml
   echo $?
   ```

   The example command above uses the following parameters:

   - `ydbd-token-file` — name of the previously obtained authentication token file
   - `2135` — grpcs service port number for static nodes
   - `ca.crt` — certificate authority certificate file name

   If the above command returns a configuration version verification error, this means that the current config version is outdated, and you need to get a new one from the cluster by repeating step 3. Example configuration version verification error message:

   ```
   ErrorDescription: "ConfigVersion mismatch ConfigVersionProvided# 0 ConfigVersionExpected# 1"
   ```

6. Create an empty directory `/opt/ydb/cfg` on each new machine for the cluster to work with configuration. If multiple nodes are started on one machine, use the same directory. By executing a special command on each new machine, initialize this directory using any static cluster node as the configuration source.

   ```
   sudo mkdir -p /opt/ydb/cfg
   sudo chown -R ydb:ydb /opt/ydb/cfg
   ydb admin node config init --config-dir /opt/ydb/cfg --seed-node <node.ydb.tech:2135>
   ```

7. Start processes serving new static cluster nodes on the corresponding servers.
8. Ensure that new static nodes are displayed on the cluster monitoring page in the YDB UI.
9. Add additional storage groups to one or more databases by executing commands of the following type on any cluster node:

   ```
   export LD_LIBRARY_PATH=/opt/ydb/lib
   /opt/ydb/bin/ydbd -f ydbd-token-file --ca-file ca.crt -s grpcs://`hostname -f`:2135 \
       admin database /Root/testdb pools add ssd:1
   echo $?
   ```

   The example command above uses the following parameters:

   - `ydbd-token-file` - name of the previously obtained authentication token file
   - `2135` - grpcs service port number for static nodes
   - `ca.crt` - certificate authority certificate file name
   - `/Root/testdb` - full path to the database
   - `ssd:1` - storage pool name and number of allocated storage groups

10. Ensure that added storage groups are displayed on the cluster monitoring page in the YDB UI.

Removing static nodes from the YDB cluster is performed according to the documented decommissioning procedure.

In case of damage and inability to repair a server running a static cluster node, it is necessary to place the unavailable static node on a new server containing a similar or greater number and volume of disks.

Removing a node from a cluster

> **Warning**
>
> This article is dedicated to YDB clusters that use configuration V2. This configuration method is currently experimental and is only available for YDB versions starting from v25.1. For production use, we recommend choosing configuration V1 — it is the main method and is officially supported for all YDB clusters.

This article describes how to remove a dynamic or static node from a YDB cluster deployed manually on virtual machines or physical servers. Removing nodes from a Kubernetes deployment is outside the scope of this procedure.

Removing a dynamic node

Removing a dynamic node does not require changing the cluster configuration.

To remove a dynamic node without affecting query processing:

1. Drain the tablets from the node and wait for the operation to complete.
2. Stop the YDB process on the node. Check first that the process can be stopped safely, then stop it.

After stopping the process, check the **Nodes** tab on the cluster monitoring page and make sure that the removed node is no longer shown as active. A dynamic node may disappear from the list immediately or remain temporarily with the **Disconnected** status until its node ID lease in NodeBroker expires. If the node becomes active again, make sure that the process was stopped on the correct host and is not configured to restart automatically, for example, by a `systemd` unit or a supervisor.

Removing a static node

Static nodes serve the storage system and are listed in the `hosts` section. A static node can contain VDisks of dynamic and static groups, as well as State Storage, Board, and SchemeBoard replicas. These resources must be moved before the node is removed from the configuration.

Before starting the procedure, use the YDB UI to check that the affected storage groups are healthy, that is, all VDisks of these groups are shown in the `Ok` state (highlighted in green), with none in `Error` or `Degraded` state.

The remaining nodes must have enough free PDisk space and slots for all VDisks from the node being removed. VDisk placement across failure domains and failure realms must comply with the configured erasure coding scheme to preserve group fault tolerance after node removal. For details on calculating the required capacity margin, see Estimating Required Equipment.

SelfHeal is enabled for dynamic groups by default. Before removing the node, make sure it is also enabled for any resources hosted on this node:

- If the node contains a static group VDisk, enable static group SelfHeal. Alternatively, you can move the static group VDisk off the node manually, see Static Group Move.
- If the node contains State Storage, Board, or SchemeBoard replicas, enable Metadata Distribution SelfHeal. Alternatively, you can move these replicas off the node manually, see Configuring the State Storage, Board, and Scheme Board metadata distribution subsystems.

To remove a static node:

1. If tablets are running on the node, drain them.
2. Check that the process can be stopped safely, then stop it.
3. Wait for SelfHeal to move the VDisks from the node. With the default settings, relocation starts approximately one hour after the node is stopped. To start relocation immediately, first obtain the IDs of all PDisks on the node being removed using YDB DSTool:

   ```
   ydb-dstool -e <bs_endpoint> pdisk list --columns NodeId:PDiskId FQDN Path
   ```

   `<bs_endpoint>` is the endpoint of any available storage node in the `[PROTOCOL://]HOST[:PORT]` format, for example, `http://node1.example.com:8765`.

   Select every row whose `FQDN` matches the host name of the node being removed. Verify the disk paths in the `Path` column and save all corresponding `NodeId:PDiskId` values.

   Then set all identified PDisks to `BROKEN` in one command:

   ```
   ydb-dstool -e <bs_endpoint> pdisk set --status BROKEN --unavail-as-offline --pdisk-ids "<pdisk_id_1>"
   ... "<pdisk_id_N>"
   ```

   Use the same `<bs_endpoint>`. Replace `"<pdisk_id_1>" ... "<pdisk_id_N>"` with a space-separated list of all saved disk IDs in the `[NodeId:PDiskId]` format, for example, `"[3:1]" "[3:2]"` for two disks on the node with `NodeId` equal to `3`. The `--unavail-as-offline` option treats PDisks unavailable through the Whiteboard monitoring service as offline.

   The command runs in the foreground. Wait for it to complete successfully, then verify that data relocation is complete in the next step. For details, see Move VDisks from a broken/missing block store volume.
4. In the YDB UI, check that no VDisks remain on the node and that the affected storage groups are healthy (all VDisks are in the `Ok` state). If State Storage, Board, or SchemeBoard replicas were moved from the node, check that the relocation is complete.
5. Fetch the current cluster configuration using the ydb admin cluster config fetch command:

   ```
   ydb [global options...] admin cluster config fetch > config.yaml
   ```

6. If the node being removed is not the last entry in the `hosts` list, removing it shifts the positions of all subsequent entries. To preserve their identifiers, explicitly set `node_id` on each subsequent entry that does not already have one, using that entry's current identifier before removal: for an entry that relied on the default, this is its current one-based position in the list. If an entry already has an explicit `node_id`, preserve its existing value. If the last entry is being removed, this step is not required.

> **Warning**
>
> Correct node numbering is critical for cluster health. An error in `node_id` assignment can move VDisks, State Storage, Board, or SchemeBoard replicas to the wrong host and may lead to irreversible data loss.

For example, given the following configuration where the node `node3` is being removed:

```
hosts:
- host: node1
- host: node2
- host: node3 # to be removed
- host: node4
- host: node5
  node_id: 50
```

Before removing `node3`, explicitly set `node_id: 4` for `node4` so that its ID does not change to `3`. Keep the existing `node_id: 50` for `node5`. After removing `node3`, the list will look like this:

```
hosts:
- host: node1
- host: node2
- host: node4
  node_id: 4
- host: node5
  node_id: 50
```

7. Remove the node entry from the `hosts` section.
8. Apply the configuration using the ydb admin cluster config replace command:

```
ydb [global options...] admin cluster config replace -f config.yaml
```

If the command returns an error

If VDisks remain on the PDisks of the node being removed, the command returns an error similar to the following:

```
failed to remove PDisk# 1:1 as it has active VSlots
```

In this case, wait for SelfHeal to move the remaining VDisks. Relocation time depends on the amount of data and disk performance. Monitor the relocation on the **Storage** tab of the node being removed in the YDB UI. When no VDisks remain on the node, rerun the `config replace` command with the same file.

If the VDisk list is not shrinking and replication is not in progress, move the remaining VDisks manually.

After the configuration is applied successfully, the server and its disks can be decommissioned.

Configuring the State Storage, Board, and Scheme Board metadata distribution subsystems

Applies if you need to change the metadata distribution subsystem configuration consisting of State Storage, Board, and Scheme Board on a YDB cluster.

When using configuration V2, the metadata distribution subsystems are partially supported automatically through the SelfHeal mechanism — see Metadata Distribution SelfHeal (moving and adding replicas on topology changes). To disable this behavior, set `state_storage_self_heal_config.enable` to `false`, as described in the same section. Disabling is not required for the steps below: the configuration after `ydb admin cluster config replace` will be applied before the next automatic trigger.

> **Warning**
>
> Errors in metadata subsystem configuration (including the `domains_config` section) or an incorrect sequence of changes can lead to YDB cluster unavailability.

To manually change the State Storage configuration in a YDB cluster, perform the following steps.

1. Get the current cluster configuration using the ydb admin cluster config fetch command:

```
ydb [global options...] admin cluster config fetch --v2-internal-state > config.yaml
```

As a result of running this command, the current configuration will be saved to the file `config.yaml`.

2. Make the required changes to the section `domains_config` of the configuration file `config.yaml`:
   For rules on changing the `domains_config` section, see State Storage configuration rules.
3. Apply the new cluster configuration using the ydb admin cluster config replace command:

```
ydb [global options...] admin cluster config replace -f config.yaml
```

State Storage configuration rules

The rules listed below apply to `state_storage` and to the separate fields `explicit_state_storage_config`, `explicit_state_storage_board_config`, `explicit_scheme_board_config` in the section `domains_config` of the file `config.yaml` (see State Storage configuration). The `explicit_*` keys correspond individually to State Storage, Board, and Scheme Board.

In the configuration, a ring refers to a `ring` block inside a `ring_groups` list element (see State Storage configuration).

Configuration changes are performed in several steps. First, a new group of rings is added, consisting of properly selected nodes (according to the failure model), and then the old group of rings is removed.

To avoid cluster unavailability, add and remove ring groups strictly in the sequence of steps described below.

1. To change the configuration of metadata distribution subsystems without cluster unavailability, do so by adding and removing ring groups.
2. You can only add and remove ring groups with the `WriteOnly: true` parameter.
3. The new configuration must always contain at least one ring group from the previous configuration without the `WriteOnly` parameter. Such a ring group must be first in the list.
4. If different ring groups use the same cluster nodes, add the `ring_group_actor_id_offset:1` parameter to the ring group. The value must be unique among ring groups.

   This parameter makes replica identifiers unique within a given ring group; they will not match identifiers from other groups, allowing multiple replicas of the same type to be placed on a single cluster node.
5. The transition to the new configuration is performed in 4 sequential steps. At each step, a new configuration is prepared and applied to the cluster.

   Newly created or ready-to-remove ring groups are marked with the `WriteOnly: true` flag. This is necessary so that read requests are handled by the already deployed ring group while the new configuration spreads to the required number of nodes, new replicas are created, or old ones are removed.

   Therefore, pause for at least `1 minute` between steps.

   - Add a new ring group with the `WriteOnly: true` parameter corresponding to the target configuration.
   - Remove the `WriteOnly` flag.
   - Set the `WriteOnly: true` flag on the ring group corresponding to the old configuration, and move the new ring group to the beginning of the ring group list.
   - Remove the old ring group.

Example

Consider the current configuration as an example:

```
config:
  domains_config:
    explicit_scheme_board_config:
      ring:
        nto_select: 5
        node: [1,2,3,4,5,6,7,8]
```

and the target configuration:

```
config:
  domains_config:
    explicit_scheme_board_config:
      ring:
        nto_select: 5
        node: [10,20,30,40,5,6,7,8]
```

We want to move some replicas to other cluster nodes.

Step 1
At the first step, prepare `ring_groups` following the configuration rules: the first ring group matches the **current** configuration from the listings above, the second matches the **target** one and is marked with `WriteOnly: true`. Specify the `ring_group_actor_id_offset` parameter as described in the same rules if the node sets of the groups match.

```
config:
  domains_config:
    explicit_scheme_board_config:
      ring_groups:
        - ring:
          nto_select: 5
          node: [1,2,3,4,5,6,7,8]
        - ring:
          nto_select: 5
          node: [10,20,30,40,5,6,7,8]
          write_only: true
          ring_group_actor_id_offset: 1
```

Step 2
Remove the `WriteOnly` flag.

```
config:
  domains_config:
    explicit_scheme_board_config:
      ring_groups:
        - ring:
          nto_select: 5
          node: [1,2,3,4,5,6,7,8]
        - ring:
          nto_select: 5
          node: [10,20,30,40,5,6,7,8]
          ring_group_actor_id_offset: 1
```

Step 3
Make the new ring group first in the list. Set the `WriteOnly: true` flag on the old configuration.

```
config:
  domains_config:
    explicit_scheme_board_config:
      ring_groups:
        - ring:
          nto_select: 5
          node: [10,20,30,40,5,6,7,8]
          ring_group_actor_id_offset: 1
        - ring:
          nto_select: 5
          node: [1,2,3,4,5,6,7,8]
          write_only: true
```

Step 4
Apply the target configuration to the cluster:

```
config:
  domains_config:
    explicit_scheme_board_config:
      ring_groups:
        - ring:
          nto_select: 5
          node: [10,20,30,40,5,6,7,8]
          ring_group_actor_id_offset: 1
```

Verifying the result

You can verify that the changes have been applied in the `CMS` section of the cluster YDB UI (available on port 8765): go to the `Tablets` tab and check the replicas of the metadata subsystem tablets to confirm that the configuration has been picked up.

State Storage Move

Article under development

> **Warning**
>
> This article is dedicated to YDB clusters that use configuration V2. This configuration method is currently experimental and is only available for YDB versions starting from v25.1. For production use, we recommend choosing configuration V1 — it is the main method and is officially supported for all YDB clusters.

If you need to decommission a YDB cluster node that contains part of State Storage, you need to move it to another node.

> **Warning**
>
> Errors in metadata subsystem configuration (including the `domains_config` section) or an incorrect sequence of changes can lead to YDB cluster unavailability.

When using Configuration V2, State Storage configuration is performed automatically. To make changes to the configuration, you need to perform the following actions: stop automatic State Storage configuration management, get the current State Storage configuration, change the current configuration in the desired way and specify it explicitly as the target, then apply it, ensure it is applied, perform node decommissioning, remove explicit State Storage configuration specification and enable automatic State Storage configuration.

As an example, consider a YDB cluster where node 1 is part of State Storage, and node 10 is not, and we will assume that the goal of changing the State Storage configuration is to decommission node 1.

1. Stop automatic State Storage configuration management
2. Get the current State Storage configuration
3. Change the current configuration in the desired way and specify it explicitly as the target

   Suppose the following State Storage configuration is obtained:

   ```
   ...
     state_storage:
     - ring:
         node: [1, 2, 3, 4, 5, 6, 7, 8, 9]
         nto_select: 9
       ssid: 1
   ...
   ```

   A static node is configured and running on the host with `node_id:1`, which is a part of State Storage. Suppose we need to decommission this host.

   To replace `node_id:1`, we use another host with a static node deployed on it with `node_id:10`.

   To move State Storage from node `node_id:1` to `node_id:10`, in the configuration file `config.yaml` change the `node` host list, replacing the identifier of the node to be removed with the identifier of the node to be added:

   ```
   ...
     state_storage:
     - ring:
         node: [10, 2, 3, 4, 5, 6, 7, 8, 9]
         nto_select: 9
       ssid: 1
   ...
   ```

4. Apply the configuration.
5. Ensure the configuration is applied.
   Note that the full application of new State Storage nodes after reconfiguration occurs with a delay of at least 15 seconds.
6. Perform node decommissioning.
7. Remove explicit State Storage configuration specification.
8. Enable automatic State Storage configuration.

Static Group Move

Article under development

> **Warning**
>
> This article is dedicated to YDB clusters that use configuration V2. This configuration method is currently experimental and is only available for YDB versions starting from v25.1. For production use, we recommend choosing configuration V1 — it is the main method and is officially supported for all YDB clusters.

When using Configuration V2, static group management is performed automatically and the SelfHeal mechanism will perform reconfiguration when one static group node fails.

When manual static group configuration management is needed, disable automatic static group management, get the current static group configuration, make changes and apply the modified configuration as the target static group configuration. Then remove the target static group configuration from the configuration file and enable automatic static group configuration management.

> **Warning**
>
> Errors in metadata subsystem configuration (including the `domains_config` section) or an incorrect sequence of changes can lead to YDB cluster unavailability.

As an example, consider a YDB cluster where a static node is configured and running on the host with `node_id:1`. This node serves part of the static group.

Static group configuration fragment:

```
...
groups:
  ...
  rings:
    ...
    fail_domains:
    - vdisk_locations:
      - node_id: 1
        path: /dev/vda
        pdisk_category: SSD
    ...
...
```

To replace `node_id:1`, use another host with a static node deployed on it with `node_id:10`.

To move part of the static group from host `node_id:1` to `node_id:10`:

1. Disable automatic static group management.
2. Get the current static group configuration.
3. Make changes and apply the modified configuration as the target static group configuration.

   In the configuration file `config.yaml`, change the `node_id` value, replacing the identifier of the host being removed with the identifier of the host being added:

   ```
   ...
   groups:
     ...
     rings:
       ...
       fail_domains:
       - vdisk_locations:
         - node_id: 10
           path: /dev/vda
           pdisk_category: SSD
       ...
   ...
   ```

   Change the `path` and disk `pdisk_category` if they differ on the host with `node_id: 10`.
4. Go to the YDB UI monitoring page and ensure that the static group VDisk appeared on the target physical disk and is replicating. For more details, see Monitoring static groups.
5. Remove the target static group configuration from the configuration file and enable automatic static group configuration management.

Replacing Node FQDN

This procedure describes how to replace the FQDN (Fully Qualified Domain Name) of a YDB cluster node without downtime.

Prerequisites

> **Note**
>
> A YDB cluster is fault-tolerant. Temporary node shutdown does not lead to cluster unavailability. For more details, see YDB Cluster Topology.

> **Warning**
>
> Errors in metadata subsystem configuration (including the `domains_config` section) or an incorrect sequence of changes can lead to YDB cluster unavailability.

Procedure Overview

The FQDN replacement process involves:

1. **Preparation**: Verify cluster health and prepare a new node configuration
2. **Node shutdown**: Gracefully stop the node to be replaced
3. **Configuration update**: Update the cluster configuration with a new FQDN
4. **Node restart**: Start the node with new FQDN
5. **Verification**: Confirm successful FQDN change

Step-by-Step Instructions

Step 1: Verify Cluster Health

Before starting the replacement, ensure the cluster is healthy:

```
ydb monitoring healthcheck
```

Step 2: Prepare New Node Configuration

1. Update DNS records to point the new FQDN to the same IP address
2. Update TLS certificates if they include hostname verification
3. Prepare updated configuration files with the new FQDN

Step 3: Stop the Target Node

Gracefully stop the node that needs FQDN replacement:

```
# For systemd-managed nodes
sudo systemctl stop ydbd-storage

# For manually started nodes
kill -TERM <ydbd_pid>
```

Step 4: Update Cluster Configuration

Update the cluster configuration to reflect the new FQDN:

```
# Example configuration update
hosts:
  - host: new-hostname.example.com  # Updated FQDN
    host_config_id: 1
    port: 19001
    location:
      unit: "1"
      data_center: "DC1"
      rack: "1"
```

Step 5: Apply Configuration Changes

Apply the updated configuration to the cluster:

```
ydb admin config replace --config-file updated-config.yaml
```

Step 6: Start Node with New FQDN

Start the node using the new FQDN:

```
# Update hostname if necessary
sudo hostnamectl set-hostname new-hostname.example.com

# Start the node
sudo systemctl start ydbd-storage
```

Step 7: Verify the Change

Confirm the FQDN change was successful:

```
# Check node status
ydb monitoring healthcheck

# Verify node registration
ydb admin config fetch | grep new-hostname
```

Troubleshooting

Common Issues

1. **DNS resolution problems**: Ensure new FQDN resolves correctly
2. **Certificate validation errors**: Update certificates if they include hostname verification
3. **Node registration failures**: Check network connectivity and firewall rules

Recovery Procedures

If the FQDN replacement fails:

1. Revert DNS changes to the original FQDN
2. Restore the original configuration
3. Restart the node with the original settings
4. Investigate and resolve the underlying issue

Best Practices

1. **Test in staging**: Always test FQDN replacement in a non-production environment first
2. **Backup configurations**: Keep backups of working configurations before making changes
3. **Monitor during change**: Watch cluster health metrics during the replacement process
4. **Document changes**: Maintain records of FQDN changes for future reference
5. **Coordinate with the team**: Ensure all team members are aware of the planned change

Database Node Authentication and Authorization

Database node authentication in a YDB cluster ensures verification of database node authenticity when making service calls to other nodes via the gRPC protocol. Node authorization ensures verification and provision of necessary permissions when processing service calls, including operations for registering starting nodes in the cluster and accessing configuration. Using database node authentication and authorization is recommended for all YDB clusters, as it helps avoid situations of unauthorized data access through the inclusion of attacker-controlled nodes in the cluster.

Database node authentication and authorization is performed in the following order:

1. The starting database node opens a gRPC connection to one of the cluster storage nodes specified in the `--node-broker` command-line option. The connection uses the TLS protocol, and the starting node's certificate is used as the client certificate in the connection settings.
2. The storage node and database node perform mutual authenticity verification using the TLS protocol: the certificate trust chain is verified and the hostname correspondence to the "Subject Name" field value of the certificate is checked.
3. The storage node verifies that the "Subject" field of the certificate meets the requirements established by settings in the static configuration.
4. Upon successful completion of the above checks, the connection from the database node is considered authenticated, and it is assigned an access subject identifier — SID, determined by the settings.
5. The database node uses the established gRPC connection to register as part of the cluster using the corresponding service call. During registration, the database node transmits its network address intended for interaction with other cluster nodes.
6. The storage node verifies that the SID assigned to the gRPC connection is in the list of allowed ones. Upon successful completion of this check, the storage node registers the database node in the cluster, mapping the received network address to the node identifier.
7. The database node joins the cluster by connecting through its network address and specifying the node identifier received during registration. Attempts to join the cluster by nodes with unknown network addresses or identifiers are blocked by other nodes.

The following describes the settings necessary to enable database node authentication and authorization.

Configuration Prerequisites

1. The deployed YDB cluster must have gRPC traffic encryption configured using the TLS protocol.
2. When preparing node certificates for a cluster where database node authentication and authorization is planned to be used, it is necessary to ensure uniform rules for filling the "Subject" field of certificates, allowing identification of certificates issued for cluster nodes. More information is provided in the certificate verification rules configuration documentation.

   > **Note**
   >
   > The proposed example script for generating self-signed YDB node certificates fills the "Subject" field with the value `O=YDB` for all node certificates. The configuration examples provided below are prepared for certificates with exactly this "Subject" field content.

3. The command-line parameters for starting database nodes must include options that specify paths to certificate files from trusted certificate authorities, a node certificate, and a node key. The list of additional options is provided in the table below.

Command-line Option	Description
`--grpc-ca`	Path to the certificate file `ca.crt` from a trusted certificate authority.
`--grpc-cert`	Path to the node certificate file `node.crt`.
`--grpc-key`	Path to the node private key file `node.key`.

   Example command for starting a database node with options specifying paths to TLS keys and certificates for the gRPC protocol:

   ```
   /opt/ydb/bin/ydbd server --config-dir /opt/ydb/cfg --tenant /Root/testdb \
       --grpcs-port 2136 --grpc-ca /opt/ydb/certs/ca.crt \
       --grpc-cert /opt/ydb/certs/node.crt --grpc-key /opt/ydb/certs/node.key \
       --ic-port 19002 --ca /opt/ydb/certs/ca.crt \
       --mon-port 8766 --mon-cert /opt/ydb/certs/web.pem \
       --node-broker grpcs://<ydb1>:2135 \
       --node-broker grpcs://<ydb2>:2135 \
       --node-broker grpcs://<ydb3>:2135
   ```

Enabling Database Node Authentication and Authorization

> **Note**
>
> Starting from version 25.2, properly configured database node authentication is mandatory.
>
> Node registration in the cluster is impossible without successful authentication.

To enable mandatory database node authorization, the following configuration blocks must be added to the cluster configuration file:

1. At the root level of the configuration, add a `client_certificate_authorization` block specifying requirements for filling the "Subject" field of trusted certificates of connecting nodes, for example:

   ```
   client_certificate_authorization:
     request_client_certificate: true
     client_certificate_definitions:
       - member_groups: ["registerNode@cert"]
         subject_terms:
         - short_name: "O"
           values: ["YDB"]
   ```

If necessary, add other certificate checks according to the documentation.

After the certificate is verified and its "Subject" field is confirmed to comply with the requirements established in the `subject_terms` block, the connection will be assigned access subjects from the `member_groups` parameter. To distinguish such access subjects, the `@cert` suffix is added to their names.

2. In the `security_config` section of the cluster configuration, add the `register_dynamic_node_allowed_sids` element with a list of access subjects allowed to register database nodes. Example:

   ```
   security_config:
     enforce_user_token_requirement: true
     ...
     register_dynamic_node_allowed_sids:
     - "registerNode@cert"
   ```

   For more information on configuring cluster authentication parameters, see Configuring Administrative and Other Privileges.

3. In the `auth_config` section of the cluster configuration, add the `node_registration_token` as an empty string. Example:

   ```
   auth_config:
     ...
     node_registration_token: ""
   ```

4. Update the static configuration files on all cluster nodes manually or using the Ansible playbook.
5. Perform a rolling restart of cluster storage nodes using ydbops or using the Ansible playbook.
6. Perform a rolling restart of cluster database nodes using ydbops or using the Ansible playbook.

Static group SelfHeal

> **Warning**
>
> This article is dedicated to YDB clusters that use configuration V2. This configuration method is currently experimental and is only available for YDB versions starting from v25.1. For production use, we recommend choosing configuration V1 — it is the main method and is officially supported for all YDB clusters.

When using configuration V2, SelfHeal can automatically move a static group VDisk from faulty PDisks and restore the group's fault tolerance.

The general SelfHeal mechanism detects a faulty PDisk and initiates VDisk relocation. For dynamic groups, the Blob Storage Controller changes the configuration, while distributed configuration changes the static group configuration.

To allow distributed configuration to change the static group automatically, enable the `automatic_static_group_management` parameter. This parameter is disabled by default.

Enabling and disabling static group SelfHeal

Static group SelfHeal requires the following components to be enabled:

- distributed configuration V2 — `self_management_config.enabled: true`;
- the general SelfHeal mechanism, which is enabled by default.

To enable or disable automatic static group management:

1. Fetch the current cluster configuration using the ydb admin cluster config fetch command:

   ```
   ydb [global options...] admin cluster config fetch > config.yaml
   ```

2. Set the `automatic_static_group_management` parameter in the `config.yaml` configuration file:

   ```
   config:
     self_management_config:
       enabled: true
       automatic_static_group_management: true
   ```

   `true` enables automatic static group management, while `false` disables it.

3. Apply the updated configuration using the ydb admin cluster config replace command:

   ```
   ydb [global options...] admin cluster config replace -f config.yaml
   ```

Restricting the set of target nodes

By default, SelfHeal can move a static group VDisk to any suitable node. To restrict the set of target nodes, specify their IDs in the `static_group_self_heal_allowed_nodes` parameter:

```
config:
  self_management_config:
    enabled: true
    automatic_static_group_management: true
    static_group_self_heal_allowed_nodes:
    - 1
    - 2
    - 3
```

An empty list means that no restrictions apply. The allowed nodes must have suitable PDisks and enough free space to move the VDisk without violating the failure model.

Cluster Configuration Migration

YDB supports two configuration management mechanisms: V1 and V2 (experimental, available from version 25.1). Key differences between them are described in the article Comparing configurations V1 and V2.

Tip

New YDB clusters are recommended to be deployed using configuration V2. If a cluster was deployed using configuration V1, it will still use it after updating to YDB version 25.1 or higher. After such an update, it is recommended to plan and perform migration to V2, because support for V1 will be discontinued in future versions of YDB. For the instructions on how to determine the configuration version of the cluster, see Checking Configuration Version.

Depending on the current state of your cluster, you can perform migration:

- **To configuration V2:** If your cluster is managed by configuration V1, you can switch to the experimental configuration V2 mechanism.
- **To configuration V1:** If unexpected problems arose after switching to configuration V2, or you need to roll back the YDB version below 25.1, you can perform reverse migration to manual configuration management (V1).

Problems during migration?

If unexpected problems arise when using migration instructions (especially when rolling back to V1), it is recommended to report them immediately as a GitHub issue, providing maximum context and diagnostics for reproduction.

Before performing migration, make sure to determine which configuration version is currently used in your cluster using the version check instructions.

Migration to Configuration V2

> **Warning**
>
> This article is dedicated to YDB clusters that use configuration V2. This configuration method is currently experimental and is only available for YDB versions starting from v25.1. For production use, we recommend choosing configuration V1 — it is the main method and is officially supported for all YDB clusters.

This document contains instructions for migrating from configuration V1 to configuration V2.

In configuration V1, there are two different mechanisms for applying configuration files:

- static configuration manages storage nodes of the YDB cluster and requires manual placement of files on each cluster node;
- dynamic configuration manages database nodes of the YDB cluster and is loaded into the cluster centrally using YDB CLI commands.

In configuration V2, this process is unified: a single configuration file is loaded into the system through YDB CLI commands, automatically delivered to all cluster nodes.

The State Storage and static group components of the YDB cluster are key to the cluster's correct operation. When working with configuration V1, these components are configured manually by specifying the `domains_config` and `blob_storage_config` sections in the configuration file.
In configuration V2, automatic configuration of these components is possible without specifying the corresponding sections in the configuration file.

Initial State

Migration to configuration V2 can be performed if the following conditions are met:

1. The YDB cluster has been updated to version 25.1 and higher.
2. The YDB cluster is configured with a configuration V1 file `config.yaml`, located in the node file system and connected through the `ydbd --yaml-config` argument.
3. The cluster configuration file contains the `domains_config` and `blob_storage_config` sections for configuring State Storage and static group respectively.

Checking the Current Configuration Version

Before starting the migration, ensure that your cluster is running on configuration V1. You can find out the current configuration version on nodes using several methods described in the article Checking Configuration Version.

You should continue following this instruction only if the nodes are running on configuration version V1. If all nodes already have version V2 enabled, migration is not required.

Instructions for Migration to Configuration V2

To migrate the YDB cluster to configuration V2, you need to perform the following steps:

1. Check for the presence of a dynamic configuration file in the cluster. To do this, run the ydb admin cluster config fetch command:

   ```
   ydb -e grpc://<node.ydb.tech>:2135 admin cluster config fetch > config.yaml
   ```

   If no such configuration exists in the cluster, the command will output the message:

   ```
   No config returned.
   ```

   If a file is found, you should use it and skip the next step of this instruction. Before proceeding, make sure that the file contains the settings that were stored in the static configuration file on storage nodes in configuration V1.
2. If there is no dynamic configuration file in the cluster, run the dynamic configuration file generation command ydb admin cluster config generate. The file will be generated based on the static configuration file located on the cluster nodes.

   ```
   ydb -e grpc://<node.ydb.tech>:2135 admin cluster config generate > config.yaml
   ```

3. Check that the `config.yaml` file obtained in step 1 or 2 contains the storage node settings from the current static configuration V1. If the file was obtained from an existing dynamic configuration, these settings may be missing because in V1 dynamic configuration might not contain storage node parameters.

   The goal of this step is to get a single combined configuration file that contains both parameters from the dynamic configuration and settings from the static configuration.

   Move all sections and parameters that describe storage nodes, disks, State Storage, static group, and channel profiles from the static configuration file to the `config` section of the `config.yaml` file. In particular, check for the following sections and parameters if they are set in the static configuration V1:

   - `hosts`;
   - `host_configs`;
   - `domains_config`;
   - `blob_storage_config`;
   - `channel_profile_config`;
   - other related storage configuration parameters, such as `static_erasure`.
4. Enable the `switch_to_config_v2` feature flag in the checked and updated `config.yaml` file:

   ```
   feature_flags:
       ...
       switch_to_config_v2: true
   ```

More details

Enabling this flag means that the DS Controller tablet, not the Console tablet, is now responsible for configuration storage and operations. This switches the main cluster configuration management mechanism.

5. Place the `config.yaml` file on all cluster nodes, replacing the previous configuration file with it.
6. Create a directory for the YDB node to work with configuration on each node. If running multiple cluster nodes on one host, create separate directories for each node. Initialize the directory by running the ydb admin node config init command on each node. In the `--from-config` parameter, specify the path to the `config.yaml` file placed on the nodes earlier.

```
sudo mkdir -p /opt/ydb/config-dir
sudo chown -R ydb:ydb /opt/ydb/config-dir
ydb admin node config init --config-dir /opt/ydb/config-dir --from-config /opt/ydb/cfg/config.yaml
```

More details

In the future, the system will independently save the current configuration in the specified directories.

7. Restart all cluster nodes using the rolling-restart procedure, adding the `ydbd --config-dir` option when starting the node with the path to the directory specified, and removing the `ydbd --yaml-config` option.

Manual

When starting manually, add the `--config-dir` option to the `ydbd server` command, without specifying the `--yaml-config` option:

```
ydbd server --config-dir /opt/ydb/config-dir
```

Using systemd

When using systemd, add the `--config-dir` option to the `ydbd server` command in the systemd configuration file, and also remove the `--yaml-config` option:

```
ExecStart=/opt/ydb/bin/ydbd server --config-dir /opt/ydb/config-dir
```

After updating the systemd file, run the following command to apply the changes:

```
sudo systemctl daemon-reload
```

8. Load the previously obtained configuration file `config.yaml` into the system using the ydb admin cluster config replace command:

```
ydb -e grpc://<node.ydb.tech>:2135 admin cluster config replace -f config.yaml
```

The command will request confirmation to perform the operation `This command may damage your cluster, do you want to continue? [y/N]`, in response to this request you need to agree and enter `y`.

More details

After executing the command, the configuration file will be loaded into the internal storage of the DS Controller tablet and saved in the directories specified in the `--config-dir` option on each node. From this moment, any configuration change on existing nodes is performed using special commands of the YDB CLI. Also, when starting a node, the current configuration will be automatically loaded from the configuration directory.

9. Get the current cluster configuration using ydb admin cluster config fetch:

```
ydb -e grpc://<node.ydb.tech>:2135 admin cluster config fetch > config.yaml
```

The `config.yaml` file should match the configuration files distributed across the cluster nodes, except for the `metadata.version` field, which should be one unit higher compared to the version on the cluster nodes.

10. Add the following block to `config.yaml` in the `config` section:

```
self_management_config:
  enabled: true
```

More details

This section is responsible for enabling the distributed configuration mechanism in the cluster. Configuration storage and any operations on it will be performed through this mechanism.

11. Load the updated configuration file into the cluster using ydb admin cluster config replace:

```
ydb -e grpc://<node.ydb.tech>:2135 admin cluster config replace -f config.yaml
```

12. Restart all storage nodes of the cluster using the rolling restart procedure.
13. If there is a `config.domains_config.security_config` section in the `config.yaml` file, move it one level up — to the `config` section.
14. Remove the `config.blob_storage_config` and `config.domains_config` sections from the `config.yaml` file.

15. Load the updated configuration file into the cluster:

```
ydb -e grpc://<node.ydb.tech>:2135 admin cluster config replace -f config.yaml
```

More details

After loading the configuration, the YDB cluster will be switched to automatic configuration management mode for State Storage and static group using the distributed configuration mechanism.

You can verify the successful completion of the migration by checking the configuration version on the cluster nodes using one of the methods described in the article Checking Configuration Version. On all cluster nodes, the `Configuration version` should be equal to `v2`.

Result

As a result of the performed actions, the cluster will be migrated to configuration V2 mode. Unified configuration management is performed using special commands of the YDB CLI, static group and State Storage are managed automatically by the system.

Migration to Configuration V1

This document contains instructions for migrating from configuration V2 to configuration V1.

> **Note**
>
> This guide is intended for emergency situations when unexpected problems arise after migrating to configuration V2 and a rollback to configuration V1 is required, for example, for subsequent rollback to a YDB version below v25-1. This procedure is not required in normal operation mode.

Initial State

Migration to configuration V1 is only possible if the cluster uses configuration V2. This can be achieved:

- as a result of migration to configuration V2
- during initial deployment of the cluster

You can determine the current configuration version on nodes using several methods described in the article Checking Configuration Version. Before starting the migration, ensure that the cluster is running on configuration V2.

Instructions for Migration to Configuration V1

To migrate the YDB cluster to configuration V1, you need to perform the following steps:

1. Get the current cluster configuration using the ydb admin cluster config fetch command:

   ```
   ydb -e grpc://<node.ydb.tech>:2135 admin cluster config fetch --v2-internal-state > config.yaml
   ```

   More details

   The `--v2-internal-state` argument specifies that the full cluster configuration will be retrieved, including State Storage and static group configuration parameters.

2. Modify the `config.yaml` configuration file by changing the `self_management_config.enabled` parameter value from `true` to `false`:

   ```
   self_management_config:
     enabled: false
   ```

   More details

   This section is responsible for managing the distributed configuration mechanism. Setting `enabled: false` disables this mechanism. Further management of State Storage and static group configuration will be performed manually through the `domains_config` and `blob_storage_config` sections respectively in the configuration file (these sections were obtained in the previous step when using the `--full` flag).

3. Load the updated configuration file into the cluster using ydb admin cluster config replace:

   ```
   ydb -e grpc://<node.ydb.tech>:2135 admin cluster config replace -f config.yaml
   ```

4. Restart all cluster nodes using the rolling restart procedure.

   More details

   After restarting the nodes, the cluster will be switched to manual State Storage and static group management mode, but will still use a unified configuration file delivered through the BSController tablet. Node configuration at startup will still be read from the directory specified in the `ydbd --config-dir` option and saved there.

5. Get the current cluster configuration using `ydb admin cluster config fetch`:

   ```
   ydb -e grpc://<node.ydb.tech>:2135 admin cluster config fetch > config.yaml
   ```

   More details

   The obtained configuration will not contain the `domains_config` and `blob_storage_config` sections, as they are managed manually and should not be part of the dynamic configuration.

6. Place the obtained `config.yaml` file (this will be your static configuration V1) in the file system of each cluster node.
7. Restart all cluster nodes using the rolling-restart procedure, specifying the path to the static configuration file through the `ydbd --yaml-config` option and removing the `ydbd --config-dir` option:

   Manual

   When starting manually, add the `--yaml-config` option to the `ydbd server` command, without specifying the `--config-dir` option:

   ```
   ydbd server --yaml-config /opt/ydb/cfg/config.yaml
   ```

   Using systemd

   When using systemd, add the `--yaml-config` option to the `ydbd server` command in the systemd configuration file, and also remove the `--config-dir` option:

```
ExecStart=/opt/ydb/bin/ydbd server --yaml-config /opt/ydb/config/config.yaml
```

After updating the systemd file, run the following command to apply the changes:

```
sudo systemctl daemon-reload
```

You can verify the successful completion of the migration by checking the configuration version on the cluster nodes using one of the methods described in the article Checking Configuration Version. All cluster nodes should use configuration `v1`.

Result

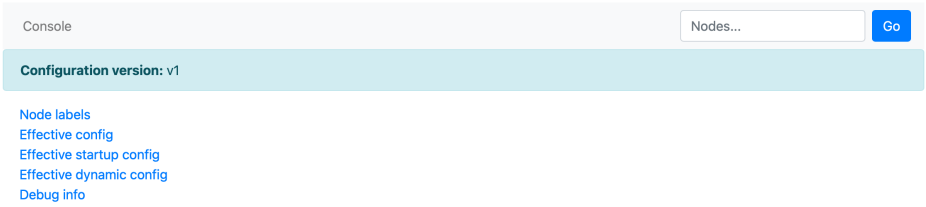
As a result of the performed actions, the cluster will be migrated to configuration V1 mode. The configuration consists of two parts: static and dynamic, static group and State Storage management is performed manually.

Checking Configuration Version

There are two main ways to check which configuration mechanism version (V1 or V2) the nodes of your YDB cluster are using:

1. YDB UI
2. Cluster metrics

With YDB UI



This method can be used if metrics collection from the YDB cluster to the monitoring system is not configured. You can check the configuration version for a specific node or switch between nodes in YDB UI:

1. Open the `configs_dispatcher` actor page for any cluster node in your browser:

   ```
   http://<endpoint>:8765/actors/configs_dispatcher
   ```

   where `<endpoint>` is the address of any YDB cluster node.
2. In the upper part of the opened page, find the `Configuration version` field. It shows the configuration version (`v1` or `v2`) used by this node.

   This is how the page of a node using configuration V1 looks:

3. To check other nodes, use the `Nodes...` search field in the upper right corner of the page to switch between nodes.

With Cluster Metrics

This method is convenient when there are a large number of nodes in the YDB cluster. If you have configured metrics collection from the YDB cluster to the monitoring system, perform the following actions:

1. Find the dashboard displaying cluster metrics.
2. Go to the `config` sensor group and the `configs_dispatcher` subsystem.
3. Pay attention to the `ConfigurationV1` and `ConfigurationV2` sensors. The values of these sensors show the number of cluster nodes running with configuration V1 and V2 respectively.

For example, if `ConfigurationV1 > 0` , it means there are nodes in the cluster that use configuration V1. If `ConfigurationV1 = 0` and `ConfigurationV2` equals the total number of nodes, it means all nodes use configuration V2.

Comparing YDB Cluster Configurations: V1 and V2

In YDB, there are two main approaches to cluster configuration management: V1 and V2. Starting from YDB version 25.1, configuration V2 is supported, which unifies YDB cluster management, allows working with configuration entirely through the YDB CLI, and also automates the most complex aspects of configuration (managing static group and State Storage). Configuration V2 is currently experimental and is not recommended for use in production environments.

> **Tip**
>
> New YDB clusters are recommended to be deployed using configuration V2. If a cluster was deployed using configuration V1, it will still use it after updating to YDB version 25.1 or higher. After such an update, it is recommended to plan and perform migration to V2, because support for V1 will be discontinued in future versions of YDB. For the instructions on how to determine the configuration version of the cluster, see Checking Configuration Version.

This article describes the key differences between these two approaches.

Characteristic	Configuration V1	Configuration V2
Configuration structure	Separate: static and dynamic.	**Unified** configuration.
File management	Static: manual file placement on each node. Dynamic: centralized upload via CLI.	Unified: centralized upload via CLI, automatic delivery to all nodes.
Delivery and application mechanism	Static: read and applied from a local file at startup. Dynamic: through `Console` tablet.	Fully automatic via the distributed configuration mechanism.
State Storage and static group management	**Manual**: mandatory `domains_config` and `blob_storage_config` sections in static configuration.	**Automatic**: managed by the distributed configuration system.
Recommended for YDB versions	Production use for all YDB versions.	Experimental use on clusters version 25.1 and above.

Configuration V1

Configuration V1 of a YDB cluster consists of two parts:

- **Static configuration:** manages key node parameters, including State Storage and static group configuration (`domains_config` and `blob_storage_config` sections respectively). Requires manual placement of the same configuration file on each cluster node. The path to the configuration is specified when starting the node using the `--yaml-config` option.
- **Dynamic configuration:** manages other cluster parameters. Loaded centrally using the `ydb admin config replace` command and distributed to database nodes.

If your cluster is running on configuration V1, it is recommended to perform migration to configuration V2.

Configuration V2

Starting from YDB version 25.1, configuration V2 is supported. Key features:

- **Unified configuration file:** the entire cluster configuration is stored and managed as a single entity.
- **Centralized management:** configuration is loaded to the cluster using the `ydb admin cluster config replace` command and automatically delivered to all nodes by the YDB cluster itself through the distributed configuration mechanism.
- **Early validation:** the configuration file is validated before delivering it to cluster nodes, not when restarting the server process.
- **Automatic State Storage and static group management:** V2 supports automatic configuration, which allows skipping these sections in the configuration file.
- **Storage on nodes:** the current configuration is automatically saved by each node in a special directory (specified by the `--config-dir` option when starting `ydbd`) and used during subsequent restarts.

Using configuration V2 is recommended for all YDB clusters version 25.1 and above.

YDB Deployment Options

This section of YDB documentation describes methods for deploying YDB clusters using various infrastructure management tools, as well as instructions for further work with them depending on the chosen method.

- **Ansible**: for deployments on bare metal and virtual machines.
- **Kubernetes**: for containerized deployments.
- **Manual**: for manual deployment.

Regardless of the chosen infrastructure management method, it is recommended to familiarize yourself with YDB system requirements before getting started.

Working With YDB Using Ansible

This section of YDB documentation contains a collection of articles intended for DevOps engineers managing YDB clusters using Ansible. This is the recommended approach to running production YDB clusters directly on virtual machines or bare metal. It is recommended to use Kubernetes instead of Ansible for containerized environments.

The key articles to get started with this section:

- Deploying a YDB cluster with Ansible
- Deploy Infrastructure for YDB Cluster using Terraform
- Restarting YDB Clusters deployed with Ansible
- Observability:
  - Logging on Clusters Deployed with Ansible

Deploying a YDB cluster with Ansible

This guide describes the process of deploying a YDB cluster on a group of servers using Ansible. This approach is recommended for environments with physical servers or virtual machines.

Key materials:

- Deployment preparation
- Deploying a cluster using configuration V1
- Deploying a cluster using configuration V2

Deployment preparation

Prerequisites

Choose a topology for installation

Before installing, choose a suitable YDB cluster topology — it determines the number of servers and disks required:

To get started with YDB, we recommend the `mirror-3dc-3-nodes` topology. It requires only 3 servers and 9 disks for user data — the simplest and fastest way to create a pilot cluster.

For large-scale deployments, choose one of the following options:

- `mirror-3-dc` — for clusters spread across multiple datacenters. Requires at least 9 servers and 9 disks for user data.
- `block-4-2` — for a cluster in a single datacenter. Requires at least 8 servers and 8 disks for user data.

Each server must have at least one dedicated disk for user data. We also recommend adding a separate small disk for the operating system. For more on topology and redundancy options, see this article.

You can expand the cluster later without stopping the cluster or interrupting user access to data.

Server configuration

Note

Recommended server requirements:

- 16 CPU cores (based on 8 CPUs used by the storage node and 8 CPUs by the dynamic node).
- 16 GB RAM (recommended minimum).
- Additional SSD disks for data, at least 120 GB each.
- SSH access.
- Network connectivity between machines in the cluster.
- OS: Ubuntu 18+, Debian 9+.
- Internet access for updating repositories and downloading required packages.

See YDB System Requirements and Recommendations for more details.

When using virtual machines from a public cloud provider, we recommend following Deploy Infrastructure for YDB Cluster using Terraform.

Software setup

To work with the project on your local (staging or installation) machine, you need:

- Python 3 version 3.10+
- Ansible core version 2.11 through 2.18
- A working directory on a machine with SSH access to all cluster servers

Tip

We recommend keeping the working directory and all files created during this guide in a version control system repository, for example Git. If multiple DevOps engineers will work with the cluster being deployed, they should collaborate in a shared repository.

If Ansible is already installed, you can go to the Ansible project setup section. If Ansible is not installed yet, install it using one of the following methods:

Installing Ansible globally

Using Ubuntu 22.04 LTS as an example:

- Update the apt package list with `sudo apt-get update`.
- Upgrade packages with `sudo apt-get upgrade`.
- Install the `software-properties-common` package to manage your distribution's software sources — `sudo apt install software-properties-common`.
- Add a new PPA to apt — `sudo add-apt-repository --yes --update ppa:ansible/ansible`.
- Install Ansible — `sudo apt-get install ansible-core` (ensure the installed version is no higher than 2.18 and no lower than 2.11; installing the `ansible` package alone will result in an outdated, unsuitable version).
- Check the Ansible core version — `ansible --version`.

Installing Ansible in a Python virtual environment

Using Ubuntu 22.04 LTS as an example:

- Update the list of available deb packages — `sudo apt-get update`.
- Install the `python3-venv` package for managing Python virtual environments — `sudo apt-get install python3-venv`.
- Create a directory where the virtual environment will be created. For example, `mkdir venv-ansible`.
- Create a Python virtual environment — `python3 -m venv venv-ansible`, where `venv-ansible` is the path to the directory created in the previous step.
- Activate the virtual environment — `source venv-ansible/bin/activate`. All further Ansible steps are performed inside the virtual environment. You can leave it with the `deactivate` command.
- Install the recommended Ansible version with `pip3 install "ansible-core>=2.11,<2.19"` (ensure the installed version is no higher than 2.18 and no lower than 2.11). Check the installed Ansible version — `ansible --version`.

For more information and other installation options, see the Ansible installation guide.

Ansible project setup

Installing YDB Ansible playbooks

Via requirements.yaml

```
cat <<EOF > requirements.yaml
roles: []
collections:
  - name: git+https://github.com/ydb-platform/ydb-ansible
    type: git
    version: latest
EOF
ansible-galaxy install -r requirements.yaml
```

One-time

```
ansible-galaxy collection install git+https://github.com/ydb-platform/ydb-ansible.git,latest
```

After completing the preparation steps, you can proceed to deploying the system. Choose the instruction that matches your configuration:

- Deploying a cluster using configuration V1
- Deploying a cluster using configuration V2

Deploying a cluster using configuration V1

Prepare the environment

Before deploying the system, complete the preparation steps. See the Deployment preparation document.

Create a working directory

```
mkdir deployment
cd deployment
mkdir inventory
mkdir files
```

Create the Ansible configuration file

Create `ansible.cfg` with Ansible configuration suitable for your target deployment environment. See the Ansible configuration reference for details. This guide assumes the `./inventory` subdirectory of the working directory is set up for inventory files.

Example starter ansible.cfg

> **Note**
>
> Using the `StrictHostKeyChecking=no` parameter in `ssh_args` makes automation easier but reduces SSH connection security (disables host key verification). For production environments, we recommend omitting this argument and configuring trusted keys manually. Use this parameter only for test and temporary installations.

```
[defaults]
conditional_bare_variables = False
force_handlers = True
gathering = explicit
interpreter_python = /usr/bin/python3
inventory = ./inventory
pipelining = True
private_role_vars = True
timeout = 5
verbosity = 1
log_path = ./ydb.log
vault_password_file = ./ansible_vault_password_file

[ssh_connection]
retries = 5
timeout = 60
ssh_args = -o UserKnownHostsFile=/dev/null -o StrictHostKeyChecking=no -o ControlMaster=auto -o ControlPe
rsist=60s -o ControlPath=/tmp/ssh-%h-%p-%r -o ServerAliveCountMax=3 -o ServerAliveInterval=10
```

Create the main inventory file

Create the file `inventory/50-inventory.yaml` and fill it according to the chosen topology (see topology selection). Examples for each supported topology are in the tabs below — choose the one that fits.

mirror-3-dc-3nodes

```
all:
  children:
    ydb:

```

Required settings to adapt for your environment in the chosen template:

1. **Server hostnames.** Replace `static-node-*.ydb-cluster.com` in `all.children.ydb.hosts` and `all.children.vars.ydb_brokers` with the actual FQDNs.
2. **SSH access configuration.** Specify the `ansible_user` and the path to the private key `ansible_ssh_private_key_file` that Ansible will use to connect to your servers.
3. **Filesystem paths to block devices.** In the `all.children.ydb.vars.ydb_disks` section, the template assumes `/dev/vda` is for the operating system and the following disks, such as `/dev/vdb`, are for the YDB storage layer. Disk labels are created by the playbooks automatically, and their names can be arbitrary.
4. **System version.** In the `ydb_version` parameter, specify the YDB version to install. The list of available versions is on the downloads page.

Recommended settings to adapt for your environment:

- `ydb_domain`. This will be the first path component for all scheme objects in the cluster. For example, you can put your company name, cluster region, and so on there.
- `ydb_dbname`. This will be the second path component for all scheme objects in the database. For example, you can put the use case or project name there.

Additional settings

There are several options to specify which YDB executables you want to use for the cluster:

- `ydb_version`: automatically download one of the official YDB releases by version number. For example, `23.4.11`.
- `ydb_archive`: a local filesystem path to a YDB distribution archive downloaded or otherwise prepared in advance.

Installing a connector may be required for using federated queries. The playbook can deploy fq-connector-go on hosts with dynamic nodes. Use the following settings:

- `ydb_install_fq_connector` — set to `true` to install the connector.
- Choose one of the available options for deploying fq-connector-go executables:
  - `ydb_fq_connector_version`: automatically download one of the fq-connector-go official releases by version number. For example, `v0.7.1`.

    - `ydb_fq_connector_git_version`: automatically compile the fq-connector-go executable from source code downloaded from the official GitHub repository. The setting value is a branch, tag, or commit name. For example, `main`.
    - `ydb_fq_connector_archive`: a local filesystem path to a fq-connector-go distribution archive downloaded or otherwise prepared in advance.
    - `ydb_fq_connector_binary`: local filesystem paths to the fq-connector-go executable, downloaded or otherwise prepared in advance.
- `ydb_tls_dir` — specify a local path to a folder with TLS certificates prepared in advance. It must contain the `ca.crt` file and subdirectories whose names match the node hostnames, each containing certificates for that node. If not specified, self-signed TLS certificates will be generated automatically for the entire YDB cluster.
- `ydb_brokers` — list the FQDNs of the broker nodes. For example:

```
ydb_brokers:
    - static-node-1.ydb-cluster.com
    - static-node-2.ydb-cluster.com
    - static-node-3.ydb-cluster.com
```

The optimal value for the `ydb_database_groups` setting in the `vars` section depends on the available disks. Assuming only one database in the cluster, use the following logic:

- For production deployments, use disks with capacity over 800 GB and high IOPS, then choose the value for this setting based on cluster topology:
    - For `block-4-2`, set `ydb_database_groups` to 95% of the total number of disks, rounded down.
    - For `mirror-3-dc`, set `ydb_database_groups` to 84% of the total number of disks, rounded down.
- For testing YDB on small disks, set `ydb_database_groups` to 1 regardless of cluster topology.

The values of the `system_timezone` and `system_ntp_servers` variables depend on the infrastructure where the YDB cluster is deployed. By default, `system_ntp_servers` includes a set of NTP servers without regard to the geographic location of the infrastructure. We strongly recommend using a local NTP server for on-premise infrastructure and the following NTP servers for cloud providers:

AWS

- `system_timezone`: USA/<region_name>
- `system_ntp_servers`: [169.254.169.123, time.aws.com] Learn more about AWS NTP server settings.

Azure

- You can read about how time synchronization is configured on Azure virtual machines in this article.

Alibaba

- The specifics of connecting to NTP servers in Alibaba are described in this article.

Yandex Cloud

- `system_timezone`: Europe/Moscow
- `system_ntp_servers`: [0.ru.pool.ntp.org, 1.ru.pool.ntp.org, ntp0.NL.net, ntp2.vniiftri.ru, ntp.ix.ru, ntps1-1.cs.tu-berlin.de] Learn more about Yandex Cloud NTP server settings.

Change the root user password

Create the file `ansible_vault_password_file` with the following content:

```
password
```

This file contains the password that Ansible will use to encrypt and decrypt sensitive data automatically, for example user password files. This way passwords are not stored in plain text in the repository. For more on how Ansible Vault works, see the official documentation.

Next, set the password for the initial user specified in the `ydb_user` setting (default `root`). This user will have full access rights in the cluster initially; you can change this later if needed. Create `inventory/99-inventory-vault.yaml` with the following content (replace `<password>` with the actual password):

```
all:
  children:
    ydb:
      vars:
        ydb_password: <password>
```

Encrypt this file with the command `ansible-vault encrypt inventory/99-inventory-vault.yaml`.

Prepare the YDB configuration file

The examples below contain a `feature_flags` section. Before changing its values, read about feature flags and guidelines for changing them.

Create the file `files/config.yaml` and fill it according to the chosen topology (see topology selection). Examples for each supported topology are in the tabs below — choose the one that fits.

```

To speed up and simplify the initial YDB deployment, the configuration file already contains most of the cluster setup. You only need to replace the placeholder host FQDNs with the actual ones in the `hosts` and `blob_storage_config` sections.

- The `hosts` section:

```
...
hosts:
  - host: static-node-1.ydb-cluster.com # VM FQDN
    host_config_id: 1
    walle_location:
      body: 1
      data_center: 'zone-a'
      rack: '1'
...
```

- The `blob_storage_config` section:

```
...
- fail_domains:
  - vdisk_locations:
    - node_id: static-node-1.ydb-cluster.com # VM FQDN
      pdisk_category: SSD
      path: /dev/disk/by-partlabel/ydb_disk_1
...
```

Leave the rest of the configuration file sections and settings unchanged.

Deploy the YDB cluster

After completing all the preparation steps above, the actual initial cluster deployment is running the following command from the working directory:

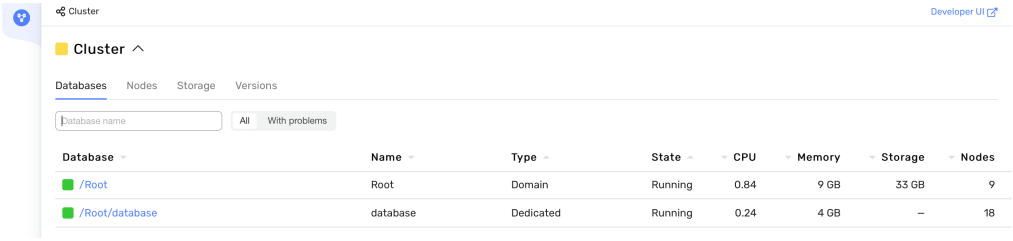
```
ansible-playbook ydb_platform.ydb.initial_setup
```

Shortly after it starts, you will need to confirm full wipe of the configured disks. Completion can then take tens of minutes depending on the environment and settings. This playbook performs roughly the same steps as in the manual YDB cluster deployment instructions.

Check cluster state

On the last step, the playbook runs several test queries using real temporary tables to verify correct operation. On success, you will see status ok, failed=0, and test query results (3 and 6) for each server when the playbook output is verbose enough.

Example output



```
...

TASK [ydb_platform.ydb.ydbd_dynamic : run test queries] ************************************************

ignored=0
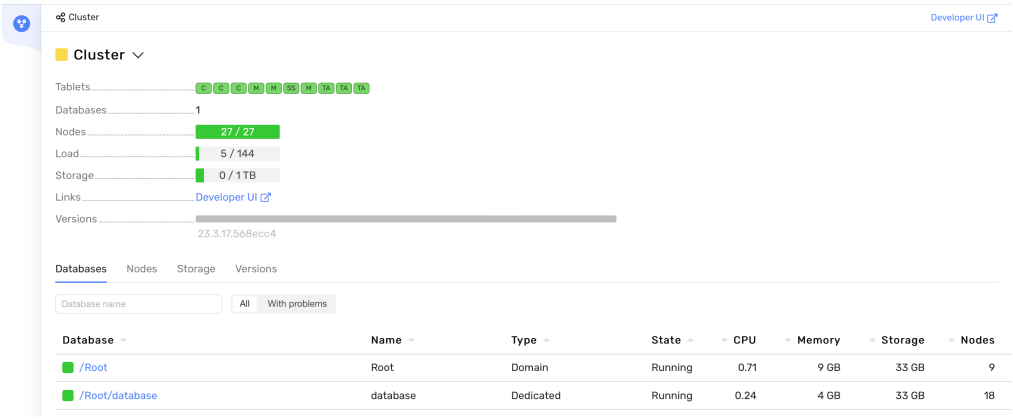
```

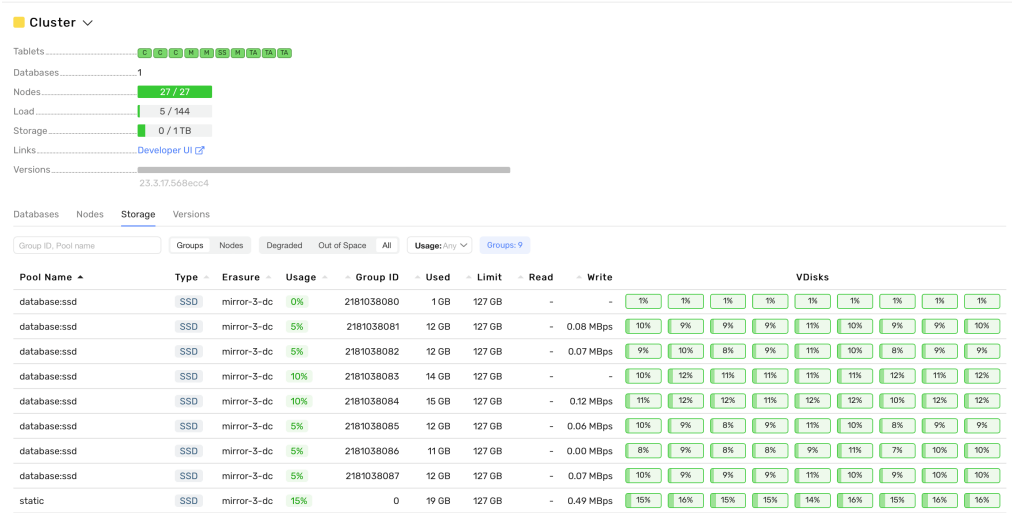


Running the `ydb_platform.ydb.initial_setup` playbook creates a YDB cluster. It will contain a domain named from the `ydb_domain` setting (default `Root`), a database named from the `ydb_dbname` setting (default `database`), and an initial user named from the `ydb_user` setting (default `root`).

Additional steps

The easiest way to explore the newly deployed cluster is YDB UI, which runs on port 8765 on each server. If you do not have direct browser access to that port, set up SSH tunneling by running `ssh -L 8765:localhost:8765 -i <private-key> <user>@<any-ydb-server-hostname>` on your local machine (add more options if needed). After the connection is established, open localhost:8765 in your browser. The browser may ask you to accept a security exception. Example:

After the YDB cluster is created, check its state on this YDB UI page: http://localhost:8765/monitoring/cluster/tenants. It might look like this:



This section shows the following YDB cluster parameters:

- `Tablets` — list of running tablets. All tablet state indicators should be green.
- `Nodes` — number and state of storage and database nodes running in the cluster. The node state indicator should be green, and the number of created and running nodes should match (e.g., 18/18 for a nine-node cluster with one database node per server).

The `Load` (RAM used) and `Storage` (disk space used) indicators should also be green.

You can check the storage group state in the `storage` section — http://localhost:8765/monitoring/cluster/storage:

The `VDisks` indicators should be green, and the `state` status (in the tooltip when hovering over the Vdisk indicator) should be `Ok`. For more on cluster state indicators and monitoring, see YDB Monitoring.

Cluster testing

You can test the cluster using the built-in load tests in YDB CLI. Install YDB CLI and create a profile with connection parameters, replacing the placeholders:

```
ydb \
  config profile create <profile-name> \
  -d /<ydb-domain>/<ydb-database> \
  -e grpcs://<any-ydb-cluster-hostname>:2135 \
  --ca-file $(pwd)/files/TLS/certs/ca.crt \
  --user root \
  --password-file <path-to-a-file-with-password>
```

Command parameters and their meaning:

- `config profile create` — creates a connection profile. Specify the profile name. For more on creating and changing profiles, see Creating and updating profiles.
- `-e` — endpoint, a string in the form `protocol://host:port`. You can specify the FQDN of any cluster node and omit the port. Port 2135 is used by default.
- `--ca-file` — path to the root certificate for database connections over `grpcs`.
- `--user` — user for database connection.
- `--password-file` — path to the password file. Omit to enter the password manually.

To verify the profile was created, use `ydb config profile list`. Activate the profile with `ydb config profile activate <profile-name>`. To confirm it is active, run `ydb config profile list` again — the active profile will show `(active)`.

To run a YQL query, use `ydb sql -s 'SELECT 1;'`, which returns the result of `SELECT 1` in table form in the terminal. After checking the connection, create a test table with:
`ydb workload kv init --init-upserts 1000 --cols 4`. This creates the test table `kv_test` with 4 columns and 1000 rows. To verify the table and data, run `ydb sql -s 'select * from kv_test limit 10;'`.

The terminal will show a table of 10 rows. You can then run cluster performance tests. Key-Value load describes workload types (`upsert`, `insert`, `select`, `read-rows`, `mixed`) and their parameters. Example for the `upsert` workload with `--print-timestamp` and default parameters: `ydb workload kv run upsert --print-timestamp`:

```
Window Txs/Sec Retries Errors  p50(ms) p95(ms) p99(ms) pMax(ms)        Timestamp
1          727 0       0       11      27      71      116     2024-02-14T12:56:39Z
2          882 0       0       10      21      29      38      2024-02-14T12:56:40Z
3          848 0       0       10      22      30      105     2024-02-14T12:56:41Z
4          901 0       0       9       20      27      42      2024-02-14T12:56:42Z
5          879 0       0       10      22      31      59      2024-02-14T12:56:43Z
...
```

When you are done, remove the `kv_test` table with `ydb workload kv clean`. For more on test table options and tests, see Key-Value load.

Deploying a cluster using configuration V2

> **Alert**
>
> This article is about YDB clusters that use **configuration V2**. This configuration method is still experimental and is only available for YDB versions starting with v25.1. For production we recommend configuration V1, which is the main, officially supported configuration for all YDB clusters.

Prepare the environment

Before deploying the system, complete the preparation steps. See the Deployment preparation document.

Create a working directory

```
mkdir deployment
cd deployment
mkdir -p inventory/group_vars/ydb
mkdir files
```

Create the Ansible configuration file

Create `ansible.cfg` with Ansible configuration suitable for your target deployment environment. See the Ansible configuration reference for details. This guide assumes the `./inventory` subdirectory of the working directory is set up for inventory files.

Example starter ansible.cfg

> **Note**
>
> Using the `StrictHostKeyChecking=no` parameter in `ssh_args` makes automation easier but reduces SSH connection security (disables host key verification). For production environments, we recommend omitting this argument and configuring trusted keys manually. Use this parameter only for test and temporary installations.

```
[defaults]
conditional_bare_variables = False
force_handlers = True
forks = 300
gathering = explicit
host_key_checking = False
interpreter_python = /usr/bin/python3
inventory = ./inventory
module_name = shell
pipelining = True
private_role_vars = True
retry_files_enabled = False
timeout = 5
vault_password_file = ./ansible_vault_password_file
verbosity = 1
log_path = ./ydb.log

[ssh_connection]
retries = 5
ssh_args = -o UserKnownHostsFile=/dev/null -o StrictHostKeyChecking=no -o ControlMaster=auto -o ControlPe
rsist=60s -o ControlPath=/tmp/ssh-%h-%p-%r -o ServerAliveCountMax=3 -o ServerAliveInterval=10
```

Create the main inventory file

Create the file `inventory/group_vars/ydb/all.yaml` and fill it.

mirror-3-dc-3nodes

```

Required settings to adapt for your environment in the chosen template:

1. **SSH access configuration.** Specify the `ansible_user` and the path to the private key `ansible_ssh_private_key_file` that Ansible will use to connect to your servers.
2. **Filesystem paths to block devices.** In the `ydb_disks` section, the template assumes `/dev/vda` is for the operating system and the following disks, such as `/dev/vdb`, are for the YDB storage layer. Disk labels are created by the playbooks automatically, and their names can be arbitrary.
3. **System version.** In the `ydb_version` parameter, specify the YDB version to install. The list of available versions is on the downloads page.

Recommended settings to adapt for your environment:

- `ydb_domain`. This will be the first path component for all scheme objects in the cluster. For example, you can put your company name, cluster region, and so on there.
- `ydb_dbname`. This will be the second path component for all scheme objects in the database. For example, you can put the use case or project name there.

Additional settings

There are several options to specify which YDB executables you want to use for the cluster:

- `ydb_version`: automatically download one of the official YDB releases by version number. For example, `23.4.11`.
- `ydb_archive`: a local filesystem path to a YDB distribution archive downloaded or otherwise prepared in advance.

Installing a connector may be required for using federated queries. The playbook can deploy fq-connector-go on hosts with dynamic nodes. Use the following settings:

- `ydb_install_fq_connector` — set to `true` to install the connector.
- Choose one of the available options for deploying fq-connector-go executables:
  - `ydb_fq_connector_version`: automatically download one of the fq-connector-go official releases by version number. For example, `v0.7.1`.
  - `ydb_fq_connector_git_version`: automatically compile the fq-connector-go executable from source code downloaded from the official GitHub repository. The setting value is a branch, tag, or commit name. For example, `main`.
  - `ydb_fq_connector_archive`: a local filesystem path to a fq-connector-go distribution archive downloaded or otherwise prepared in advance.
  - `ydb_fq_connector_binary`: local filesystem paths to the fq-connector-go executable, downloaded or otherwise prepared in advance.
- `ydb_tls_dir` — specify a local path to a folder with TLS certificates prepared in advance. It must contain the `ca.crt` file and subdirectories whose names match the node hostnames, each containing certificates for that node. If not specified, self-signed TLS certificates will be generated automatically for the entire YDB cluster.
- `ydb_brokers` — list the FQDNs of the broker nodes. For example:

```
ydb_brokers:
    - static-node-1.ydb-cluster.com
    - static-node-2.ydb-cluster.com
    - static-node-3.ydb-cluster.com
```

The optimal value for the `ydb_database_groups` setting in the `vars` section depends on the available disks. Assuming only one database in the cluster, use the following logic:

- For production deployments, use disks with capacity over 800 GB and high IOPS, then choose the value for this setting based on cluster topology:
  - For `block-4-2`, set `ydb_database_groups` to 95% of the total number of disks, rounded down.
  - For `mirror-3-dc`, set `ydb_database_groups` to 84% of the total number of disks, rounded down.
- For testing YDB on small disks, set `ydb_database_groups` to 1 regardless of cluster topology.

The values of the `system_timezone` and `system_ntp_servers` variables depend on the infrastructure where the YDB cluster is deployed. By default, `system_ntp_servers` includes a set of NTP servers without regard to the geographic location of the infrastructure. We strongly recommend using a local NTP server for on-premise infrastructure and the following NTP servers for cloud providers:

AWS

- `system_timezone`: USA/<region_name>
- `system_ntp_servers`: [169.254.169.123, time.aws.com] Learn more about AWS NTP server settings.

Azure

- You can read about how time synchronization is configured on Azure virtual machines in this article.

Alibaba

- The specifics of connecting to NTP servers in Alibaba are described in this article.

Yandex Cloud

- `system_timezone`: Europe/Moscow
- `system_ntp_servers`: [0.ru.pool.ntp.org, 1.ru.pool.ntp.org, ntp0.NL.net, ntp2.vniiftri.ru, ntp.ix.ru, ntps1-1.cs.tu-berlin.de] Learn more about Yandex Cloud NTP server settings.

Change the root user password

Create the file `ansible_vault_password_file` with the following content:

```
password
```

This file contains the password that Ansible will use to encrypt and decrypt sensitive data automatically, for example user password files. This way passwords are not stored in plain text in the repository. For more on how Ansible Vault works, see the official documentation.

Next, set the password for the initial user specified in the `ydb_user` setting (default `root`). This user will have full access rights in the cluster initially; you can change this later if needed. Create `inventory/group_vars/ydb/vault.yaml` with the following content (replace `<password>` with the actual password):

```
ydb_password: <password>
```

Encrypt this file with the command `ansible-vault encrypt inventory/group_vars/ydb/vault.yaml`.

Prepare the YDB configuration file

Create the file `files/config.yaml` and fill it.

      - "ADMINS"
      - "DATABASE-ADMINS"
      register_dynamic_node_allowed_sids:
      - databaseNodes@cert
      - root@builtin
```

To speed up and simplify the initial YDB deployment, the configuration file already contains most of the cluster setup. You only need to replace the placeholder host FQDNs in the `hosts` section and the disk paths in the `host_configs` section with the actual values.

- The `hosts` section:

```
...
hosts:
  - host: ydb-node-zone-a.local
  host_config_id: 1
  location:
    body: 1
    data_center: 'zone-a'
    rack: '1'
...
```

- The `host_configs` section:

```
...
host_configs:
- host_config_id: 1
  drive:
  - path: /dev/disk/by-partlabel/ydb_disk_1
    type: SSD
  - path: /dev/disk/by-partlabel/ydb_disk_2
    type: SSD
  - path: /dev/disk/by-partlabel/ydb_disk_3
    type: SSD
...
```

Leave the rest of the configuration file sections and settings unchanged.

Create the file `inventory/ydb_inventory.yaml` with the following content:

```
plugin: ydb_platform.ydb.ydb_inventory
ydb_config: "files/config.yaml"
```

Deploy the YDB cluster

After completing all the preparation steps above, the actual initial cluster deployment is running the following command from the working directory:

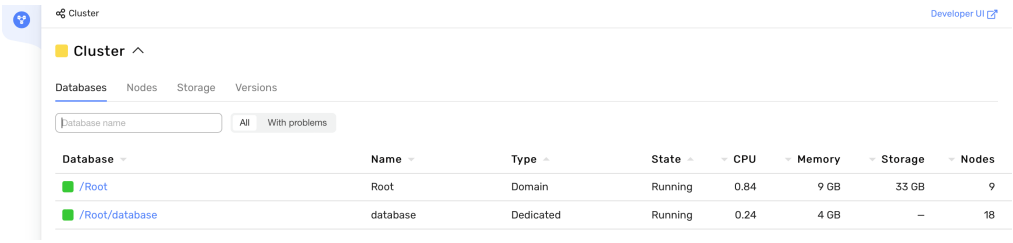
```
ansible-playbook ydb_platform.ydb.initial_setup
```

Shortly after it starts, you will need to confirm full wipe of the configured disks. Completion can then take tens of minutes depending on the environment and settings. This playbook performs roughly the same steps as in the manual YDB cluster deployment instructions.

Check cluster state

On the last step, the playbook runs several test queries using real temporary tables to verify correct operation. On success, you will see status ok, failed=0, and test query results (3 and 6) for each server when the playbook output is verbose enough.

Example output



```
...

TASK [ydb_platform.ydb.ydbd_dynamic : run test queries] ************************************************
*********************************************************************************************

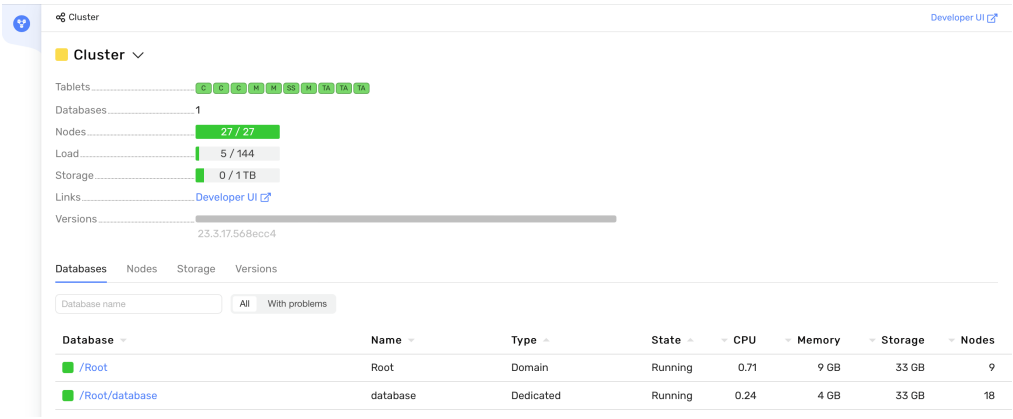
```

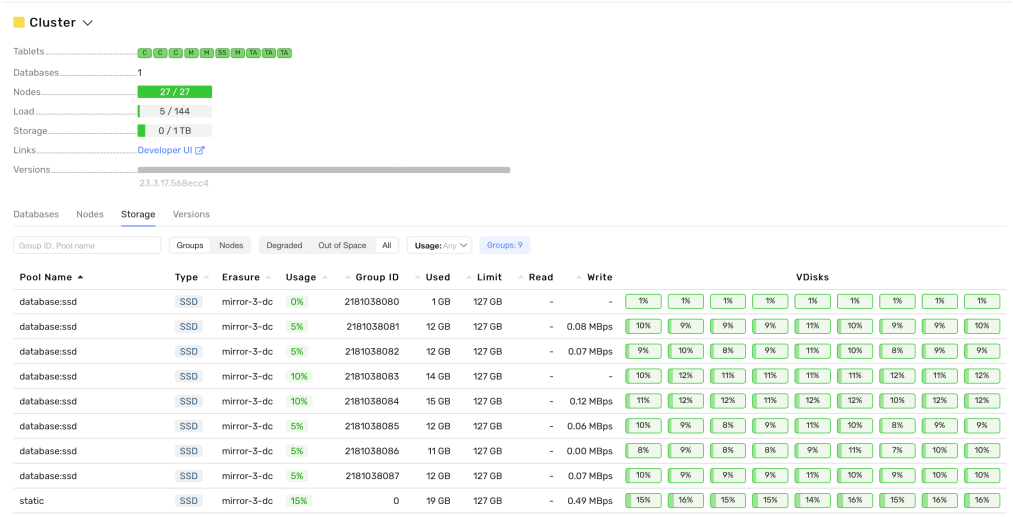


Running the `ydb_platform.ydb.initial_setup` playbook creates a YDB cluster. It will contain a domain named from the `ydb_domain` setting (default `Root`), a database named from the `ydb_dbname` setting (default `db`), and an initial user named from the `ydb_user` setting (default `root`).

Additional steps

The easiest way to explore the newly deployed cluster is YDB UI, which runs on port 8765 on each server. If you do not have direct browser access to that port, set up SSH tunneling by running `ssh -L 8765:localhost:8765 -i <private-key> <user>@<any-ydb-server-hostname>` on your local machine (add more options if needed). After the connection is established, open localhost:8765 in your browser. The browser may ask you to accept a security exception. Example:

After the YDB cluster is created, check its state on this YDB UI page: http://localhost:8765/monitoring/cluster/tenants. It might look like this:



This section shows the following YDB cluster parameters:

- `Tablets` — list of running tablets. All tablet state indicators should be green.
- `Nodes` — number and state of storage and database nodes running in the cluster. The node state indicator should be green, and the number of created and running nodes should match (e.g., 18/18 for a nine-node cluster with one database node per server).

The `Load` (RAM used) and `Storage` (disk space used) indicators should also be green.

You can check the storage group state in the `storage` section — http://localhost:8765/monitoring/cluster/storage:

The `VDisks` indicators should be green, and the `state` status (in the tooltip when hovering over the Vdisk indicator) should be `Ok`. For more on cluster state indicators and monitoring, see YDB Monitoring.

Cluster testing

You can test the cluster using the built-in load tests in YDB CLI. Install YDB CLI and create a profile with connection parameters, replacing the placeholders:

```
ydb \
  config profile create <profile-name> \
  -d /<ydb-domain>/<ydb-database> \
  -e grpcs://<any-ydb-cluster-hostname>:2135 \
  --ca-file $(pwd)/files/TLS/certs/ca.crt \
  --user root \
  --password-file <path-to-a-file-with-password>
```

Command parameters and their meaning:

- `config profile create` — creates a connection profile. Specify the profile name. For more on creating and changing profiles, see Creating and updating profiles.
- `-e` — endpoint, a string in the form `protocol://host:port`. You can specify the FQDN of any cluster node and omit the port. Port 2135 is used by default.
- `--ca-file` — path to the root certificate for database connections over `grpcs`.
- `--user` — user for database connection.
- `--password-file` — path to the password file. Omit to enter the password manually.

To verify the profile was created, use `ydb config profile list`. Activate the profile with `ydb config profile activate <profile-name>`. To confirm it is active, run `ydb config profile list` again — the active profile will show `(active)`.

To run a YQL query, use `ydb sql -s 'SELECT 1;'`, which returns the result of `SELECT 1` in table form in the terminal. After checking the connection, create a test table with:
`ydb workload kv init --init-upserts 1000 --cols 4`. This creates the test table `kv_test` with 4 columns and 1000 rows. To verify the table and data, run `ydb sql -s 'select * from kv_test limit 10;'`.

The terminal will show a table of 10 rows. You can then run cluster performance tests. Key-Value load describes workload types (`upsert`, `insert`, `select`, `read-rows`, `mixed`) and their parameters. Example for the `upsert` workload with `--print-timestamp` and default parameters: `ydb workload kv run upsert --print-timestamp`:

```
Window Txs/Sec Retries Errors  p50(ms) p95(ms) p99(ms) pMax(ms)        Timestamp
1          727 0       0       11      27      71      116     2024-02-14T12:56:39Z
2          882 0       0       10      21      29      38      2024-02-14T12:56:40Z
3          848 0       0       10      22      30      105     2024-02-14T12:56:41Z
4          901 0       0       9       20      27      42      2024-02-14T12:56:42Z
5          879 0       0       10      22      31      59      2024-02-14T12:56:43Z
...
```

When you are done, remove the `kv_test` table with `ydb workload kv clean`. For more on test table options and tests, see Key-Value load.

Deploy Infrastructure for YDB Cluster using Terraform

You can deploy a YDB cluster for production use in three recommended ways: using Ansible, Kubernetes or manually. While the Kubernetes option is almost self-sufficient, the Ansible and manual options require SSH access to properly configured servers or virtual machines.

This article describes how to create and configure the necessary set of virtual machines in various cloud providers for a YDB cluster, using Terraform.

Terraform is an open-source infrastructure management software based on the "Infrastructure as Code" model. The same approach is used in Ansible, a configuration management system. Terraform and Ansible work at different levels: Terraform manages the infrastructure, and Ansible configures the environments on virtual machines (VM).

The configuration for setting up the VM environment is described in YAML format, and the infrastructure code is written in HCL (Terraform configuration language). The basic logical unit of recording in HCL is a "block". A block consists of a keyword identifying its type, name, and the block's body inside curly brackets. For example, this is what a virtual server control block in AWS might look like:

```
resource "aws_instance" "ydb-vm" {
  count                  = var.instance_count
  ami                    = "ami-008fe2fc65df48dac"
  instance_type          = "t2.micro"
  key_name               = var.req_key_pair
  vpc_security_group_ids = [var.input_security_group_id]
  subnet_id              = element(var.input_subnet_ids, count.index % length(var.input_subnet_ids))

  tags = {
    Name                 = "ydb-node-${count.index +1}"
    Username             = "ubuntu"
  }
}
```

Blocks can be independent, refer to each other, and thus be dependent, or they can also be nested inside each other.

Main block types:

- `resource` – a block for initializing an infrastructure resource (VM, network, subnet, disk, DNS zone, etc.).
- `provider` – a block for initializing the provider, API versions, and authentication data.
- `variable` – a variable either with a default value or empty for storing data entered by the user or passed by other blocks.
- `output` – outputs data to the terminal and saves it in a variable.
- `data` – a variable for requesting data from external cloud resources not presented in the created infrastructure.
- `module` – a logical grouping of resources that can be reused several times within the same or different projects.
- `terraform` – a block for configuring the behavior of Terraform itself, including the version of Terraform and used providers, as well as the backend settings, which are used for storing Terraform's state.

Blocks are written in files with the `.tf` extension and are logically grouped in directories, which in Terraform terminology are called modules. A module usually consists of the following files:

- `main.tf` – the main file where the infrastructure code is located. There can be several files containing infrastructure code.
- `variables.tf` – local variables of the module, which receive data from other modules or have default values.
- `outputs.tf` – variables that contain the results of the resource's operation (VM IP addresses, network/subnet IDs, etc.).

Modules are connected to the project in the root file `main.tf` as follows:

```
module "vpc" {
  source                     = "./modules/vpc"
  subnets_count              = var.subnets_count
  subnets_availability_zones = var.availability_zones
}
```

In the example, the `vpc` module is connected (the module name is assigned when connecting). The required parameter is `source`, a path to the directory where the module is located. `subnets_count` and `subnets_availability_zones` are variables inside the `vpc` module that take values from the global level variables `var.subnets_count`, `var.availability_zones`.

Modules, just like blocks, are placed one after another in the root `main.tf` file of the project. The main advantage of the modular approach to project organization is the ability to manage logically related sets of resources easily. Therefore, our repository with ready-made Terraform scenarios is organized as follows:

```
.
├── README.md
├── README_RU.md
├── aws
│   ├── README.md
│   ├── README_RU.md
│   ├── main.tf
│   ├── modules
│   │   ├── dns
│   │   ├── eip
│   │   ├── instance
│   │   ├── key_pair
│   │   ├── security
│   │   └── vpc
│   └── variables.tf
├── azure
│   ├── README.md
│   ├── README_RU.md
│   ├── main.tf
│   ├── modules
│   │   ├── dns
│   │   ├── resource_group
│   │   ├── security
│   │   ├── vm
│   │   └── vpc
│   └── variables.tf
├── ...
```

The subdirectories contain readme files, a file `variables.td` with local module variables and a central file `main.tf`, which includes modules from the `modules` subdirectory. The set of modules depends on the cloud provider. Basic modules, functionally the same for all providers, have the same names:

- `vpc` – cloud network and subnet management module.
- `dns` – DNS zone and DNS records management module.
- `security` – security group management module.
- `instance` – VM control module.

To use ready-made Terraform scripts from the repository, you need to download the repository with the command `git clone https://github.com/ydb-platform/ydb-terraform.git`, make changes to the Terraform configuration file `~/.terraformrc`, set the current values of global script variables and download the CLI of the cloud provider where the infrastructure will be created.

If you plan to use multiple providers, you can add the following code to `~/.terraformrc`, which will set the download paths for all providers described below:

```
provider_installation {
  network_mirror {
    url     = "https://terraform-mirror.yandexcloud.net/"
    include = ["registry.terraform.io/*/*"]
  }
  direct {
    exclude = ["registry.terraform.io/*/*"]
    exclude = ["terraform.storage.ydb.tech/*/*"]
  }
```

If you already use Terraform providers provided in the official repository, they will continue to work.

Deployment Overview

The following are step-by-step instructions for creating infrastructure in AWS, Azure, GCP, or Yandex Cloud. By default, example Terraform scenarios deploy the same type of infrastructure:

- VMs in three availability zones.
- Cloud network, public and private subnets (per subnet per availability zone).
- Private DNS zone.
- Security groups allowing ICMP and traffic on ports: 22, 65535, 19001, 8765, and 2135.

Most cluster parameters are adjustable (number of VMs, size and type of connected disks, number of networks, DNS zone domain name, etc.), but please note that the defaults are minimum recommended values, so changing them downwards may cause issues.

Create Infrastructure in AWS to Deploy a YDB Cluster

Create an account in AWS and add enough balance to run 9 VMs. Using the calculator, you can estimate the approximate cost of maintaining infrastructure depending on the region and other circumstances.

Create a user and connection key in AWS Cloud to run the AWS CLI:

1. The user is created in the Security credentials → Access management → Users → Create User section.
2. The next step is to assign rights to the user. Select `AmazonEC2FullAccess`.
3. After creating a user, go to its page, open the `Security credentials` tab, and click the **Create access key** button in the **Access keys** section.
4. Select `Command Line Interface` from the proposed options.
5. Next, create a tag for the key and click the **Create access key** button.
6. Copy the values of the `Access key` and `Secret access key` fields.

Install AWS CLI and run the `aws configure` command. Enter the values of the `Access key` and `Secret access key` fields saved earlier. Edit the `~/.aws/credentials` and `~/.aws/config` files as follows:

1. Add `[AWS_def_reg]` to `~/.aws/config` before `region = ...`.
2. Add `[AWS]` before the connection key secret information.

Go to the `aws` directory in the downloaded repository and edit the following variables in the `variable.tf` file:

1. `aws_region` – the region in which the infrastructure will be deployed.
2. `aws_profile` – security profile name from the file `~/.aws/credentials`.
3. `availability_zones` – list of region availability zones. It is formed from the name of the region and the serial letter. For example, for the `us-west-2` region, the list of availability zones will look like this: `["us-west-2a", "us-west-2b", "us-west-2c"]`.

Now, being in the `aws` subdirectory, you can run the following sequence of commands to install the provider, initialize modules, and create the infrastructure:

1. `terraform init` – installing the provider and initializing modules.
2. `terraform plan` – creating a plan for future infrastructure.
3. `terraform apply` – create resources in the cloud.

Next, use the commands `terraform plan`, `terraform apply`, and `terraform destroy` (destruction of the created infrastructure) to apply further changes as necessary.

Create Infrastructure in Azure to Deploy a YDB Cluster

Create an account in Azure and top up your account account with the amount, sufficient to operate 9 VMs. You can estimate the approximate cost of maintaining infrastructure depending on the region and other circumstances using calculator.

Authentication to the Azure Provider for Terraform goes through the CLI:

1. You can download, install, and configure the Azure CLI by following these instructions.
2. Log in using the Azure CLI interactively with the `az login` command.
3. The easiest way to create a pair of SSH keys (Linux, macOS) is to use the `ssh-keygen` command.

After logging into Azure and generating SSH keys, you need to change the default value of the following variables in the root file `variables.tf`:

1. `auth_location` —the name of the region where the infrastructure will be deployed. The command `az account list-locations | grep "displayName"` can obtain a list of available regions depending on the subscription.
2. `ssh_key_path` – path to the public part of the generated SSH key.

Now, being in the `azure` subdirectory, you can run the following sequence of commands to install the provider, initialize modules, and create the infrastructure:

1. `terraform init` – installing the provider and initializing modules.
2. `terraform plan` – creating a plan for future infrastructure.
3. `terraform apply` – create resources in the cloud.

Next, use the commands `terraform plan`, `terraform apply`, and `terraform destroy` (destruction of the created infrastructure) to apply further changes as necessary.

Creating Infrastructure in Google Cloud Platform to Deploy a YDB Cluster

Register in the Google Cloud console and create a project. Activate your payment account and top it up with funds to launch nine VMs. You can estimate the approximate cost in calculator.

Set up GCP CLI:

1. Activate Compute Engine API and Cloud DNS API.
2. Download and install GCP CLI by following these instructions.
3. Go to the `.../google-cloud-sdk/bin` subdirectory and run the `./gcloud compute regions list` command to get a list of available regions.
4. Run the command `./gcloud auth application-default login` to configure the connection profile.

Go to the `gcp` subdirectory (located in the downloaded repository), and in the `variables.tf` file set the current values for the following variables:

1. `project` – the project's name that was set in the Google Cloud cloud console.
2. `region` – the region where the infrastructure will be deployed.
3. `zones` – list of availability zones in which subnets and VMs will be created.

Now, being in the `gcp` subdirectory, you can run the following sequence of commands to install the provider, initialize modules, and create the infrastructure:

1. `terraform init` – installing the provider and initializing modules.
2. `terraform plan` – creating a plan for future infrastructure.
3. `terraform apply` – create resources in the cloud.

Next, use the commands `terraform plan`, `terraform apply`, and `terraform destroy` (destruction of the created infrastructure) to apply further changes as necessary.

Creating an Infrastructure in Yandex Cloud to Deploy a YDB Cluster

To create infrastructure in Yandex Cloud using Terraform, you need:

1. Prepare the cloud for work:
   - Register in Yandex Cloud.
   - Connect payment account.

    - Make sure that there are enough funds to create nine VMs.
2. Install and configure Yandex Cloud CLI:
    - Download Yandex Cloud CLI.
    - Create profile
3. Create service account using the CLI.
4. Generate Authorized key in JSON format for connecting Terraform to the cloud using the CLI: `yc iam key create --service-account-name <acc name> --output <file name> --folder-id <cloud folder id>`. Information about the created key will be displayed in the terminal:

    ```
    id: ajenap572v8e1l...
    service_account_id: aje90em65r69...
    created_at: "2024-09-03T15:34:57.495126296Z"
    key_algorithm: RSA_2048
    ```

    The authorized key will be created in the directory where the command was executed.
5. Configure Yandex Cloud Terraform provider.
6. Download this repository with the command `git clone https://github.com/ydb-platform/ydb-terraform.git`.
7. Go to the `yandex_cloud` directory in the downloaded repository and make changes to the following variables in the `variables.tf` file:
    - `key_path` – path to the SA key generated using the CLI.
    - `cloud_id` – cloud ID. You can get a list of available clouds with the command `yc resource-manager cloud list`.
    - `folder_id` – Cloud folder ID. Can be obtained with the command `yc resource-manager folder list`.

Now, being in the `yandex_cloud` subdirectory, you can run the following sequence of commands to install the provider, initialize modules, and create the infrastructure:

1. `terraform init` – installing the provider and initializing modules.
2. `terraform plan` – creating a plan for future infrastructure.
3. `terraform apply` – create resources in the cloud.

Next, use the commands `terraform plan`, `terraform apply`, and `terraform destroy` (destruction of the created infrastructure) to apply further changes as necessary.

Restarting YDB Clusters deployed with Ansible

YDB clusters provide strong availability guarantees; thus, the cluster's fault tolerance model needs to be considered during any maintenance, including cluster restarts. There are two kinds of nodes that might need to be restarted:

- Database nodes (also known as dynamic) are stateless; thus, the primary consideration is having enough of them running to handle each database's load. A basic rolling restart with a little delay is usually sufficient for dynamic nodes.
- Storage nodes (also known as static) are stateful and responsible for safely persisting data. Thus, they require special handling to ensure data availability. Each YDB cluster has a dedicated component that keeps track of all outages and maintenance and can tell if it is currently safe to stop or restart a particular node. Thus, asking for its permission for each operation is essential, and a complete restart of storage nodes often takes a while.

Restart via Ansible Playbook

ydb-ansible repository contains a playbook called `ydb_platform.ydb.restart` that can be used to restart a YDB cluster. Run it from the same directory used for the initial deployment.

Restart All Nodes

By default, the `ydb_platform.ydb.restart` restarts all cluster nodes. Static nodes go first, then dynamic nodes. The command to run it:

```
ansible-playbook ydb_platform.ydb.restart
```

Filter by Node Type

Tasks in the `ydb_platform.ydb.restart` playbook are tagged with node types, so you can use Ansible's tags functionality to filter nodes by their kind.

These two commands are equivalent and will restart all storage nodes:

```
ansible-playbook ydb_platform.ydb.restart --tags storage
ansible-playbook ydb_platform.ydb.restart --tags static
```

These two commands are equivalent and will restart all database nodes:

```
ansible-playbook ydb_platform.ydb.restart --tags database
ansible-playbook ydb_platform.ydb.restart --tags dynamic
```

Filter by Hostname

To restart a specific host or subset of hosts, use the `--limit` argument:

```
ansible-playbook ydb_platform.ydb.restart --limit='<hostname>'
ansible-playbook ydb_platform.ydb.restart --limit='<hostname-1,hostname-2>'
```

It can be used together with tags, too:

```
ansible-playbook ydb_platform.ydb.restart --tags database --limit='<hostname>'
```

Restart Nodes Manually

The ydbops tool properly implements various YDB cluster manipulations, including restarts. The `ydb_platform.ydb.restart` playbook explained above uses it behind the scenes, but it can be used manually, too.

There are more guidelines and information on how this works in the Maintenance without downtime article.

Updating Configuration of YDB Clusters Deployed with Ansible

During initial deployment, the Ansible playbook used the provided config file to create the initial cluster configuration. Technically, it generates two variants of the original config file and deploys them to all hosts via Ansible's mechanism for cross-server file copy. This article explains which options are available to change the cluster's configuration after the initial deployment.

Update Configuration via Ansible Playbook

ydb-ansible repository contains a playbook called `ydb_platform.ydb.update_config` that can be used to update YDB cluster's configuration. Go to the same directory used for the initial deployment, edit `files/config.yaml` as needed, and then run this playbook:

```
ansible-playbook ydb_platform.ydb.update_config
```

The playbook deploys the new version of the config files and then performs a rolling restart.

Filter by Node Type

Tasks in the `ydb_platform.ydb.update_config` playbook are tagged with node types, so you can use Ansible's tags functionality to filter nodes by their kind.

These two commands are equivalent and will change the configuration of all storage nodes:

```
ansible-playbook ydb_platform.ydb.update_config --tags storage
ansible-playbook ydb_platform.ydb.update_config --tags static
```

These two commands are equivalent and will change the configuration of all database nodes:

```
ansible-playbook ydb_platform.ydb.update_config --tags database
ansible-playbook ydb_platform.ydb.update_config --tags dynamic
```

Skip Restart

There's a `no_restart` tag to only deploy the config files and skip the cluster restart. This might be useful if the cluster will be restarted later manually or as part of some other maintenance tasks. Example:

```
ansible-playbook ydb_platform.ydb.update_config --tags no_restart
```

Updating YDB Version on Clusters Deployed with Ansible

During the initial deployment, the Ansible playbook provides several options for selecting the YDB server executable (`ydbd`). This article explains the available options for changing the cluster's version after the initial deployment.

> **Warning**
>
> YDB has specific rules regarding version compatibility. It is essential to refer to the version compatibility guide and changelog to correctly choose a new version to upgrade to and prepare for any nuances.

Update Executables via Ansible Playbook

The ydb-ansible repository contains a playbook called `ydb_platform.ydb.update_executable` that can be used to upgrade or downgrade a YDB cluster to another version. Navigate to the same directory used for the initial deployment, edit `inventory/50-inventory.yaml` to specify the target YDB version to install (typically, via the `ydb_version` or `ydb_git_version` variables), and then run this playbook:

```
ansible-playbook ydb_platform.ydb.update_executable
```

The playbook obtains a new binary and then deploys it to the cluster via Ansible's cross-server copying. After that, it performs a rolling restart.

Filter by Node Type

Tasks in the `ydb_platform.ydb.update_executable` playbook are tagged with node types, so you can use Ansible's tags functionality to filter nodes by their kind.

These two commands are equivalent and will change the configuration of all storage nodes:

```
ansible-playbook ydb_platform.ydb.update_executable --tags storage
ansible-playbook ydb_platform.ydb.update_executable --tags static
```

These two commands are equivalent and will change the configuration of all database nodes:

```
ansible-playbook ydb_platform.ydb.update_executable --tags database
ansible-playbook ydb_platform.ydb.update_executable --tags dynamic
```

Skip Restart

There's a `no_restart` tag to only deploy the executable files and skip the cluster restart. This might be useful if the cluster will be restarted later manually or as part of some other maintenance tasks. Example:

```
ansible-playbook ydb_platform.ydb.update_executable --tags no_restart
```

Ensuring Observability of a YDB Cluster Deployed with Ansible

This section of YDB documentation covers various observability-related topics specific to clusters deployed with Ansible.

- Logging on Clusters Deployed with Ansible

Additionally, there's a separate section with Reference on YDB observability that contains articles that do not depend on a chosen cluster deployment method.

Logging on Clusters Deployed with Ansible

During initial deployment, the Ansible playbook sets up several systemd units that run YDB nodes. Typically, there are multiple YDB nodes per physical server or virtual machine, each having its own log. There are two main ways to view logs of such cluster: via an Ansible playbook or via `ssh`.

View Logs via Ansible Playbook

ydb-ansible repository contains a playbook called `ydb_platform.ydb.logs` that can be used to show logs of all YDB nodes in a cluster. The playbook gathers logs from nodes and outputs them to `stdout`, which allows to pipe them for further processing, for example with commands like `grep` or `awk`.

All Logs of All Nodes

By default, the `ydb_platform.ydb.logs` playbook fetches logs of all YDB nodes. The command to do it:

```
ansible-playbook ydb_platform.ydb.logs
```

Filter by Node Type

There are two main node types in a YDB cluster:

- Storage (also known as static)
- Database (also known as dynamic)

Tasks in the `ydb_platform.ydb.logs` playbook are tagged with node types, so you can use Ansible's tags functionality to filter logs by node type.

These two commands are equivalent and will output the storage node logs:

```
ansible-playbook ydb_platform.ydb.logs --tags storage
ansible-playbook ydb_platform.ydb.logs --tags static
```

These two commands are equivalent, too, and will output the database node logs:

```
ansible-playbook ydb_platform.ydb.logs --tags database
ansible-playbook ydb_platform.ydb.logs --tags dynamic
```

Filter by hostname

To show logs of a specific host or subset of hosts, use the `--limit` argument:

```
ansible-playbook ydb_platform.ydb.logs --limit='<hostname>'
ansible-playbook ydb_platform.ydb.logs --limit='<hostname-1,hosntname-2>'
```

It can be used together with tags, too:

```
ansible-playbook ydb_platform.ydb.logs --tags database --limit='<hostname>'
```

View Logs via SSH

To manually access YDB cluster logs via `ssh`, perform the following steps:

1. Construct a `ssh` command to access the server that runs a YDB node you need logs for. The basic version would look like `ssh -i <path-to-ssh-key> <username>@<hostname>`. Take values for these placeholders from the `inventory/50-inventory.yaml` you used for deployment:
   - `<path-to-ssh-key>` is `children.ydb.ansible_ssh_private_key_file`
   - `<username>` is `children.ydb.ansible_user`
   - `<hostname>` is one of `children.ydb.hosts`
2. Choose which systemd unit's logs you need. You can skip this step if you already know the unit name. After logging in to the server using the `ssh` command constructed in the previous step, obtain the list of YDB-related systemd units using `systemctl list-units | grep ydb`. There'll likely be one storage node and multiple database nodes.

   Example output

   ```
   $ systemctl list-units | grep ydb
   ydb-transparent-hugepages.service                                          loaded active     exit
   ed    Configure Transparent Huge Pages (THP)
   ydbd-database-a.service                                                    loaded active     runn
   ing   YDB dynamic node / database / a
   ydbd-database-b.service                                                    loaded active     runn
   ing   YDB dynamic node / database / b
   ydbd-storage.service                                                       loaded active     runn
   ing   YDB storage node
   ```

3. Take the systemd unit name from the previous step and use it in the following command `journalctl -u <systemd-unit>` to actually show logs. You can specify `-u` multiple times to show logs of multiple units or use any other arguments from `man journalctl` to adjust the output.

Working With YDB Using Kubernetes

This section of YDB documentation contains a collection of articles intended for DevOps Engineers deploying YDB clusters using Kubernetes. This is the recommended approach to running production YDB clusters in containerized environments. For running YDB clusters on virtual machines or bare metal, use Ansible instead.

The key articles to get started with this section:

- Initial deployment

Getting Started with YDB in Kubernetes

Deploying YDB in Kubernetes is a simple way to set up and run a YDB cluster. Kubernetes allows to use an universal approach to managing your application in any cloud service provider. This guide provides instructions on how to deploy YDB in AWS EKS or Yandex Managed Service for Kubernetes.

Prerequisites

YDB is delivered as a Helm chart that is a package with templates of Kubernetes structures. For more information about Helm, see the documentation. The YDB chart can be deployed in the following environment:

1. A Kubernetes cluster with version 1.20 or higher. It needs to support Dynamic Volume Provisioning. Follow the instructions below if you don't have a suitable cluster yet.
2. The `kubectl` command line tool is installed and Kubernetes cluster access is configured.
3. The Helm package manager with a version higher than 3.1.0 is installed.

For YDB to work efficiently, we recommend using physical (not virtual) disks larger than 800 GB as block devices.

The minimum disk size is 80 GB, otherwise the YDB node won't be able to use the device. Correct and uninterrupted operation with minimum-size disks is not guaranteed. We recommend using such disks exclusively for informational purposes.

> **Warning**
>
> Configurations with disks less than 800 GB or any types of storage system virtualization cannot be used for production services or system performance testing.
>
> We don't recommend storing YDB data on disks shared with other processes (for example, the operating system).

Creating a Kubernetes Cluster

Skip this section if you have already configured a suitable Kubernetes cluster.

AWS EKS

1. Configure `awscli` and `eksctl` to work with AWS resources according to the documentation.
2. Configure `kubectl` to work with a Kubernetes cluster.
3. Run the following command:

```
eksctl create cluster \
  --name ydb \
  --nodegroup-name standard-workers \
  --node-type c5a.2xlarge \
  --nodes 3 \
  --nodes-min 1 \
  --nodes-max 4
```

This command will create a Kubernetes cluster named `ydb`. The `--node-type` flag indicates that the cluster is deployed using `c5a.2xlarge` (8vCPUs, 16 GiB RAM) instances. This meets minimal guidelines for running YDB.

It takes 10 to 15 minutes on average to create a Kubernetes cluster. Wait for the process to complete before proceeding to the next step of YDB deployment. The `kubectl` configuration will be automatically updated to work with the cluster after it is created.

Yandex Managed Service for Kubernetes

Follow the instructions in the Yandex Managed Service for Kubernetes quick start guide.

Overview of YDB Helm chart

The Helm chart installs YDB Kubernetes Operator to the Kubernetes cluster. It is a controller that follows the Operator design pattern. It implements the logic required for deploying and managing YDB components.

A YDB cluster consists of two kinds of nodes:

- **Storage nodes** (Storage resource) provide the data persistence layer.
- **Dynamic nodes** (Database resource) implement data access and processing.

Create both resources with the desired parameters to deploy a YDB cluster in Kubernetes. The schema for these resources is hosted on GitHub.

After the chart data is processed by the controller, the following resources are created:

- StatefulSet: A workload controller that assigns stable network IDs and disk resources to each container.
- Service: An object that is used to access the created databases from applications.
- ConfigMap: An object that is used to store the cluster configuration.

See the operator's source code on GitHub. The Helm chart is in the deploy folder.
YDB containers are deployed using `cr.yandex/yc/ydb` images. Currently, they are only available as prebuilt artifacts.

Environment Preparation

1. Add the YDB repository to Helm:

Run the command:

```
helm repo add ydb https://charts.ydb.tech/
```

`ydb`: The repository alias.
`https://charts.ydb.tech/`: The YDB repository URL.

Output:

```
"ydb" has been added to your repositories
```

2. Update the Helm chart index:

Run the command:

```
helm repo update
```

Output:

```
Hang tight while we grab the latest from your chart repositories...
...Successfully got an update from the "ydb" chart repository
Update Complete. ⎈Happy Helming!⎈
```

Deploying a YDB Cluster

Install the YDB Kubernetes operator

Use `helm` to deploy the YDB Kubernetes operator to the cluster:

```
helm install ydb-operator ydb/ydb-operator
```

- `ydb-operator`: The installation name.
- `ydb/ydb-operator`: The name of the chart in the repository you have added earlier.

Result:

```
NAME: ydb-operator
LAST DEPLOYED: Thu Aug 12 19:32:28 2021
NAMESPACE: default
STATUS: deployed
REVISION: 1
TEST SUITE: None
```

Deploy Storage Nodes

YDB supports a number of storage topologies. YDB Kubernetes operator comes with a few sample configuration files for the most common topologies. This guide uses them as-is, but feel free to adjust them as needed or implement a new configuration file from scratch.

Apply the manifest for creating storage nodes:

block-4-2

```
kubectl apply -f https://raw.githubusercontent.com/ydb-platform/ydb-kubernetes-operator/master/samples/storag
e-block-4-2.yaml
```

This will create 8 YDB storage nodes that persist data using erasure coding. This takes only 50% of additional storage space to provide fault-tolerance.

mirror-3-dc

```
kubectl apply -f https://raw.githubusercontent.com/ydb-platform/ydb-kubernetes-operator/master/samples/storag
e-mirror-3dc.yaml
```

This will create 9 YDB storage nodes that store data with replication factor 3.

This command creates a `StatefulSet` object that describes a set of YDB containers with stable network IDs and disks assigned to them, as well as `Service` and `ConfigMap` objects that are required for the cluster to work.

YDB storage nodes take a while to initialize. You can check the initialization progress with `kubectl get storages.ydb.tech` or `kubectl describe storages.ydb.tech`. Wait until the status of the Storage resource changes to `Ready`.

> **Warning**
>
> The cluster configuration is static. The controller won't process any changes when the manifest is reapplied. You can only update cluster parameters such as version or disk size by creating a new cluster.

Create a database and dynamic nodes

YDB database is a logical entity that is served by a set of dynamic nodes. A sample manifest that comes with YDB Kubernetes operator creates a database named `database-sample` with 3 dynamic nodes. As with storage nodes, feel free to adjust the configuration as needed.

Apply the manifest for creating a database and dynamic nodes:

```
kubectl apply -f https://raw.githubusercontent.com/ydb-platform/ydb-kubernetes-operator/master/samples/databa
se.yaml
```

> **Note**
>
> The value referenced by `.spec.storageClusterRef.name` key must match the name of the `Storage` resource with storage nodes.

A `StatefulSet` object that describes a set of dynamic nodes is created after processing the manifest. The created database will be accessible from inside the Kubernetes cluster by the `database-sample` hostname or the `database-sample.<namespace>.svc.cluster.local` FQDN, where `namespace` indicates the namespace that was used for the installation. You can connect the database via port 2135.

View the status of the created resource:

```
kubectl describe database.ydb.tech
```

Result:

```
Name:         database-sample
Namespace:    default
Labels:       <none>
Annotations:  <none>
API Version:  ydb.tech/v1alpha1
Kind:         Database
...
  Storage Endpoint:  grpc://storage-sample-grpc.default.svc.cluster.local:2135
Status:
  State:  Ready
Events:
  Type     Reason              Age    From          Message
  ----     ------              ----   ----          -------
  Normal   Provisioning        8m10s  ydb-operator  Resource sync is in progress
  Normal   Provisioning        8m9s   ydb-operator  Resource sync complete
  Normal   TenantInitialized   8m9s   ydb-operator  Tenant /root/database-sample created
```

`State: Ready` means that the database is ready to be used.

Test Cluster Operation

Check how YDB works:

1. Check that all nodes are in the `Running` status:

   ```
   kubectl get pods
   ```

   Result:

   ```
   NAME                READY   STATUS    RESTARTS   AGE
   database-sample-0   1/1     Running   0          1m
   database-sample-1   1/1     Running   0          1m
   database-sample-2   1/1     Running   0          1m
   database-sample-3   1/1     Running   0          1m
   database-sample-4   1/1     Running   0          1m
   database-sample-5   1/1     Running   0          1m
   storage-sample-0    1/1     Running   0          1m
   storage-sample-1    1/1     Running   0          1m
   storage-sample-2    1/1     Running   0          1m
   storage-sample-3    1/1     Running   0          1m
   storage-sample-4    1/1     Running   0          1m
   storage-sample-5    1/1     Running   0          1m
   storage-sample-6    1/1     Running   0          1m
   storage-sample-7    1/1     Running   0          1m
   storage-sample-8    1/1     Running   0          1m
   ```

2. Start a new pod with YDB CLI:

   ```
   kubectl run -it --image=cr.yandex/crptqonuodf51kdj7a7d/ydb:24.4.4.2 --rm ydb-cli bash
   ```

3. Query the YDB database (you can get the endpoint from the output of `kubectl describe database.ydb.tech`):

   ```
   /opt/ydb/bin/ydb \
     --endpoint grpc://database-sample-grpc:2135 \
     --database /Root/database-sample \
     sql -s 'SELECT 2 + 2;'
   ```

   - `--endpoint`: The database endpoint.
   - `--database`: The name of the created database.
   - `--query`: The query text.

   Result:

```
┌──────────┐
| column0 |
├──────────┤
| 4       |
└──────────┘
```

Further Steps

After you have tested that the created YDB cluster operates fine you can continue using it as you see fit. For example, if you just want to continue experimenting, you can use it to follow the YQL tutorial.

Below are a few more things to consider.

Monitoring

YDB provides standard mechanisms for collecting logs and metrics. Logging is done to standard `stdout` and `stderr` streams and can be redirected using popular solutions. For example, you can use a combination of Fluentd and Elastic Stack.

To collect metrics, `ydb-controller` provides resources like `ServiceMonitor`. They can be handled using kube-prometheus-stack.

Tuning Allocated Resources

You can limit resource consumption for each YDB pod. If you leave the limit values empty, a pod can use the entire CPU time and VM RAM. This may cause undesirable effects. We recommend that you always specify the resource limits explicitly.

To learn more about resource allocation and limits, see the Kubernetes documentation.

Release the Unused Resources

If you no longer need the created YDB cluster, delete it by following these steps:

1. To delete a YDB database and its dynamic nodes, just delete the respective `Database` resource:

   ```
   kubectl delete database.ydb.tech database-sample
   ```

2. To delete YDB storage nodes, run the following commands:

   ```
   kubectl delete storage.ydb.tech storage-sample
   kubectl delete pvc -l app.kubernetes.io/name=ydb
   ```

3. To remove the YDB Kubernetes operator, delete it with Helm:

   ```
   helm delete ydb-operator
   ```

   - `ydb-operator`: The name of the release that the controller was installed under.

Manual YDB Cluster Management Overview

This section provides information about deploying, configuring, maintaining, monitoring, and performing diagnostics of multi-node YDB clusters.

Main resources:

- Deploying YDB Cluster Manually
- Cluster Disk Subsystem Management Overview
- Setting Up YDB Cluster Monitoring
- Logging in YDB
- Backup and recovery
- Using YDB UI
- Cluster System Views

Deploying YDB Cluster Manually

This document describes how to deploy a multi-tenant YDB cluster with distributed architecture on multiple bare-metal or virtual servers.

Main guides:

- Deployment Preparation
- Deploying a Cluster Using Configuration V1
- Deploying a Cluster Using Configuration V2

Deployment Preparation

Getting Started

Prerequisites

Review the system requirements and the cluster topology.

Make sure you have SSH access to all servers. This is required to install artifacts and run the YDB executable.

The network configuration must allow TCP connections on the following ports (these are defaults, but you can change them by settings):

- 22: SSH service
- 2135, 2136: GRPC for client-cluster interaction.
- 19001, 19002: Interconnect for intra-cluster node interaction
- 8765, 8766: HTTP interface of YDB UI.

Distinct ports are necessary for gRPC, Interconnect and HTTP interface of each dynamic node when hosting multiple dynamic nodes on a single server.

Make sure that the system clocks running on all the cluster's servers are synced by `ntpd` or `chrony`. We recommend using the same time source for all servers in the cluster to maintain consistent leap seconds processing.

If the Linux flavor run on the cluster servers uses `syslogd` for logging, set up log file rotation using `logrotate` or similar tools. YDB services can generate substantial amounts of system logs, particularly when you elevate the logging level for diagnostic purposes. That's why it's important to enable system log file rotation to prevent the `/var` file system overflow.

Select the servers and disks to be used for storing data:

- Use the `block-4-2` fault tolerance model for cluster deployment in one availability zone (AZ). Use at least eight servers to safely survive the loss of two servers.
- Use the `mirror-3-dc` fault tolerance model for cluster deployment in three availability zones (AZ). To survive the loss of one AZ and one server in another AZ, use at least nine servers. Make sure that the number of servers running in each AZ is the same.

> **Note**
>
> Run each static node (data node) on a separate server. Both static and dynamic nodes can run together on the same server. A server can also run multiple dynamic nodes if it has enough computing power.

For more information about hardware requirements, see YDB System Requirements and Recommendations.

Preparing TLS Keys and Certificates

The TLS protocol provides traffic protection and authentication for YDB server nodes. Before you install your cluster, determine which servers it will host, establish the node naming convention, come up with node names, and prepare your TLS keys and certificates.

You can use existing certificates or generate new ones. Prepare the following files with TLS keys and certificates in the PEM format:

- `ca.crt`: CA-issued certificate used to sign the other TLS certificates (these files are the same on all the cluster nodes).
- `node.key`: Secret TLS keys for each cluster node (one key per cluster server).
- `node.crt`: TLS certificates for each cluster node (each certificate corresponds to a key).
- `web.pem`: Concatenation of the node secret key, node certificate, and the CA certificate needed for the monitoring HTTP interface (a separate file is used for each server in the cluster).

Your organization should define the parameters required for certificate generation in its policy. The following parameters are commonly used for generating certificates and keys for YDB:

- 2048-bit or 4096-bit RSA keys
- Certificate signing algorithm: SHA-256 with RSA encryption
- Validity period of node certificates: at least 1 year
- CA certificate validity period: at least 3 years.

Make sure that the CA certificate is appropriately labeled, with the CA property enabled along with the "Digital Signature, Non Repudiation, Key Encipherment, Certificate Sign" usage types.

For node certificates, it's key that the actual host name (or names) match the values in the "Subject Alternative Name" field. Enable both the regular usage types ("Digital Signature, Key Encipherment") and advanced usage types ("TLS Web Server Authentication, TLS Web Client Authentication") for the certificates. Node certificates must support both server authentication and client authentication (the `extendedKeyUsage = serverAuth,clientAuth` option in the OpenSSL settings).

For batch generation or update of YDB cluster certificates by OpenSSL, you can use the sample script from the YDB GitHub repository. Using the script, you can streamline preparation for installation, automatically generating all the key files and certificate files for all your cluster nodes in a single step.

Create a System User and a Group to Run YDB

On each server that will be running YDB, execute the command below:

```
sudo groupadd ydb
sudo useradd ydb -g ydb
```

To ensure that YDB can access block disks, add the user that will run YDB processes, to the `disk` group:

```
sudo usermod -aG disk ydb
```

Configure File Descriptor Limits

For proper operation of YDB, especially when using spilling in multi-node clusters, it is recommended to increase the limit of simultaneously open file descriptors.

To change the file descriptor limit, add the following lines to the `/etc/security/limits.conf` file:

```
ydb soft nofile 10000
ydb hard nofile 10000
```

Where `ydb` is the username under which `ydbd` runs.

After changing the file, you need to reboot the system or log in again to apply the new limits.

> **Note**
>
> For more information about spilling configuration and its relationship with file descriptors, see the Spilling Configuration section.

Install YDB Software on Each Server

1. Download and unpack an archive with the `ydbd` executable and the libraries required for YDB to run:

```
mkdir ydbd-stable-linux-amd64
curl -L https://binaries.ydb.tech/ydbd-stable-linux-amd64.tar.gz | tar -xz --strip-component=1 -C ydbd-stable
-linux-amd64
```

1. Create directories for YDB software:

```
sudo mkdir -p /opt/ydb /opt/ydb/cfg
```

1. Copy the executable and libraries to the appropriate directories:

```
sudo cp -iR ydbd-stable-linux-amd64/bin /opt/ydb/
sudo cp -iR ydbd-stable-linux-amd64/lib /opt/ydb/
```

1. Set the owner of files and folders:

```
sudo chown -R root:bin /opt/ydb
```

Prepare and Clear Disks on Each Server

For YDB to work efficiently, we recommend using physical (not virtual) disks larger than 800 GB as block devices.

The minimum disk size is 80 GB, otherwise the YDB node won't be able to use the device. Correct and uninterrupted operation with minimum-size disks is not guaranteed. We recommend using such disks exclusively for informational purposes.

> **Warning**
>
> Configurations with disks less than 800 GB or any types of storage system virtualization cannot be used for production services or system performance testing.
>
> We don't recommend storing YDB data on disks shared with other processes (for example, the operating system).

To get a list of available block devices on the server, you can use the `lsblk` command. Example output:

```
NAME   MAJ:MIN RM   SIZE RO TYPE MOUNTPOINTS
loop0    7:0    0  63.3M  1 loop /snap/core20/1822
...
vda    252:0    0    40G  0 disk
├─vda1 252:1    0     1M  0 part
└─vda2 252:2    0    40G  0 part /
vdb    252:16   0   186G  0 disk
└─vdb1 252:17   0   186G  0 part
```

The names of block devices depend on the operating system settings provided by the base image or manually configured. Typically, device names consist of up to three parts:

- A fixed prefix or a prefix indicating the device type
- A device sequential identifier (which can be a letter or a number)
- A partition sequential identifier on the given device (usually a number)

1. Create partitions on the selected disks:

> **Alert**
>
> The next operation will delete all partitions on the specified disk. Make sure that you specified a disk that contains no external data.

```
DISK=/dev/nvme0n1
sudo parted ${DISK} mklabel gpt -s
sudo parted -a optimal ${DISK} mkpart primary 0% 100%
sudo parted ${DISK} name 1 ydb_disk_ssd_01
sudo partx --u ${DISK}
```

Execute the command `ls -l /dev/disk/by-partlabel/` to ensure that a disk with the label `/dev/disk/by-partlabel/ydb_disk_ssd_01` has appeared in the system.

If you plan to use more than one disk on each server, replace `ydb_disk_ssd_01` with a unique label for each one. Disk labels should be unique within each server. They are used in configuration files, see the following guides.

To streamline the next setup step, it makes sense to use the same disk labels on cluster servers having the same disk configuration.

2. Clear the disk by this command built-in the `ydbd` executable:

> **Warning**
>
> After executing this command, data on the disk will be erased.

```
sudo LD_LIBRARY_PATH=/opt/ydb/lib /opt/ydb/bin/ydbd admin bs disk obliterate /dev/disk/by-partlabel/ydb_disk_
ssd_01
```

Perform this operation for each disk to be used for YDB data storage.

After completing the preparation steps, proceed to deployment. Select the guide that matches your configuration:

- Deploying a cluster using configuration V1

Deploying a Cluster Using Configuration V1

Prepare the Environment

Before deploying the system, complete the preparatory steps. Review the Deployment Preparation document.

Prepare Configuration Files

Prepare the YDB configuration file according to your chosen topology (see cluster topology). Examples for each supported topology are provided below in tabs — select and use the one that fits your case.

mirror-3-dc-3nodes

          storage_pool_kind: ssd
        - erasure_species: block-4-2
          pdisk_category: 1
          storage_pool_kind: ssd
      profile_id: 0
interconnect_config:
  start_tcp: true
  encryption_mode: OPTIONAL
  path_to_certificate_file: "/opt/ydb/certs/node.crt"
  path_to_private_key_file: "/opt/ydb/certs/node.key"
  path_to_ca_file: "/opt/ydb/certs/ca.crt"
grpc_config:
  cert: "/opt/ydb/certs/node.crt"
  key: "/opt/ydb/certs/node.key"
  ca: "/opt/ydb/certs/ca.crt"
  services_enabled:
    - legacy
  client_certificate_authorization:
    request_client_certificate: true
    client_certificate_definitions:
      - member_groups: ["registerNode@cert"]
        subject_terms:
          - short_name: "O"
            values: ["YDB"]
```

To speed up and simplify the initial YDB deployment, the configuration file already contains most cluster setup settings. Replace the default host FQDNs with your actual ones in the `hosts` and `blob_storage_config` sections.

- `hosts` section:

```
...
hosts:
  - host: static-node-1.ydb-cluster.com  # VM FQDN
    host_config_id: 1
    walle_location:
      body: 1
      data_center: 'zone-a'
      rack: '1'
...
```

- `blob_storage_config` section:

```
...
- fail_domains:
  - vdisk_locations:
    - node_id: static-node-1.ydb-cluster.com  # VM FQDN
      pdisk_category: SSD
      path: /dev/disk/by-partlabel/ydb_disk_1
...
```

Leave all other configuration sections and settings unchanged.

Save the YDB configuration file as `/opt/ydb/cfg/config.yaml` on each cluster server.

For more detailed information about creating the configuration file, see YDB Cluster Configuration.

Copy TLS Keys and Certificates to Each Server

Copy the prepared TLS keys and certificates to a protected directory on each YDB cluster node. Below are sample commands to create a protected directory and copy the key and certificate files.

```
sudo mkdir -p /opt/ydb/certs
sudo cp -v ca.crt /opt/ydb/certs/
sudo cp -v node.crt /opt/ydb/certs/
sudo cp -v node.key /opt/ydb/certs/
sudo cp -v web.pem /opt/ydb/certs/
sudo chown -R ydb:ydb /opt/ydb/certs
sudo chmod 700 /opt/ydb/certs
```

Start Static Nodes

Manually

Run the YDB data storage service on each static cluster node:

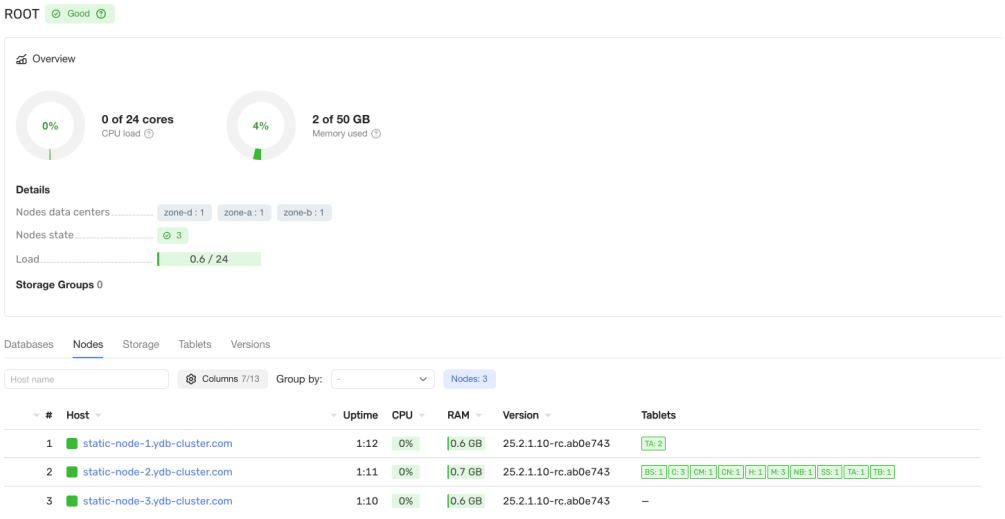
```
sudo su - ydb
cd /opt/ydb
export LD_LIBRARY_PATH=/opt/ydb/lib
/opt/ydb/bin/ydbd server --log-level 3 --syslog --tcp --yaml-config  /opt/ydb/cfg/config.yaml \
    --grpcs-port 2135 --ic-port 19001 --mon-port 8765 --mon-cert /opt/ydb/certs/web.pem --node static &
```

Using systemd

On each server that will host a static cluster node, create a systemd configuration file `/etc/systemd/system/ydbd-storage.service` using the template below. You can also download the sample file from the repository.

```
[Unit]
Description=YDB storage node
After=network-online.target rc-local.service
Wants=network-online.target
StartLimitInterval=10
StartLimitBurst=15

[Service]
Restart=always
RestartSec=1
User=ydb
PermissionsStartOnly=true
StandardOutput=syslog
StandardError=syslog
SyslogIdentifier=ydbd
SyslogFacility=daemon
SyslogLevel=err
Environment=LD_LIBRARY_PATH=/opt/ydb/lib
ExecStart=/opt/ydb/bin/ydbd server --log-level 3 --syslog --tcp \
    --yaml-config  /opt/ydb/cfg/config.yaml \
    --grpcs-port 2135 --ic-port 19001 --mon-port 8765 \
    --mon-cert /opt/ydb/certs/web.pem --node static
LimitNOFILE=65536
LimitCORE=0
LimitMEMLOCK=3221225472



[Install]
WantedBy=multi-user.target
```

Run the service on each static YDB node:

```
sudo systemctl start ydbd-storage
```

After starting the static nodes, verify they are running via YDB UI:

1. Open `https://<node.ydb.tech>:8765` in your browser, where `<node.ydb.tech>` is the FQDN of the server running any static node;
2. Go to the **Nodes** tab;
3. Ensure all 3 static nodes are listed.

Initialize the Cluster

The cluster initialization operation configures the set of static nodes listed in the cluster configuration file for storing YDB data.

To initialize the cluster, you need the Certificate Authority `ca.crt` file; its path must be specified when running the commands. Before running the commands, copy `ca.crt` to the server where you will execute them.

On one of the storage servers in the cluster, run the following commands:

First, obtain an authentication token for request authorization. Run the command below:

```
/opt/ydb/bin/ydb --ca-file ca.crt -e grpcs://`hostname -f`:2135 -d /Root --user root --no-password auth get-t
oken -f > auth_token
```

Initialize the cluster using the obtained token:

```
export LD_LIBRARY_PATH=/opt/ydb/lib
/opt/ydb/bin/ydbd --ca-file ca.crt -s grpcs://`hostname -f`:2135 -f auth_token \
    admin blobstorage config init --yaml-file  /opt/ydb/cfg/config.yaml
echo $?
```

On successful cluster initialization, the cluster initialization command exit code should be zero.

Create a Database

To work with row-oriented or column-oriented tables, you need to create at least one database and run the process or processes serving it (dynamic nodes).

To run the administrative database creation command, you need the Certificate Authority `ca.crt` file, same as for cluster initialization above.

When creating the database, you set the initial number of storage groups, which determines the available I/O throughput and maximum storage capacity. The number of storage groups can be increased after database creation if needed.

On one of the storage servers in the cluster, run the following commands:

```
export LD_LIBRARY_PATH=/opt/ydb/lib
/opt/ydb/bin/ydbd --ca-file ca.crt -s grpcs://`hostname -f`:2135 -f auth_token \
    admin database /Root/testdb create ssd:8
echo $?
```

On successful database creation, the command exit code should be zero.

The command example above uses the following parameters:

- `/Root` — name of the root domain, automatically generated during cluster initialization;
- `testdb` — name of the database to create;
- `ssd:8` — defines the storage pool for the database and the number of groups in it. The pool name (`ssd`) must match the disk type specified in the cluster configuration (for example, in `default_disk_type`) and is case-insensitive. The number after the colon is the number of storage groups to allocate.

Run Dynamic Nodes

Manually

Run the YDB dynamic node for the `/Root/testdb` database:

```
sudo su - ydb
cd /opt/ydb
export LD_LIBRARY_PATH=/opt/ydb/lib
/opt/ydb/bin/ydbd server --grpcs-port 2136 --grpc-ca /opt/ydb/certs/ca.crt \
    --ic-port 19002 --ca /opt/ydb/certs/ca.crt \
    --mon-port 8766 --mon-cert /opt/ydb/certs/web.pem \
    --yaml-config  /opt/ydb/cfg/config.yaml \
    --tenant /Root/testdb \
    --grpc-cert /opt/ydb/certs/node.crt \
    --grpc-key /opt/ydb/certs/node.key \
    --node-broker grpcs://<ydb-static-node1>:2135 \
    --node-broker grpcs://<ydb-static-node2>:2135 \
    --node-broker grpcs://<ydb-static-node3>:2135 &
```

In the command example above, `<ydb-static-node1>` , `<ydb-static-node2>` , `<ydb-static-node3>` are the FQDNs of any three servers running the cluster's static nodes.

Using systemd

Create a systemd configuration file `/etc/systemd/system/ydbd-testdb.service` using the template below. You can also download the sample file from the repository.

```
[Unit]
Description=YDB testdb dynamic node
After=network-online.target rc-local.service
Wants=network-online.target
StartLimitInterval=10
StartLimitBurst=15

[Service]
Restart=always
RestartSec=1
User=ydb
PermissionsStartOnly=true
StandardOutput=syslog
StandardError=syslog
SyslogIdentifier=ydbd
SyslogFacility=daemon
SyslogLevel=err
Environment=LD_LIBRARY_PATH=/opt/ydb/lib
ExecStart=/opt/ydb/bin/ydbd server \
    --grpcs-port 2136 --grpc-ca /opt/ydb/certs/ca.crt \
    --ic-port 19002 --ca /opt/ydb/certs/ca.crt \
    --mon-port 8766 --mon-cert /opt/ydb/certs/web.pem \
    --yaml-config  /opt/ydb/cfg/config.yaml \
    --tenant /Root/testdb \
    --grpc-cert /opt/ydb/certs/node.crt \
    --grpc-key /opt/ydb/certs/node.key \
    --node-broker grpcs://<ydb-static-node1>:2135 \
    --node-broker grpcs://<ydb-static-node2>:2135 \
    --node-broker grpcs://<ydb-static-node3>:2135
LimitNOFILE=65536
LimitCORE=0
LimitMEMLOCK=32212254720

[Install]
WantedBy=multi-user.target
```

In the command example above, `<ydb-static-node1>`, `<ydb-static-node2>`, `<ydb-static-node3>` are the FQDNs of any three servers running the cluster's static nodes.

Run the YDB dynamic node for the `/Root/testdb` database:

```
sudo systemctl start ydbd-testdb
```

Run additional dynamic nodes on other servers for database scaling and fault tolerance.

Account Setup

1. Install the YDB CLI as described in the documentation.
2. Set the password for the `root` account using the token obtained earlier:

   ```
   ydb --ca-file ca.crt -e grpcs://<node.ydb.tech>:2136 -d /Root/testdb --token-file auth_token \
       yql -s 'ALTER USER root PASSWORD "passw0rd"'
   ```

   Replace `passw0rd` with the desired password. Save the password in a separate file. Subsequent commands as the `root` user will use the password passed with the `--password-file <path_to_user_password>` option. You can also save the password in a connection profile, as described in the YDB CLI documentation.
3. Create additional accounts:

   ```
   ydb --ca-file ca.crt -e grpcs://<node.ydb.tech>:2136 -d /Root/testdb --user root --password-file <path_t
   o_root_pass_file> \
       yql -s 'CREATE USER user1 PASSWORD "passw0rd"'
   ```

4. Set account permissions by adding them to built-in groups:

   ```
   ydb --ca-file ca.crt -e grpcs://<node.ydb.tech>:2136 -d /Root/testdb --user root --password-file <path_t
   o_root_pass_file> \
       yql -s 'ALTER GROUP `ADMINS` ADD USER user1'
   ```

In the command examples above, `<node.ydb.tech>` is the FQDN of the server running any dynamic node serving the `/Root/testdb` database. When connecting via SSH to a YDB dynamic node, you can use `grpcs://$(hostname -f):2136` to get the FQDN.

When running account creation and group assignment commands, the YDB CLI client will prompt for the `root` user password. To avoid repeated password entry, create a connection profile as described in the YDB CLI documentation.

Test the Created Database

1. Install the YDB CLI as described in the documentation.
2. Create a test row-oriented table (`test_row_table`) or column-oriented table (`test_column_table`):

Creating a row-oriented table

```
ydb --ca-file ca.crt -e grpcs://<node.ydb.tech>:2136 -d /Root/testdb --user root \
    yql -s 'CREATE TABLE `testdir/test_row_table` (id Uint64, title Utf8, PRIMARY KEY (id));'
```

Creating a column-oriented table

```
ydb --ca-file ca.crt -e grpcs://<node.ydb.tech>:2136 -d /Root/testdb --user root \
    yql -s 'CREATE TABLE `testdir/test_column_table` (id Uint64 NOT NULL, title Utf8, PRIMARY KEY (id)) WITH
(STORE = COLUMN);'
```

Where `<node.ydb.tech>` is the FQDN of the server running the dynamic node serving the `/Root/testdb` database.

Checking Access to YDB UI

To check access to YDB UI, open `https://<node.ydb.tech>:8765` in your browser, where `<node.ydb.tech>` is the FQDN of the server running any static YDB node.

Configure your browser to trust the Certificate Authority that issued certificates for the YDB cluster. Otherwise, you will see a warning about an untrusted certificate.

If authentication is enabled in the cluster, the browser will prompt for login and password. After entering valid credentials, the YDB UI welcome page will appear. The available features and user interface are described in Using YDB UI.

Note

A common way to provide access to YDB UI is to set up a fault-tolerant HTTP balancer using `haproxy`, `nginx`, or similar software. HTTP balancer configuration details are beyond the scope of the standard YDB installation guide.

Installing YDB in Unprotected Mode

Warning

We do not recommend using the unprotected YDB mode for production or application development.

The installation procedure above assumes YDB deployment in the standard protected mode.

The unprotected YDB mode is intended for test scenarios, primarily related to YDB software development and testing. In unprotected mode:

- Traffic between cluster nodes and between applications and the cluster uses unencrypted connections;
- User authentication is not used (enabling authentication without traffic encryption makes no sense, since the login and password would be transmitted over the network in plain text).

To install YDB for operation in unprotected mode, follow the procedure above with the following exceptions:

1. When preparing for installation, you do not need to generate TLS certificates and keys or copy certificates and keys to the cluster nodes.
2. Remove the `security_config`, `interconnect_config`, and `grpc_config` sections from the cluster node configuration files.
3. Use simplified commands to run static and dynamic cluster nodes: omit options specifying certificate and key file names; use the `grpc` protocol instead of `grpcs` when specifying connection endpoints.
4. Skip the authentication token step before cluster initialization and database creation, as it is not needed in unprotected mode.
5. The cluster initialization command has the following format:

```
export LD_LIBRARY_PATH=/opt/ydb/lib
/opt/ydb/bin/ydbd admin blobstorage config init --yaml-file  /opt/ydb/cfg/config.yaml
echo $?
```

6. The database creation command has the following format:

```
export LD_LIBRARY_PATH=/opt/ydb/lib
/opt/ydb/bin/ydbd admin database /Root/testdb create ssd:1
```

7. When accessing the database from the YDB CLI and applications, use grpc instead of grpcs and do not use authentication.

Deploying a Cluster Using Configuration V2

Alert

This article covers YDB clusters that use **configuration V2**. This configuration method is experimental and is only available for YDB versions starting with v25.1. For production use, we recommend choosing configuration V1 — it is the main and officially supported configuration for all YDB clusters.

Prepare the Environment

Before deploying the system, complete the preparatory steps. Review the Deployment Preparation document.

Prepare Configuration Files

Prepare the YDB configuration file:

```
metadata:
  kind: MainConfig
  cluster: ""
  version: 0
config:
  erasure: mirror-3-dc
  fail_domain_type: disk
  self_management_config:
    enabled: true
  default_disk_type: SSD
  host_configs:
  - host_config_id: 1
    drive:
    - path: /dev/disk/by-partlabel/ydb_disk_ssd_01
      type: SSD
    - path: /dev/disk/by-partlabel/ydb_disk_ssd_02
      type: SSD
    - path: /dev/disk/by-partlabel/ydb_disk_ssd_03
      type: SSD
  hosts:
  - host: ydb-node-zone-a.local
    host_config_id: 1
    location:
      body: 1
      data_center: 'zone-a'
      rack: '1'
  - host: ydb-node-zone-b.local
    host_config_id: 1
    location:
      body: 2
      data_center: 'zone-b'
      rack: '2'
  - host: ydb-node-zone-c.local
    host_config_id: 1
    location:
      body: 3
      data_center: 'zone-c'
      rack: '3'
  actor_system_config:
    use_auto_config: true
    cpu_count: 8
  interconnect_config:
    start_tcp: true
    encryption_mode: OPTIONAL
    path_to_certificate_file: "/opt/ydb/certs/node.crt"
    path_to_private_key_file: "/opt/ydb/certs/node.key"
    path_to_ca_file: "/opt/ydb/certs/ca.crt"
  grpc_config:
    cert: "/opt/ydb/certs/node.crt"
    key: "/opt/ydb/certs/node.key"
    ca: "/opt/ydb/certs/ca.crt"
    services_enabled:
    - legacy
  security_config:
    enforce_user_token_requirement: true
    monitoring_allowed_sids:
    - "root"
    - "ADMINS"
    - "DATABASE-ADMINS"
    administration_allowed_sids:
    - "root"
    - "ADMINS"
    - "DATABASE-ADMINS"
    viewer_allowed_sids:
    - "root"
    - "ADMINS"
    - "DATABASE-ADMINS"
    register_dynamic_node_allowed_sids:
    - databaseNodes@cert
    - root@builtin
    bootstrap_allowed_sids:
    - "root"
    - "ADMINS"
    - "DATABASE-ADMINS"
  client_certificate_authorization:
    request_client_certificate: true
    client_certificate_definitions:
        - member_groups: ["ADMINS", "databaseNodes@cert"]
          subject_terms:
          - short_name: "O"
            values: ["YDB"]
```

Note

The configuration shown above is prepared for running YDB on 3 physical or virtual servers using mirror-3-dc cluster operating mode.

To speed up and simplify the initial deployment of YDB, the provided configuration file example already contains most of the cluster setup settings. You only need to replace the default host FQDNs in the `hosts` section and disk paths in the `host_configs` section with your actual values.

- The `hosts` section:

```
...
hosts:
- host: ydb-node-zone-a.local
  host_config_id: 1
  location:
    body: 1
    data_center: 'zone-a'
    rack: '1'
...
```

- The `host_configs` section:

```
...
host_configs:
- host_config_id: 1
  drive:
  - path: /dev/disk/by-partlabel/ydb_disk_ssd_01
    type: SSD
  - path: /dev/disk/by-partlabel/ydb_disk_ssd_02
    type: SSD
  - path: /dev/disk/by-partlabel/ydb_disk_ssd_03
    type: SSD
...
```

Leave the other sections and configuration file settings unchanged.

Save the YDB configuration file as `/tmp/config.yaml` on each cluster server.

For more information on creating the configuration file, see YDB Cluster Configuration.

Copy TLS Keys and Certificates to Each Server

Copy the prepared TLS keys and certificates to a secure directory on each YDB cluster node. Below is an example of commands to create a secure directory and copy the key and certificate files.

```
sudo mkdir -p /opt/ydb/certs
sudo cp -v ca.crt /opt/ydb/certs/
sudo cp -v node.crt /opt/ydb/certs/
sudo cp -v node.key /opt/ydb/certs/
sudo cp -v web.pem /opt/ydb/certs/
sudo chown -R ydb:ydb /opt/ydb/certs
sudo chmod 700 /opt/ydb/certs
```

Prepare Configuration on Static Cluster Nodes

Create an empty `opt/ydb/cfg` directory on each machine for the cluster to work with the configuration. If running multiple cluster nodes on a single machine, create separate directories for each node.

```
sudo mkdir -p /opt/ydb/cfg
sudo chown -R ydb:ydb /opt/ydb/cfg
```

Run a special command on each machine to initialize this directory with the configuration file.

```
sudo /opt/ydb/bin/ydb admin node config init --config-dir /opt/ydb/cfg --from-config /tmp/config.yaml
```

After running this command, the source file `/tmp/config.yaml` is no longer used and can be removed.

Start Static Nodes

Manually

Start the YDB storage service on each static cluster node:

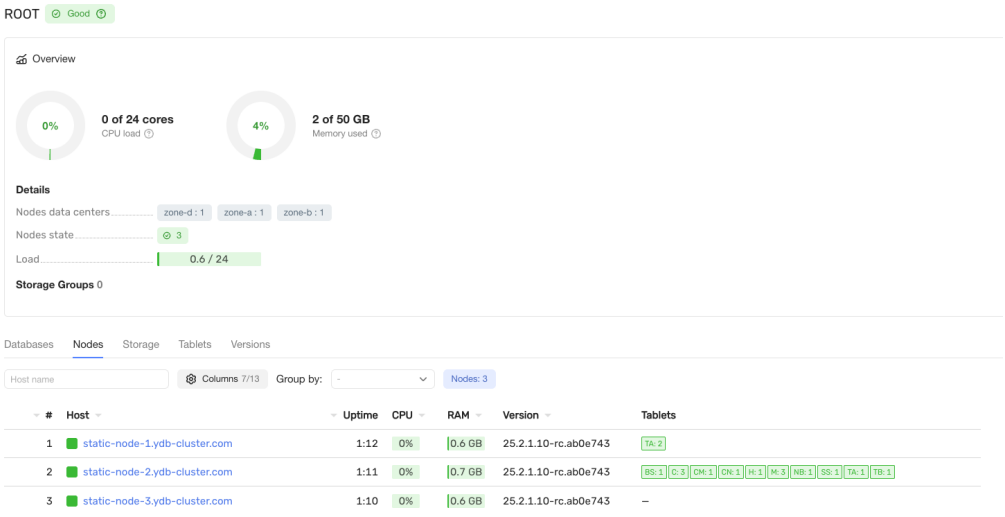
```
sudo su - ydb
cd /opt/ydb
export LD_LIBRARY_PATH=/opt/ydb/lib
/opt/ydb/bin/ydbd server --log-level 3 --syslog --tcp --yaml-config  /opt/ydb/cfg/config.yaml \
    --grpcs-port 2135 --ic-port 19001 --mon-port 8765 --mon-cert /opt/ydb/certs/web.pem --node static
```

Using systemd

Create the systemd configuration file `/etc/systemd/system/ydbd-storage.service` on each server that will host a static cluster node, using the template below. You can also download the template from the repository.

```
[Unit]
Description=YDB storage node
After=network-online.target rc-local.service
Wants=network-online.target
StartLimitInterval=10
StartLimitBurst=15

[Service]
Restart=always
RestartSec=1
User=ydb
PermissionsStartOnly=true
StandardOutput=syslog
StandardError=syslog
SyslogIdentifier=ydbd
SyslogFacility=daemon
SyslogLevel=err
Environment=LD_LIBRARY_PATH=/opt/ydb/lib
ExecStart=/opt/ydb/bin/ydbd server --log-level 3 --syslog --tcp \
    --yaml-config  /opt/ydb/cfg/config.yaml \
    --grpcs-port 2135 --ic-port 19001 --mon-port 8765 \
    --mon-cert /opt/ydb/certs/web.pem --node static
LimitNOFILE=65536
LimitCORE=0
LimitMEMLOCK=3221225472



[Install]
WantedBy=multi-user.target
```

Start the service on each YDB static node:

```
sudo systemctl start ydbd-storage
```

After starting the static nodes, verify they are working via YDB UI:

1. Open `https://<node.ydb.tech>:8765` in your browser, where `<node.ydb.tech>` is the FQDN of the server running any static node;
2. Go to the **Nodes** tab;
3. Make sure all 3 static nodes are displayed in the list.

Initialize the Cluster

The cluster initialization operation configures the set of static nodes listed in the cluster configuration file for YDB data storage.

You will need the Certificate Authority (CA) certificate file `ca.crt` for cluster initialization; its path must be specified when running the relevant commands. Before running these commands, copy the `ca.crt` file to the server where they will be executed.

On one of the storage servers in the cluster, run the commands:

Initialize the cluster using the obtained token

```
export LD_LIBRARY_PATH=/opt/ydb/lib
/opt/ydb/bin/ydb --ca-file ca.crt \
    --client-cert-file node.crt \
    --client-cert-key-file node.key \
    -e grpcs://`hostname -f`:2135 \
    admin cluster bootstrap --uuid <string>
echo $?
```

After initializing the cluster, you must obtain an authentication token before running further administrative commands.

```
/opt/ydb/bin/ydb -e grpcs://`hostname -f`:2135 -d /Root --ca-file ca.crt \
--user root --no-password auth get-token --force > auth_token
```

If the cluster initialization completes successfully, the command exit code should be zero.

Create a Database

To work with row or column tables, you need to create at least one database and start the process or processes that serve it (dynamic nodes).

You will need the Certificate Authority (CA) certificate file `ca.crt` to run the administrative command for creating a database, similar to the cluster initialization procedure described above.

When creating a database, you set the initial number of storage groups, which determines the available I/O throughput and maximum storage capacity. The number of storage groups can be increased after database creation if needed.

On one of the storage servers in the cluster, run the commands:

```
export LD_LIBRARY_PATH=/opt/ydb/lib
/opt/ydb/bin/ydbd --ca-file ca.crt -s grpcs://`hostname -f`:2135 -f auth_token \
    admin database /Root/testdb create ssd:8
echo $?
```

If the database is created successfully, the command exit code should be zero.

The example commands above use the following parameters:

- `/Root` — the root domain name, generated automatically during cluster initialization;
- `testdb` — the name of the database being created;
- `ssd:8` — specifies the storage pool for the database and the number of groups in it. The pool name (`ssd`) must match the disk type specified in the cluster configuration (for example, in `default_disk_type`) and is case-insensitive. The number after the colon is the number of allocated storage groups.

Start Dynamic Nodes

Manually

Start the YDB dynamic node for the `/Root/testdb` database:

```
sudo su - ydb
cd /opt/ydb
export LD_LIBRARY_PATH=/opt/ydb/lib
/opt/ydb/bin/ydbd server --grpcs-port 2136 --grpc-ca /opt/ydb/certs/ca.crt \
    --ic-port 19002 --ca /opt/ydb/certs/ca.crt \
    --mon-port 8766 --mon-cert /opt/ydb/certs/web.pem \
    --yaml-config  /opt/ydb/cfg/config.yaml \
    --tenant /Root/testdb \
    --grpc-cert /opt/ydb/certs/node.crt \
    --grpc-key /opt/ydb/certs/node.key \
    --node-broker grpcs://<ydb-static-node1>:2135 \
    --node-broker grpcs://<ydb-static-node2>:2135 \
    --node-broker grpcs://<ydb-static-node3>:2135
```

In the example above, `<ydb-static-node1>` , `<ydb-static-node2>` , and `<ydb-static-node3>` are the FQDNs of any three servers running static cluster nodes.

Using systemd

Create the systemd configuration file `/etc/systemd/system/ydbd-testdb.service` using the template below. You can also download the template from the repository.

```
[Unit]
Description=YDB testdb dynamic node
After=network-online.target rc-local.service
Wants=network-online.target
StartLimitInterval=10
StartLimitBurst=15

[Service]
Restart=always
RestartSec=1
User=ydb
PermissionsStartOnly=true
StandardOutput=syslog
StandardError=syslog
SyslogIdentifier=ydbd
SyslogFacility=daemon
SyslogLevel=err
Environment=LD_LIBRARY_PATH=/opt/ydb/lib
ExecStart=/opt/ydb/bin/ydbd server \
    --grpcs-port 2136 --grpc-ca /opt/ydb/certs/ca.crt \
    --ic-port 19002 --ca /opt/ydb/certs/ca.crt \
    --mon-port 8766 --mon-cert /opt/ydb/certs/web.pem \
    --yaml-config  /opt/ydb/cfg/config.yaml \
    --tenant /Root/testdb \
    --grpc-cert /opt/ydb/certs/node.crt \
    --grpc-key /opt/ydb/certs/node.key \
    --node-broker grpcs://<ydb-static-node1>:2135 \
    --node-broker grpcs://<ydb-static-node2>:2135 \
    --node-broker grpcs://<ydb-static-node3>:2135
LimitNOFILE=65536
LimitCORE=0
LimitMEMLOCK=32212254720

[Install]
WantedBy=multi-user.target
```

In the example above, `<ydb-static-node1>`, `<ydb-static-node2>`, and `<ydb-static-node3>` are the FQDNs of any three servers running static cluster nodes.

Start the YDB dynamic node for the `/Root/testdb` database:

```
sudo systemctl start ydbd-testdb
```

Start additional dynamic nodes on other servers to scale and ensure database fault tolerance.

Configure User Accounts

1. Set a password for the `root` account using the token obtained earlier:

   ```
   ydb --ca-file ca.crt -e grpcs://<node.ydb.tech>:2136 -d /Root/testdb --token-file auth_token \
       yql -s 'ALTER USER root PASSWORD "passw0rd"'
   ```

   Replace `passw0rd` with your desired password. Save the password in a separate file. Subsequent commands as the `root` user will use the password passed via the `--password-file <path_to_user_password>` option. You can also save the password in a connection profile, as described in the YDB CLI documentation.
2. Create additional user accounts:

   ```
   ydb --ca-file ca.crt -e grpcs://<node.ydb.tech>:2136 -d /Root/testdb --user root --password-file <path_t
   o_root_pass_file> \
       yql -s 'CREATE USER user1 PASSWORD "passw0rd"'
   ```

3. Set account permissions by adding them to built-in groups:

   ```
   ydb --ca-file ca.crt -e grpcs://<node.ydb.tech>:2136 -d /Root/testdb --user root --password-file <path_t
   o_root_pass_file> \
       yql -s 'ALTER GROUP `ADMINS` ADD USER user1'
   ```

In the examples above, `<node.ydb.tech>` is the FQDN of the server running any dynamic node that serves the `/Root/testdb` database. When connecting via SSH to the YDB dynamic node, you can use `grpcs://$(hostname -f):2136` to get the FQDN.

When running user account creation and group assignment commands, the YDB CLI client will prompt for the `root` user password. To avoid entering the password multiple times, create a connection profile as described in the YDB CLI documentation.

Test Working with the Created Database

1. Install YDB CLI as described in the documentation.
2. Create a test row table (`test_row_table`) or column table (`test_column_table`):

Creating a row table

```
ydb --ca-file ca.crt -e grpcs://<node.ydb.tech>:2136 -d /Root/testdb --user root \
    yql -s 'CREATE TABLE `testdir/test_row_table` (id Uint64, title Utf8, PRIMARY KEY (id));'
```

Creating a column table

```
ydb --ca-file ca.crt -e grpcs://<node.ydb.tech>:2136 -d /Root/testdb --user root \
    yql -s 'CREATE TABLE `testdir/test_column_table` (id Uint64 NOT NULL, title Utf8, PRIMARY KEY (id)) WITH
(STORE = COLUMN);'
```

Where `<node.ydb.tech>` is the FQDN of the server running the dynamic node that serves the `/Root/testdb` database.

Verifying Access to YDB UI

To verify access to YDB UI, open `https://<node.ydb.tech>:8765` in a web browser, where `<node.ydb.tech>` is the FQDN of the server running any YDB static node.

The web browser must be configured to trust the Certificate Authority that issued the certificates for the YDB cluster; otherwise, a warning about using an untrusted certificate will be displayed.

If authentication is enabled in the cluster, the web browser will display a login and password prompt. After entering valid authentication credentials, the YDB UI home page should appear. A description of the available features and user interface is provided in Using YDB UI.

Note

Typically, to provide access to YDB UI, a fault-tolerant HTTP load balancer is configured using software such as `haproxy`, `nginx`, or similar. HTTP load balancer configuration details are beyond the scope of the standard YDB installation instructions.

Installing YDB in Insecure Mode

Warning

We do not recommend using YDB in insecure mode for either production or application development.

The installation procedure described above deploys YDB in the standard secure mode.

The insecure mode of YDB is intended for test tasks, primarily related to YDB software development and testing. In insecure mode:

- traffic between cluster nodes, as well as between applications and the cluster, uses unencrypted connections;
- user authentication is not used (enabling authentication without traffic encryption would be pointless, since login and password would be transmitted over the network in plain text).

To install YDB for operation in insecure mode, follow the procedure described above with the following exceptions:

1. No TLS certificates and keys need to be created during preparation, and certificates and keys are not copied to cluster nodes.
2. The `security_config`, `interconnect_config`, and `grpc_config` sections are removed from cluster node configuration files.
3. Use simplified commands for starting static and dynamic cluster nodes: omit options with certificate and key file names, and use the `grpc` protocol instead of `grpcs` when specifying connection endpoints.
4. Skip the authentication token step before cluster initialization and database creation, as it is not needed in insecure mode.
5. Run the cluster initialization command in the following form:

   ```
   export LD_LIBRARY_PATH=/opt/ydb/lib
   ydb admin cluster bootstrap --uuid <string>
   echo $?
   ```

6. Run the database creation command in the following form:

   ```
   export LD_LIBRARY_PATH=/opt/ydb/lib
   /opt/ydb/bin/ydbd admin database /Root/testdb create ssd:1
   ```

7. When accessing the database from YDB CLI and applications, use the grpc protocol instead of grpcs, and do not use authentication.

Updating configuration of manually deployed YDB clusters

When manually deploying a YDB cluster, configuration management is performed through YDB CLI. This article covers methods for changing cluster configuration after initial deployment.

Basic configuration operations

Getting current configuration

To get the current cluster configuration, use the command:

```
ydb -e grpcs://<endpoint>:2135 admin cluster config fetch > config.yaml
```

Use the address of any cluster node as `<endpoint>`.

Applying new configuration

To upload updated configuration to the cluster, use the following command:

```
ydb -e grpcs://<endpoint>:2135 admin cluster config replace -f config.yaml
```

Some configuration parameters are applied on the fly after executing the command, however some require performing the cluster restart procedure.

Cluster maintenance

The ydbops utility uses CMS to perform cluster maintenance without losing availability. You can also use CMS directly through the gRPC API.

Rolling restart

To perform a rolling restart of the entire cluster, you can use the command:

```
$ ydbops restart
```

By default, the `strong` availability mode will be used, minimizing the risk of losing availability. You can override it using the `--availability-mode` parameter.

The `ydbops` utility will automatically create a maintenance task to restart the entire cluster using the specified availability mode. As it progresses, `ydbops` will update the maintenance task and obtain exclusive locks on nodes in CMS until all nodes are restarted.

Take a host out for maintenance

To take a host out for maintenance, follow these steps:

1. Create a maintenance task using the command:

   ```
   $ ydbops maintenance create --hosts=<fqdn> --duration=<seconds>
   ```

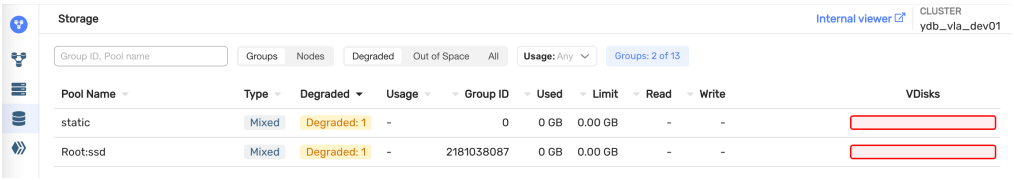
   This command will create a maintenance task that will take an exclusive lock on the host with the fully qualified domain name `<fqdn>` for `<seconds>` seconds.
2. After creating the task, you need to update its state until the lock is taken, using the command:

   ```
   $ ydbops maintenance refresh --task-id=<id>
   ```

   This command will update the task with identifier `<id>` and attempt to take the required lock. When you receive a `PERFORMED` response, you can proceed to the next step.
3. Perform host maintenance while the lock is held.
4. After completing the work, you need to release the lock on the host using the command:

   ```
   $ ydbops maintenance complete --task-id=<id> --hosts=<fqdn>
   ```

Updating YDB



YDB is a distributed system that supports rolling restart without downtime or performance degradation.

Update Procedure

The basic scenario is updating the executable file and restarting each node one by one:

1. Updating and restarting storage nodes.
2. Updating and restarting dynamic nodes.

The shutdown and startup process is described on the Safe restart and shutdown of nodes page.
You must update YDB nodes one by one and monitor the cluster status after each step in YDB Monitoring: make sure the `Storage` tab has no pools in the `Degraded` status (as shown in the example below). Otherwise, stop the update process.

Version Compatibility

All minor versions within a major version are compatible for updates. Major versions are consecutively compatible. To update to the next major version, you must first update to the latest minor release of the current major version. For example:

- `X.Y.* → X.Y.*`: Update is possible, all minor versions within a single major version are compatible.
- `X.Y.Z` (the latest available version in `X.Y.*`) → `X.Y+1.*` : Update is possible, major versions are consistent.
- `X.Y.* → X.Y+2.*`: Update is impossible, major versions are inconsistent.
- `X.Y.* → X.Y-2.*`: Update is impossible, major versions are inconsistent.

A list of available versions can be found on the download page. The YDB release policy is described in more details in the Release management article of the YDB development documentation.

> **Warning**
>
> Also, in any case, you cannot roll back more than 2 major versions relative to the version that was deployed at least once. This is because such an old version may not know how to work with data on the disks that the newer version persisted.

Examples of Version Compatibility

- `v.22.2.5 → v.22.2.47`: Update is possible.
- `v.22.2.47 → v.22.3.21`: Update is possible.
- `v.22.2.40 → v.22.3.21`: Update is impossible, first upgrade to the latest minor version (v.22.2.47).
- `v.22.2.47 → v.22.4.5`: Update is impossible, upgrade to the next major version first (v.22.3.*).

Checking Update Results

You can check the updated node versions on the `Nodes` page in Monitoring.

Database node authentication and authorization

Node authentication in the YDB cluster ensures that database nodes are authenticated when making service requests to other nodes via the gRPC protocol. Node authorization ensures that the privileges required by the service requests are checked and granted during request processing. These service calls include database node registration within the cluster and access to dynamic configuration information. The use of node authorization is recommended for all YDB clusters, as it helps prevent unauthorized access to data by adding nodes to the cluster.

Database node authentication and authorization are performed in the following order:

1. The database node being started opens a gRPC connection to one of the cluster storage nodes specified in the `--node-broker` command-line option. The connection uses the TLS protocol, and the certificate of the running node is used as the client certificate for the connection.
2. The storage node and the database node perform mutual authentication checks using the TLS protocol: the certificate trust chain is checked, and the hostname is matched against the value of the "Subject Name" field of the certificate.
3. The storage node checks the "Subject" field of the certificate for compliance with the requirements set up through settings in the static configuration.
4. If the above checks are successful, the connection from the database node is considered authenticated, and it is assigned a security identifier - SID, which is determined by the settings.
5. The database node uses the established gRPC connection to register with the cluster through the corresponding service request. When registering, the database node sends its network address intended to be used for communication with other cluster nodes.
6. The storage node checks whether the SID assigned to the gRPC connection is in the list of acceptable ones. If this check is successful, the storage node registers the database node within the cluster, saving the association between the network address of the registered node and its identifier.
7. The database node joins the cluster by connecting via its network address and providing the node ID it received during registration. Attempts to join the cluster by nodes with unknown network addresses or IDs are blocked by other nodes.

Below are the steps required to enable the node authentication and authorization feature.

Configuration prerequisites

1. The deployed YDB cluster must have gRPC traffic encryption configured to use the TLS protocol.
2. When preparing node certificates for a cluster where you plan to use the node authorization feature, uniform rules must be used for populating the "Subject" field of the certificates. This allows the identification of certificates issued for the cluster nodes. For more information, see the certificate verification rules documentation.

   > **Note**
   >
   > The proposed example script generates self-signed certificates for YDB nodes and ensures that the "Subject" field is populated with the value `O=YDB` for all node certificates. The configuration examples provided below are prepared for certificates with this specific "Subject" field configuration, but feel free to use your real organization name instead.

3. The command-line parameters for starting database nodes must include options that specify the paths to the trusted CA certificate, the node certificate, and the node key files. The required additional command-line parameters are:

Command-line option	Description
`--grpc-ca`	Path to the trusted certification authority file `ca.crt`
`--grpc-cert`	Path to the node certificate file `node.crt`
`--grpc-key`	Path to the node secret key file `node.key`

   Below is an example of the complete command to start the database node, including the extra options for gRPC TLS key and certificate files:

   ```
   /opt/ydb/bin/ydbd server --yaml-config  /opt/ydb/cfg/config.yaml --tenant /Root/testdb \
       --grpcs-port 2136 --grpc-ca /opt/ydb/certs/ca.crt \
       --grpc-cert /opt/ydb/certs/node.crt --grpc-key /opt/ydb/certs/node.key \
       --ic-port 19002 --ca /opt/ydb/certs/ca.crt \
       --mon-port 8766 --mon-cert /opt/ydb/certs/web.pem \
       --node-broker grpcs://<ydb1>:2135 \
       --node-broker grpcs://<ydb2>:2135 \
       --node-broker grpcs://<ydb3>:2135
   ```

Enabling database node authentication and authorization

To enable mandatory database node authorization, add the following configuration blocks to the static cluster configuration file:

1. At the root level, add the `client_certificate_authorization` block to define the requirements for the "Subject" field of trusted node certificates. For example:

   ```
   client_certificate_authorization:
     request_client_certificate: true
     client_certificate_definitions:
       - member_groups: ["registerNode@cert"]
         subject_terms:
         - short_name: "O"
           values: ["YDB"]
   ```

   Add other certificate validation settings as defined in the documentation, if required.

   If the certificate is successfully verified and the components of the "Subject" field comply with the requirements defined in the `subject_terms` sub-block, the connection will be assigned the access subjects listed in the `member_groups` parameter. To distinguish these subjects from other user groups and accounts, their names typically have the `@cert` suffix.

2. Add the `register_dynamic_node_allowed_sids` element to the cluster authentication settings `security_config` block, and list the subjects permitted for database node registration. Example:

```
domains_config:
    ...
    security_config:
        enforce_user_token_requirement: true
        monitoring_allowed_sids:
        ...
        administration_allowed_sids:
        ...
        viewer_allowed_sids:
        ...
        register_dynamic_node_allowed_sids:
        - "registerNode@cert"
```

   For more detailed information on configuring cluster authentication parameters, see the relevant documentation section.

3. In the `auth_config` section of the cluster configuration, add the `node_registration_token` as an empty string. Example:

```
auth_config:
  ...
  node_registration_token: ""
```

4. Deploy the static configuration files on all cluster nodes either manually, or using the Ansible playbook action.
5. Perform the rolling restart of storage nodes by using ydbops or Ansible playbook action.
6. Perform the rolling restart of database nodes through ydbops or Ansible playbooks.

Managing a cluster in bridge mode

> **Feature of Yandex Enterprise Database**
>
> This functionality is available only in the Yandex Enterprise Database. In the open-source version of YDB it is absent.

Below are typical operations for a cluster in bridge mode using the corresponding YDB CLI commands.

View current state

Shows the current state of each pile configured on the YDB cluster.

```
ydb admin cluster bridge list
```

Example output:

```
pile-a: PRIMARY
pile-b: SYNCHRONIZED
```

Planned `PRIMARY` change (switchover)

If planned maintenance is scheduled in the foreseeable future in the data center or on the equipment where the current `PRIMARY` pile is running, it is recommended to switch the cluster to use another pile as `PRIMARY` in advance. Select another pile in the `SYNCHRONIZED` state to switch it to the `PRIMARY` state with the following command:

```
ydb admin cluster bridge switchover --new-primary <pile>
```

The switchover is performed smoothly: roles go through `PRIMARY/PROMOTED` and end in the `SYNCHRONIZED/PRIMARY` state.

Planned pile disconnection (takedown)

If planned maintenance will make one of the pile unavailable, it must be taken out of the cluster before starting using the following command:

```
ydb admin cluster bridge takedown --pile <pile>
# if disconnecting the current PRIMARY:
ydb admin cluster bridge takedown --pile <current-primary> --new-primary <synchronized-pile>
```

When the operation is performed, the pile is transitioned to `SUSPENDED`, then to `DISCONNECTED`; further cluster operations are performed without the disconnected pile.

If disconnecting the current `PRIMARY` and it was not possible to change it in advance, these operations can be combined by specifying the new `PRIMARY` in the `--new-primary` argument, which must be in the `SYNCHRONIZED` state.

```
ydb admin cluster bridge takedown --pile <pile>
# if disconnecting the current PRIMARY:
ydb admin cluster bridge takedown --pile <current-primary> --new-primary <synchronized-pile>
```

> **Warning**
>
> Before starting planned maintenance, always verify using the list command that the pile disconnection operation has completed successfully and all pile are in the expected state.

Emergency disconnection of unavailable pile (failover)

Since synchronous replication operates between pile, when one of them unexpectedly fails, cluster operation stops by default, and a decision must be made whether to continue cluster operation without this pile. This decision can be made by a person (for example, an on-call DevOps engineer) or by automation external to the YDB cluster.

If the decision is to continue cluster operation, run the following command:

```
ydb admin cluster bridge failover --pile <unavailable-pile>
```

If the current `PRIMARY` is unavailable, you must add the `--new-primary` parameter with the name of a pile in the `SYNCHRONIZED` state. If the parameter is not specified or is specified incorrectly, the command will fail with an error without any changes to the cluster.

```
ydb admin cluster bridge failover --pile <unavailable-pile>
# if the current PRIMARY is unavailable:
ydb admin cluster bridge failover --pile <unavailable-primary> --new-primary <synchronized-pile>
```

The unavailable pile will be transitioned to the `DISCONNECTED` state, and when a new `PRIMARY` is specified, that role will be switched. If other pile are in states other than `SYNCHRONIZED`, emergency disconnection can also be performed. Valid transitions depend on the current state pair and are shown on the state diagram and in the transition table.

> **Warning**
>
> If mandatory authentication is enabled on the cluster, login and password authentication cannot be used while the cluster is in an emergency state — use client certificate authentication instead. For details, see Authentication specifics when the cluster is in an emergency state.

Return pile to the cluster (rejoin)

After planned maintenance is complete or the causes of the failure have been resolved, previously disconnected pile must be explicitly brought back into operation with the following command:

```
ydb admin cluster bridge rejoin --pile <pile>
```

Immediately after the operation starts, the pile transitions to the `NOT_SYNCHRONIZED` state and a background data synchronization process starts; when synchronization completes, the pile automatically becomes `SYNCHRONIZED`. After waiting for this state, you can switch the `PRIMARY` role to this pile if needed.

Authentication specifics when the cluster is in an emergency state

Bridge cluster management commands require cluster administrator privileges. If mandatory authentication is enabled (`enforce_user_token_requirement: true`), all authentication methods are available during normal cluster operation, including login and password authentication.

However, when a pile fails, the cluster suspends serving requests until failover is performed. In this state, login and password authentication cannot be used: validating credentials requires access to SchemeShard, which is unavailable while the cluster is in an emergency state. A login attempt fails with the following error:

```
SchemeShard is unreachable
```

The only authentication method available while the cluster is in an emergency state is client certificate authentication. The client certificate is verified locally by the node that received the request, so this check does not depend on the availability of the cluster as a whole.

Client certificate authentication must be configured on the cluster in advance:

1. The `client_certificate_authorization` section of the cluster configuration must assign an administrative group SID to connections with a trusted client certificate:

   ```
   client_certificate_authorization:
     request_client_certificate: true
     client_certificate_definitions:
       - member_groups: ["ADMINS"]
         subject_terms:
         - short_name: "O"
           values: ["YDB"]
   ```

2. This SID must be included in the `administration_allowed_sids` list of the `security_config` section:

   ```
   security_config:
     enforce_user_token_requirement: true
     administration_allowed_sids:
     - "root"
     - "ADMINS"
   ```

If the cluster is deployed following the deployment guide, these settings are already included in the configuration, and the `node.crt` and `node.key` files from the `~/CA/certs/` directory on any cluster node can be used as the client certificate.

To authenticate with a client certificate, specify it in the YDB CLI global options `--client-cert-file` and `--client-cert-key-file`. Connect to a node of a healthy pile. Failover example:

```
ydb -e grpcs://<node.ydb.tech>:2135 \
    --ca-file ca.crt \
    --client-cert-file node.crt \
    --client-cert-key-file node.key \
    admin cluster bridge failover --pile <unavailable-pile> --new-primary <synchronized-pile>
```

where:

- `<node.ydb.tech>` — FQDN of a node in a healthy pile;
- `ca.crt` — certificate of the cluster's trusted certificate authority;
- `node.crt`, `node.key` — client certificate and its private key that satisfy the requirements of the `client_certificate_authorization` section.

> **Warning**
>
> Verify that client certificate authentication works in advance, before an emergency occurs. If client certificate authentication was not configured before the emergency, bringing the cluster out of the emergency state becomes significantly more complicated and requires manual intervention on the cluster nodes.

Cluster Disk Subsystem Management Overview

Managing a cluster's disk subsystem includes the following actions:

- Configuration changes:
  - Cluster Expansion.
  - Adding storage groups.
- Maintenance:
  - Replacing Node FQDN.
  - Safe restart and shutdown of nodes.
  - Enabling/disabling Scrubbing.
  - SelfHeal.
  - Data Center Decommissioning.
  - Decommissioning groups using virtual groups.
  - Moving VDisks.
  - Blob Depot.
  - Group Decommissioning.
- Troubleshooting:
  - Staying within the failure model.
  - Disk load balancing.
  - Freeing up space on physical devices.

Adding storage groups

As the amount of stored data grows, you may need to add disks to your YDB cluster. You can add disks either to existing nodes or along with new nodes. To make the resources of new disks available to the database, add storage groups.

To add new storage groups, use YDB DSTool.

View a list of cluster storage pools:

```
ydb-dstool -e <bs_endpoint> pool list
```

Result example:

```
┌──────────────┬──────────────────┬─────────────────┬──────┬──────────────┬──────────────┐
| BoxId:PoolId | PoolName         | ErasureSpecies | Kind | Groups_TOTAL | VDisks_TOTAL |
├──────────────┼──────────────────┼─────────────────┼──────┼──────────────┼──────────────┤
| [1:1]        | /Root/testdb:ROT | mirror-3-dc    | ROT  | 1            | 9            |
└──────────────┴──────────────────┴─────────────────┴──────┴──────────────┴──────────────┘
```

The command below adds 10 groups to the `/Root/testdb:ROT` pool:

```
ydb-dstool -e <bs_endpoint> group add --pool-name /Root/testdb:ROT --groups 10
```

If successful, the command returns a zero `exit status`. Or else, it returns a non-zero exit status and outputs an error message to `stderr`.

To check if groups can be added without actually adding them, use the `--dry-run` global parameter. The command below checks if 100 groups can be added to the `/Root/testdb:ROT` pool:

```
ydb-dstool --dry-run -e <bs_endpoint> group add --pool-name /Root/testdb:ROT --groups 100
```

The `--dry-run` parameter lets you estimate the maximum number of groups that you can add to the pool.

Safe restart and shutdown of nodes

Stopping/restarting a YDB process on a node

To make sure that the process is stoppable, follow these steps.

1. Access the node via SSH.
2. Execute the command

   ```
   ydbd cms request restart host {node_id} --user {user} --duration 60 --dry --reason 'some-reason'
   ```

   If the process is stoppable, you'll see `ALLOW`.
3. Stop the process

   ```
   sudo service ydbd stop
   ```

4. Restart the process if needed

   ```
   sudo service ydbd start
   ```

Replacing equipment

Before replacing equipment, make sure that the YDB process is stoppable.
If the replacement is going to take a long time, first move all the VDisks from this node and wait until replication is complete.
After replication is complete, you can safely shut down the node.

To make sure that disabling the dynamic node doesn't affect query handling, drain the tablets from this node first.

Go to the Hive web-viewer page.
Click "View Nodes" to see a list of all nodes.

Before disabling the node, first disable the transfer of tablets through the Active button, then click Drain, and wait for all the tablets to be moved away.

Enabling/disabling Scrubbing

Scrubbing is a process that reads data, checks its integrity, and restores it if needed. The process is run by default. The interval between completing a scrub and starting the next one is 1 month. You can change the interval using YDB DSTool. The process checks data that was accessed before the previous scrub. Scrubbing is started and stopped for the entire YDB cluster. Scrubbing is performed in the background without overloading the system.

To set a 48-hour interval, run the command:

```
ydb-dstool -e <bs_endpoint> cluster set --scrub-periodicity 48h
```

You can also set the maximum number of cluster disks to be scrubbed at a time. For example, to only scrub one disk at a time, run the command:

```
ydb-dstool -e <bs_endpoint> cluster set --max-scrubbed-disks-at-once
```

To stop cluster scrubbing, run the command:

```
ydb-dstool -e <bs_endpoint> cluster set --scrub-periodicity disable
```

Data Center Decommissioning

> **Note**
>
> Use this procedure only to decommission an entire data center.

Decommissioning is the procedure for moving a VDisk from a PDisk that needs to be decommissioned.

Data is moved to PDisk clusters where there is enough free space to create new slots. Moving is performed only when there is a possibility of moving with at least partial preservation of the failure model. It may happen that the system can't strictly follow the failure model during decommissioning. However, it does its best to ensure fault-tolerance as fully as under normal operation. For example, when encoding `mirror-3-dc`, a situation may arise when a group is located in four rather than three data centers.

Decommissioning is done asynchronously, meaning that data is not moved immediately while handling the command. If the failure model allows, SelfHeal moves slots one by one in the background to completely release the specified PDisks.

Managing Decommission

To manage the state of decommissioning, set the `DecommitStatus` parameter for the appropriate PDisk. The parameter can take the following values:

- `DECOMMIT_NONE`: The disk is not being decommissioned and is running normally, according to its condition.
- `DECOMMIT_PENDING`: Disk decommissioning is scheduled. Data is not transferred from the disk. However, slots for new groups won't be created and the slots of the previously created groups won't be moved.
- `DECOMMIT_IMMINENT`: Disk decommissioning is required. Data is transferred in the background to disks that have the `DECOMMIT_NONE` status and satisfy the failure model.

The `DECOMMIT_PENDING` and `DECOMMIT_IMMINENT` values shouldn't be removed under normal decommissioning, since the equipment is removed from the cluster by running the `DefineBox` command.

To cancel decommissioning, just change the disk status to `DECOMMIT_NONE`. In this case, BS_CONTROLLER won't take any additional actions: the previously moved VDisks remain where they are. To return them, you can use commands to move slots point by point, depending on the specific situation.

By managing the `DECOMMIT_PENDING` and `DECOMMIT_IMMINENT` states, you can perform cluster decommissioning in parts.

For example, you need to move equipment from data center-1 (DC-1) to data center-2 (DC-2):

1. The DC-2 hosts buffer equipment to transfer the first chunk of data to.
2. Switch the status of all DC-1 disks to `DECOMMIT_PENDING` at once so that no data can be moved inside the DC-1. Set this status for every disk in the data center simultaneously: applying `DECOMMIT_PENDING` to only a subset of disks in the data center may cause violation of the storage group failure model.
3. Switch the status of all DC-1 disks to `DECOMMIT_IMMINENT` on the equipment that is equivalent to the buffer one.
4. Wait until all the disks in the `DECOMMIT_IMMINENT` status are released.
5. Move the released equipment from the DC-1 to the DC-2 and switch the status of its disks to `DECOMMIT_NONE`.

Repeat the above steps for the next set of equipment in the DC-1 until all the equipment is moved.

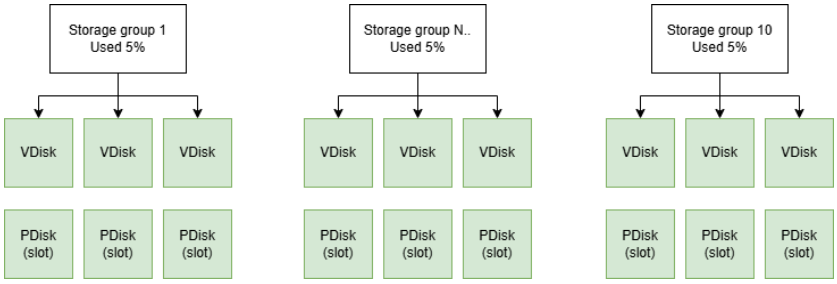
To set the desired state of disk decommissioning, use the YDB DSTool utility. The command below sets the `DECOMMIT_IMMINENT` status for the disk with the ID `1000` on the node with the ID `1`:

```
ydb-dstool -e  <bs_endpoint> pdisk set --decommit-status DECOMMIT_IMMINENT --pdisk-ids "[1:1000]"
```

Decommissioning groups using virtual groups

Alert

The decommission operation is extremely dangerous and can lead to irreversible data loss. Before performing a decommission, **be sure** to create a backup of all cluster data.

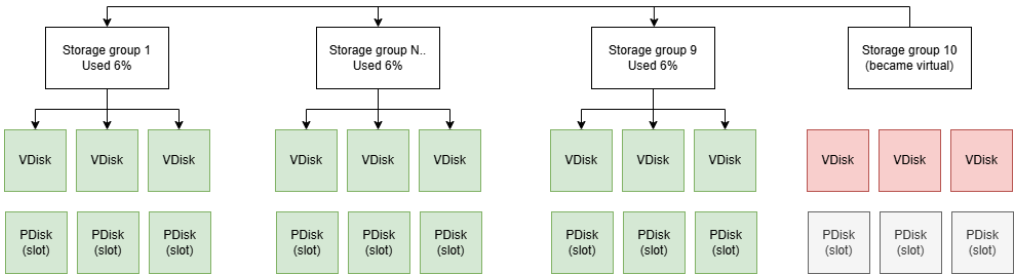


Alert

The ability to roll back a storage group decommission is under development. At the moment, the operation is irreversible. It is recommended to use decommissioning only in exceptional cases when it is necessary to free up resources once.

How it works

Physical storage groups are a limited resource in a cluster: their number is determined by the cluster size, and they cannot be deleted as long as they store data. This can lead to a situation where there are not enough groups to create a new database or expand an existing one, and space on physical disks cannot be freed because old groups contain data.



Consider an example: a database uses 10 storage groups. Each of these groups contains some amount of user data, but they are only 5% full. Throughput is also not fully utilized. As a result, all groups are formally occupied, and when trying to create a new database, a new storage group cannot be allocated — there are no more free slots on PDisks. At the same time, existing groups are used inefficiently.

In such a situation, the task arises to free up some of the storage groups (decommission them) from the current database in order to return them to the pool of available resources for subsequent use.

To solve this problem, a storage group decommission mechanism is used. As part of this mechanism, one new virtual storage group is created for the original physical group, which replaces this physical group. After performing the operation, the system moves to the following state:

- The original physical storage group is replaced by a virtual one.
- Data is copied from the source group to the remaining physical groups of the cluster (increasing their usage).
- The virtual group stores data in the remaining physical groups of the cluster.
- Resources used by the source group are freed (VDisks are deleted, PDisk slots are freed).

Decommissioning process stages

Note

Access to data is preserved during decommissioning — users can read and write data as usual. All data movements occur in the background in parallel with the main application work. It is worth noting that during decommissioning, an increased load is still created on the storage system.

In the following, by the source physical group we will mean the group over which the decommissioning process is taking place.

Initialization of a virtual storage group and blocking writes to the source physical group

What happens:

- A virtual group is created.
- Writing new data to the source physical group is blocked.
- All new writes start going to the virtual group.

Status: `DecommitStatus: PENDING` → `IN_PROGRESS`

Time: Usually fractions of a second

Metadata copying

What happens:

- Metadata of all blobs (information about what data exists, but not the data itself) is copied from the source physical group to the remaining physical storage groups

Status: `DecommitStatus: IN_PROGRESS`

Time: Usually seconds

Data copying

What happens:

- Data is read from the source physical group.
- Written to the remaining physical groups of the cluster through the virtual group.
- Data is distributed across several groups for balancing.

Status: `DecommitStatus: IN_PROGRESS`

Time: Depends on the volume of data (can be hours for large groups)

Freeing resources of the source physical group

What happens:

- All data is copied.
- The source physical group and its VDisks are deleted.
- PDisk resources are freed.
- The group is marked as decommissioned.

Status: `DecommitStatus: IN_PROGRESS` → `DONE`

Time: Minutes (VDisk deletion)

Prerequisites

The group decommission instructions work if the following conditions are met:

1. A deployed YDB cluster. Deployment instructions are available in the Initial Deployment section.
2. The `ydb-dstool` utility is installed. Installation instructions are available in the YDB DSTool installation documentation.
3. An authentication token generated for cluster access:

```
ydb -e grpc://<cluster-endpoint> -d <db_path> --user <user> auth get-token -f > ~/ydb_token
```

Replace `<cluster-endpoint>` with your cluster address, `<db_path>` with the database path, and `<user>` with the username for authorization.

> **Note**
>
> Decommissioning can be performed even on an empty cluster; the presence of data is not required. However, if there is data in the cluster, this will allow checking its consistency after decommissioning. If necessary, you can load test data using the `ydb workload tpcc` utility:
>
> ```
> ydb workload tpcc --path tpcc/10wh init -w 100
> ydb workload tpcc --path tpcc/10wh import -w 100
> ```
>
> And run the TPC-C test before and after decommissioning:
>
> ```
> ydb workload tpcc --path tpcc/10wh run -w 100
> ```
>
> More about working with test load in the ydb workload tpcc documentation.

Starting decommissioning

Selecting a group for decommissioning

Before starting decommissioning, you must select the group (group ID) you want to decommission. You can choose any group, but it is recommended to choose a less busy group — this will help complete the decommissioning process faster. This can be done through the cluster web interface or using the CLI:

UI (Web interface)

1. Open the cluster management web interface `https://<cluster-endpoint>:8765`.
2. Open the `Storage` tab.
3. Select the group you need and save the `Group ID`.

CLI

1. Run the command to get a list of storage groups

```
ydb-dstool -e <cluster-endpoint> \
  --ca-file <path-to-ca-cert> \
  --token-file ~/ydb_token \
  group list
```

2. In the command output, find the group you need and save its `Group ID`.

Command to start

To start decommissioning, run the `ydb-dstool` command with the `group decommit` parameter; it will automatically create a virtual group and start the decommissioning process:

```
ydb-dstool -e grpcs://<cluster-endpoint>:2135 \
  --ca-file <path-to-ca-cert> \
  --token-file ~/ydb_token \
  group decommit \
  --group-ids <GROUP_ID> \
  --database /Root/<database-name> \
  --wait
```

Command parameters

- `-e <endpoint>` — cluster address (e.g., `grpcs://static-node-1.ydb-cluster.com:2135`);
- `--ca-file <path>` — path to the CA certificate file for TLS connection;
- `--token-file <path>` — path to the file with the authentication token;
- `--group-ids <GROUP_ID>` — ID of the group to decommission (multiple groups can be specified separated by spaces);
- `--database=<DB>` — path to the database or domain where decommissioning is performed (e.g., `/Root/database`);
- `--wait` — wait for decommissioning to start; if a start error occurs, the error is displayed on the screen, and decommissioning is cancelled automatically (only when this option is specified).

Command example

```
ydb-dstool -e grpcs://static-node-1.ydb-cluster.com:2135 \
  --ca-file /home/ubuntu/ansible-11-nov-244/3-nodes-mirror-3-dc/files/TLS/certs/ca.crt \
  --token-file ~/ydb_token \
  group decommit \
  --group-ids 2181038081 \
  --database=/Root/database \
  --wait
```

Checking decommissioning status

After starting decommissioning, you can check its status using the command:

```
ydb-dstool -e grpcs://<cluster-endpoint>:2135 \
  --ca-file <path-to-ca-cert> \
  --token-file ~/ydb_token \
  group list --columns GroupId PoolName \
  ErasureSpecies OperatingStatus VDisks_TOTAL BlobDepotId DecommitStatus
```

In the command output for groups for which the decommissioning procedure was started, an additional `DecommitStatus` field appears, which can take one of the following values:

- `NONE` — decommissioning for the specified group is not performed;
- `PENDING` — group decommissioning is expected but not yet running (a virtual group is being created);
- `IN_PROGRESS` — group decommissioning is being performed (all writes already go to the virtual group, reads go to the virtual group and the old group);
- `DONE` — decommissioning is fully completed (the physical group has turned into a virtual one).

Command output example

```
┌─────────────┬──────────────────────┬─────────────────┬─────────────────┬──────────────┬──────────────────────┬──────────────┐
| GroupId     | PoolName             | ErasureSpecies | OperatingStatus | VDisks_TOTAL | BlobDepotId          | DecommitStatus |
├─────────────┼──────────────────────┼─────────────────┼─────────────────┼──────────────┼──────────────────────┼──────────────┤
| 2181038080 | /Root/database:ssd | mirror-3-dc    | FULL            | 9            | 0                    | NONE           |
| 2181038081 | /Root/database:ssd | mirror-3-dc    | FULL            | 0            | 72075186224038889    | DONE           |
| 2181038082 | /Root/database:ssd | mirror-3-dc    | FULL            | 9            | 0                    | NONE           |
| 2181038083 | /Root/database:ssd | mirror-3-dc    | FULL            | 9            | 0                    | NONE           |
| 2181038084 | /Root/database:ssd | mirror-3-dc    | FULL            | 9            | 0                    | NONE           |
| 2181038085 | /Root/database:ssd | mirror-3-dc    | FULL            | 9            | 0                    | NONE           |
| 2181038086 | /Root/database:ssd | mirror-3-dc    | FULL            | 9            | 0                    | NONE           |
| 2181038087 | /Root/database:ssd | mirror-3-dc    | FULL            | 9            | 0                    | NONE           |
└─────────────┴──────────────────────┴─────────────────┴─────────────────┴──────────────┴──────────────────────┴──────────────┘
```

Note that in the above output example for group `2181038081`, the number of VDisks has changed (it became 0), the virtual group ID appeared in the `BlobDepotId` field, and the decommissioning status (`DecommitStatus`) changed to `DONE`. This reflects the successful completion of the decommissioning procedure for this group.

Moving VDisks

Sometimes you may need to free up a block store volume to replace equipment. Or a VDisk may be in active use, affecting the performance of other VDisks running on the same PDisk. In cases like this, VDisks need to be moved.

Move a VDisk from a block store volume

Get a list of VDisk IDs using YDB DSTool:

```
ydb-dstool -e <bs_endpoint> vdisk list --format tsv --columns VDiskId --no-header
```

To move a VDisk from a block store volume, run the following commands on the cluster node:

```
ydb-dstool -e <bs_endpoint> vdisk evict --vdisk-ids VDISK_ID1 ... VDISK_IDN
ydbd admin bs config invoke --proto 'Command { ReassignGroupDisk { GroupId: <Storage group ID> GroupGeneratio
n: <Storage group generation> FailRealmIdx: <FailRealm> FailDomainIdx: <FailDomain> VDiskIdx: <Slot number> }
}'
```

- `VDISK_ID1 ... VDISK_IDN`: The list of VDisk IDs like `[GroupId:GroupGeneration:FailRealmIdx:FailDomainIdx:VDiskIdx]`. The IDs are separated by a space.
- `GroupId`: The ID of the storage group.
- `GroupGeneration`: Storage group generation.
- `FailRealmIdx`: Fail realm number.
- `FailDomainIdx`: Fail domain number.
- `VDiskIdx`: Slot number.

Move VDisks from a broken/missing block store volume

If SelfHeal is disabled or fails to move VDisks automatically, you'll have to run this operation manually:

1. Go to monitoring and make sure that the VDisk has actually failed.
2. Get the appropriate `[NodeId:PDiskId]` using YDB DSTool:

   ```
   ydb-dstool -e <bs_endpoint> vdisk list | fgrep VDISK_ID
   ```

3. Move the VDisk:

   ```
   ydb-dstool -e <bs_endpoint> pdisk set --status BROKEN --pdisk-ids "[NodeId:PDiskId]"
   ```

Enable the VDisk back after reassignment

To enable the VDisk back after reassignment:

1. Go to monitoring and make sure that the VDisk is actually operable.
2. Get the appropriate `[NodeId:PDiskId]` using YDB DSTool:

   ```
   ydb-dstool -e <bs_endpoint> pdisk list
   ```

3. Enable the PDisk back:

   ```
   ydb-dstool -e <bs_endpoint> pdisk set --status ACTIVE --pdisk-ids "[NodeId:PDiskId]"
   ```

Staying within the failure model

One VDisk in the storage group failed

With SelfHeal enabled, this situation is considered normal. SelfHeal will move the VDisk over the time specified in the settings, then data replication will start on a different PDisk.

If SelfHeal is disabled, you'll have to manually move the VDisk. Before moving it, make sure that **only one** VDisk in the storage group has failed.
Then follow the instructions.

More than one VDisk in the same storage group have failed without going beyond the failure model

In this kind of failure, no data is lost, the system maintains operability, and read and write queries are executed successfully. Performance might degrade because of the load handover from the failed disks to the operable ones.

If multiple VDisks have failed in the group, SelfHeal stops moving VDisks. If the maximum number of failed VDisks for the failure model has been reached, recover at least one VDisk before you start moving the VDisks. You may also need to be more careful when moving VDisks one by one.

The number of failed VDisks has exceeded the failure model

The availability and operability of the system might be lost. Make sure to revive at least one VDisk without losing the data stored on it.

Disk load balancing

YDB supports two methods for disk load balancing:

- Distribute the load evenly across groups.
- Distribute VDisks evenly across block store volumes.

Distribute the load evenly across groups

At the bottom of the Hive web-viewer page, there is a button named "Reassign Groups".

Distribute VDisks evenly across block store volumes

As a result of some operations, such as decommissioning, VDisks can be distributed across block store volumes unevenly. You can distribute them more evenly in one of the following ways:

- Move VDisks one by one from overloaded block store volumes.
- Use YDB DSTool. The command below moves a VDisk from an overloaded block store volume to a less loaded one:

  ```
  ydb-dstool -e <bs_endpoint> cluster balance
  ```

  The command moves a single VDisk per run.

Changing the number of slots for VDisks on PDisks

To add storage groups, redefine the host config by increasing the number of slots on PDisks.

Before that, you need to get the config to be changed. You can do this with the following command:

```
Command {
  TReadHostConfig{
    HostConfigId: <host-config-id>
  }
}
```

```
ydbd -s <endpoint> admin bs config invoke --proto-file ReadHostConfig.txt
```

Insert the obtained config into the protobuf below and edit the `PDiskConfig/ExpectedSlotCount` field value in it.

```
Command {
  TDefineHostConfig {
    <host config>
  }
}
```

```
ydbd -s <endpoint> admin bs config invoke --proto-file DefineHostConfig.txt
```

Freeing up space on physical devices

When the disk space is used up, the database may start responding to all queries with an error. To keep the database healthy, we recommend deleting a part of the data or adding block store volumes to extend the cluster.

Below are instructions that can help you add or free up disk space.

Defragment a VDisk

When working with the DB, internal VDisk fragmentation is done. You can find out the percentage of fragmentation on the VDisk monitoring page. We do not recommend that you perform defragmentation of VDisks that are fragmented by 20% or less.

According to the failure model, the cluster survives the loss of two VDisks in the same group without data loss. If all VDisks in the group are up and there are no VDisks with the error or replication status, then deleting data from one VDisk will result in the VDisk recovering it in a compact format. Please keep in mind that data storage redundancy will be decreased until automatic data replication is complete.

During data replication, the load on all the group's VDisks increases, and response times may deteriorate.

1. View the fragmentation coefficient on the VDisk page in the viewer.

   If its value is more than 20%, defragmentation can help free up VDisk space.
2. Check the status of the group that hosts the VDisk. There should be no VDisks that are unavailable or in the error or replication status in the group.

   You can view the status of the group in the viewer.
3. Run the wipe command for the VDisk.

   All data stored on a VDisk will be permanently deleted, whereupon the VDisk will begin restoring the data by reading them from the other VDisks in the group.

   ```
   ydbd admin blobstorage group reconfigure wipe --domain <Domain number> --node <Node ID> --pdisk <pdisk-id> --vslot <Slot number>
   ```

   You can view the details for the command in the viewer.

If the block store volume is running out of space, you can apply defragmentation to the entire block store volume.

1. Check the health of the groups in the cluster. There shouldn't be any problem groups on the same node with the problem block store volume.
2. Log in via SSH to the node hosting this block store volume
3. Check if you can restart the process.
4. Stop the process

   ```
   sudo systemctl stop ydbd
   ```
5. Format the block store volume

   ```
   sudo ydbd admin blobstorage disk obliterate <path to the store volume part label>
   ```
6. Run the process

   ```
   sudo systemctl start ydbd
   ```

Moving individual VDisks from full block store volumes

If defragmentation doesn't help free up space on the block store volume, you can move individual VDisks.

Replacing a node's FQDN

Sometimes, a node's FQDN changes, but the node itself remains in the system under a different name. Simply changing the node name in the hosts section will not work because `BS_CONTROLLER` internally stores the resource bindings to the `FQDN:IcPort` pairs, where IcPort is the Interconnect port number on which the node operates.

Replacement procedure

1. Determine the NodeId of the node to be replaced.
2. Prepare the DefineBox command that describes the cluster resources, in which an element `EnforcedNodeId: <NodeId>` will be added for the resources of the node to be replaced.
3. Execute this command.
4. Replace the FQDN in the hosts list in `cluster.yaml`.
5. Perform a rolling restart.
6. Remove the EnforcedNodeId field from DefineBox and replace the Fqdn with the new node name.
7. Execute DefineBox with the new values.

Example

Suppose a cluster consisting of three nodes:

`config.yaml`:

```
- host: host1.my.sub.net
  node_id: 1
  location: {unit: 12345, data_center: MYDC, rack: r1}
- host: host2.my.sub.net
  node_id: 2
  location: {unit: 23456, data_center: MYDC, rack: r2}
- host: host3.my.sub.net
  node_id: 3
  location: {unit: 34567, data_center: MYDC, rack: r3}
```

DefineBox looks like this:

```
DefineBox {
    BoxId: 1
    Host { Key { Fqdn: "host1.my.sub.net" IcPort: 19001 } HostConfigId: 1 }
    Host { Key { Fqdn: "host2.my.sub.net" IcPort: 19001 } HostConfigId: 1 }
    Host { Key { Fqdn: "host3.my.sub.net" IcPort: 19001 } HostConfigId: 1 }
}
```

Suppose we want to rename host1.my.sub.net to host4.my.sub.net. First, we create a DefineBox as follows:

```
DefineBox {
    BoxId: 1
    Host { Key { Fqdn: "host1.my.sub.net" IcPort: 19001 } HostConfigId: 1 EnforcedNodeId: 1 }
    Host { Key { Fqdn: "host2.my.sub.net" IcPort: 19001 } HostConfigId: 1 }
    Host { Key { Fqdn: "host3.my.sub.net" IcPort: 19001 } HostConfigId: 1 }
}
```

Then modify `config.yaml`:

```
- host: host4.my.sub.net
  node_id: 1
  location: {unit: 12345, data_center: MYDC, rack: r1}
- host: host2.my.sub.net
  node_id: 2
  location: {unit: 23456, data_center: MYDC, rack: r2}
- host: host3.my.sub.net
  node_id: 3
  location: {unit: 34567, data_center: MYDC, rack: r3}
```

Next, perform a rolling restart of the cluster.

Finally, perform the second adjusted DefineBox:

```
DefineBox {
    BoxId: 1
    Host { Key { Fqdn: "host4.my.sub.net" IcPort: 19001 } HostConfigId: 1 }
    Host { Key { Fqdn: "host2.my.sub.net" IcPort: 19001 } HostConfigId: 1 }
    Host { Key { Fqdn: "host3.my.sub.net" IcPort: 19001 } HostConfigId: 1 }
}
```

Blob Depot

Blob depot extends the functionality of the storage subsystem by adding virtual group functionality.

A virtual group, like a physical group, is a fault tolerance unit of the storage subsystem in the cluster. However, a virtual group stores its data in other groups (unlike a physical group, which stores data on VDisks).

This method of data storage allows for more flexible use of the YDB storage subsystem, in particular:

- Using more "heavy" tablets in conditions where the size of one physical group is limited.
- Providing tablets with a wider write bandwidth by balancing writes across all groups on which the blob depot is running.
- Ensuring transparent data migration between different groups for client tablets.

Blob depot can also be used for group decommissioning, that is, to remove a VDisk within a physical group while preserving all data that was written to this group. In this usage scenario, data from the physical group is transparently transferred to the virtual group for the client, then all VDisks of the physical group are removed to free up the resources they occupy.

Virtual Group Mode

In virtual group mode, blob depot allows combining several groups into a single space for storing large amounts of data. Load balancing by occupied space is provided, as well as increased throughput by distributing writes across different groups. Background (completely transparent to the client) data transfer is also possible.

Virtual groups are also created within Storage Pools, like physical groups, but for virtual groups it is recommended to create a separate pool with the command `dstool pool create virtual`. These pools can be specified in Hive for creating other tablets. However, to avoid latency degradation, channels 0 and 1 of tablets are recommended to be placed on physical groups, and only data channels should be placed on virtual groups with blob depot.

How to Launch

A virtual group is created through BS_CONTROLLER by passing a special command. The virtual group creation command is idempotent, so to avoid creating extra blob depots, each virtual group is assigned a name. The name must be unique within the entire cluster. In case of repeated command execution, an error will be returned with the `Already: true` field filled and indicating the number of the previously created virtual group.

```
dstool -e ... --direct group virtual create --name vg1 vg2 --hive-id=72057594037968897 --storage-pool-name=/R
oot:virtual --log-channel-sp=/Root:ssd --data-channel-sp=/Root:ssd*8
```

Command line parameters:

- `--name` — unique name for the virtual group (or several virtual groups with similar parameters)
- `--hive-id=N` — number of the Hive tablet that will manage this blob depot; you must specify the Hive of the tenant within which the blob depot is launched
- `--storage-pool-name=POOL_NAME` — name of the Storage Pool within which the blob depot needs to be created
- `--storage-pool-id=BOX:POOL` — alternative to `--storage-pool-name`, where you can specify an explicit numeric pool identifier
- `--log-channel-sp=POOL_NAME` — name of the pool where channel 0 of the blob depot tablet will be placed
- `--snapshot-channel-sp=POOL_NAME` — name of the pool where channel 0 of the blob depot tablet will be placed; if not specified, the value from --log-channel-sp is used
- `--data-channel-sp=POOL_NAME[*COUNT]` — name of the pool where data channels are placed; if the COUNT parameter is specified (after the asterisk), COUNT data channels are created in the specified pool; it is recommended to create a large number of data channels for blob depot in virtual group mode (64..250) to most efficiently use storage
- `--wait wait` — for blob depot creation to complete; if this option is not specified, the command terminates immediately after responding to the blob depot creation request, without waiting for the creation and launch of the tablets themselves

How to Check that the Virtual Group is Running

You can view the result of virtual group creation in the following ways:

- via the BS_CONTROLLER monitoring page
- via the `dstool group list --virtual-groups-only` command

In both cases, creation should be controlled through the `VirtualGroupName` field, which should match what was passed in the `--name` parameter. If the `dstool group virtual create` command completed successfully, the virtual group unconditionally appears in the group list, but the `VirtualGroupState` field can take one of the following values:

- `NEW` — group is waiting for initialization (tablet creation through Hive, its configuration and launch is in progress)
- `WORKING` — group is created and working, ready to execute user requests
- `CREATE_FAILED` — an error occurred during group creation, the text description of which can be seen in the ErrorReason field

```
$ dstool --cluster=$CLUSTER --direct group list --virtual-groups-only
┌─────────────┬──────────────┬──────────────┬────────────┬─────────────────┬──────────────────┬──────────────┬──
──────────────┬──────────────┬──────────────────┬──────────────┬──────────────────┐
| GroupId     | BoxId:PoolId | PoolName     | Generation | ErasureSpecies | OperatingStatus | VDisks_TOTAL |
VirtualGroupState | VirtualGroupName | BlobDepotId       | ErrorReason | DecommitStatus |
├─────────────┼──────────────┼──────────────┼────────────┼─────────────────┼──────────────────┼──────────────┼──

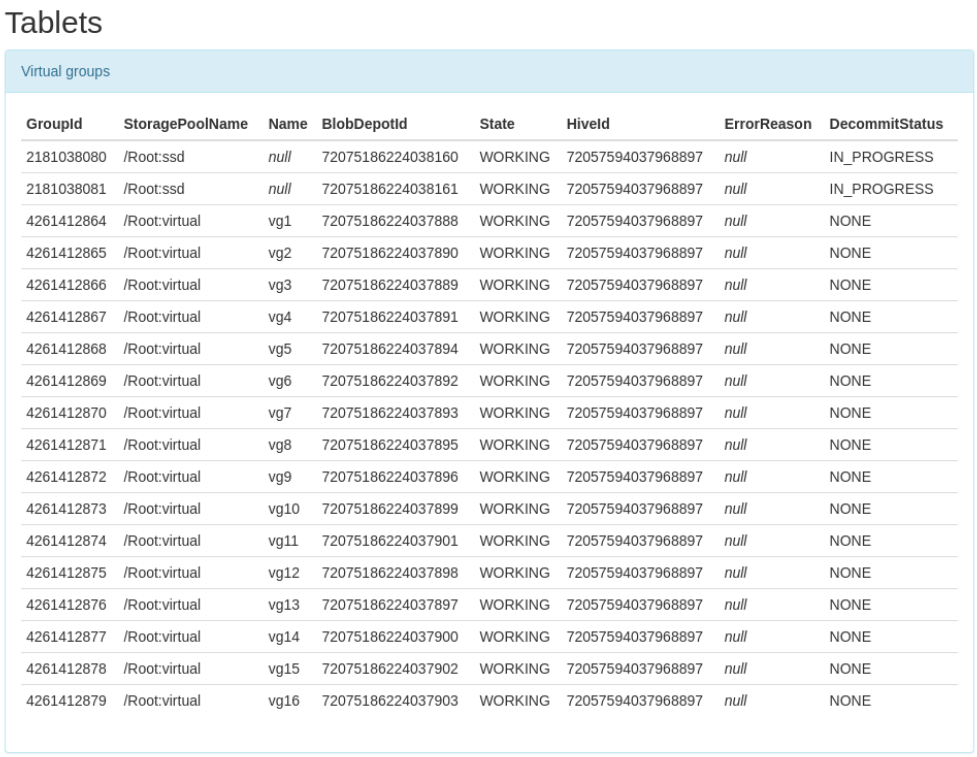
Architecture

Blob depot is a tablet that, in addition to two system channels (0 and 1), also contains a set of additional channels where the actual data written to the storage. Client data is written to these additional channels.

Blob depot as a tablet can be launched on any cluster node.

When blob depot operates in virtual group mode, agents (BlobDepotAgent) are used to access it. These are actors that perform functions similar to DS proxy — they are launched on each node that uses a virtual group with blob depot. These same actors convert storage requests into commands for blob depot and provide data exchange with it.



Diagnostic Mechanisms

The following mechanisms are provided for diagnosing blob depot operability:

- BS_CONTROLLER monitoring page
- blob depot monitoring page
- internal viewer
- event log
- charts

BS_CONTROLLER Monitoring Page

On the BS_CONTROLLER monitoring page there is a special Virtual groups tab, which shows all groups that use blob depot:

Tablets

Virtual groups

GroupId	StoragePoolName	Name	BlobDepotId	State	HiveId	ErrorReason	DecommitStatus

The table provides the following columns:

Field	Description
GroupId	Group number.
StoragePoolName	Name of the pool where the group is located.
Name	Virtual group name; it is unique for the entire cluster. For decommissioned groups this will be null.
BlobDepotId	Number of the blob depot tablet responsible for serving this group.
State	Blob depot state; can be NEW, WORKING, CREATED_FAILED.
HiveId	Number of the Hive tablet within which the specified blob depot was created.
ErrorReason	For CREATE_FAILED state contains a text description of the creation error reason.
DecommitStatus	Group decommission state; can be NONE, PENDING, IN_PROGRESS, DONE.

Blob Depot Monitoring Page

The blob depot monitoring page presents the main tablet operation parameters, which are grouped by tabs available via the "Contained data" link:

- data
- refcount
- trash
- barriers
- blocks
- storage

In addition, the main page provides brief information about the blob depot state:

Contained data

Stats

Parameter	Value
Data, bytes	21.83 GiB

Data in GroupId# 2181038113, bytes	720.35 MiB
Data in GroupId# 2181038114, bytes	657.61 MiB

This table provides the following data:

- Data, bytes — amount of saved data bytes (TotalStoredDataSize).
- Trash in flight, bytes — amount of bytes of unnecessary data waiting for transactions to complete to become garbage (InFlightTrashSize).
- Trash pending, bytes — amount of garbage bytes that have not yet been passed to garbage collection (TotalStoredTrashSize).
- Data in GroupId# XXX, bytes — amount of data bytes in group XXX (both useful data and not yet collected garbage).

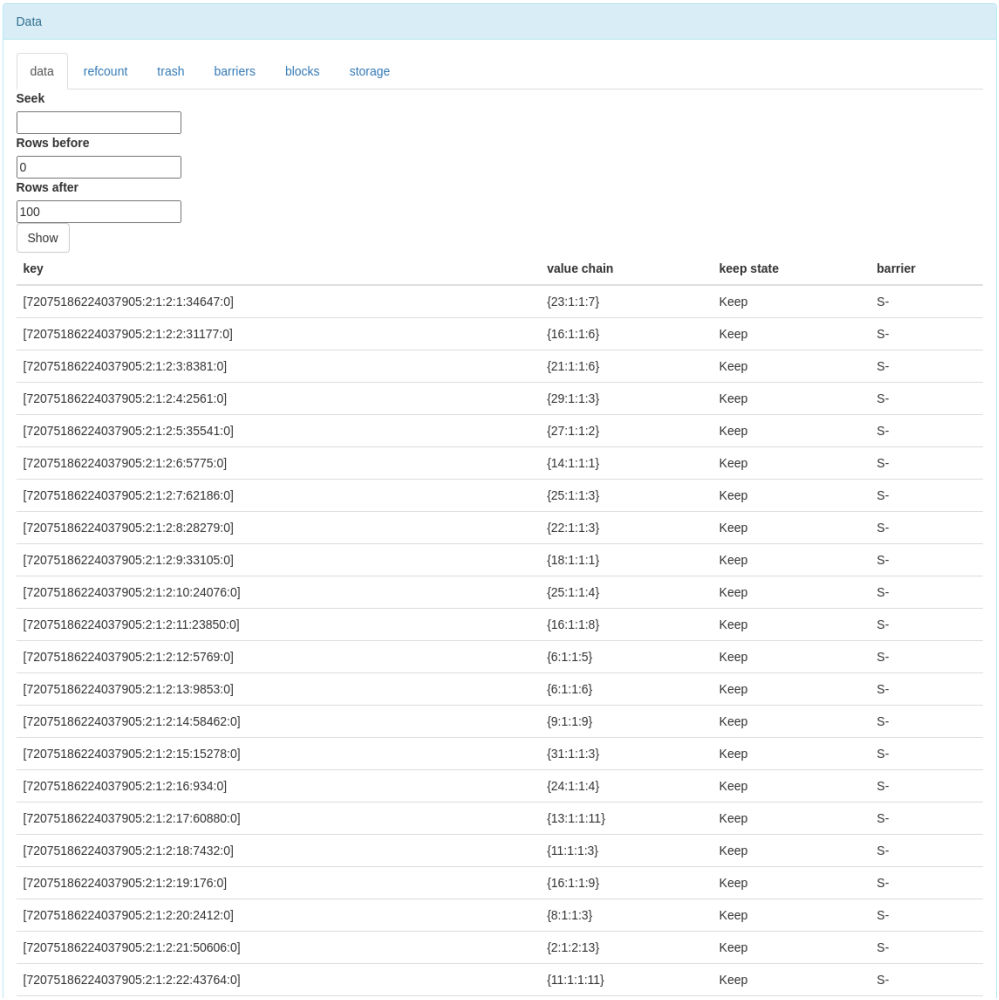
Data

Main

Parameter	Value
Loaded	true
Last assimilated blob id	
Data size, number of keys	284398
RefCount size, number of blobs	284398
Total stored data size, bytes	21.83 GiB
Keys made certain, number of keys	0

Uncertainty resolver

Parameter	Value
Keys queried	0
Gets issued	0
Keys resolved	0
Keys unresolved	0
Keys dropped	498590
Keys being processed	0
Blobs in flight	0



Parameter purposes are as follows:

- Loaded — boolean value showing whether all metadata from the tablet's local database is loaded into memory.
- Last assimilated blob id — BlobId of the last read blob (metadata copying during decommission).
- Data size, number of keys — number of saved data keys.

- RefCount size, number of blobs — number of unique data blobs that the blob depot stores in its namespace.
- Total stored data size, bytes — similar to "Data, bytes" from the table above.
- Keys made certain, number of keys — number of unwritten keys that were then confirmed by reading.

The "Uncertainty resolver" section relates to the component that works with data written but not confirmed to the blob depot.

The data table contains the following columns:

- key — key identifier (BlobId in the client namespace)
- value chain — key value formed by concatenating blob fragments from the blob depot namespace (this field lists these blobs)
- keep state — keep flag values for this blob from the client's perspective (Default, Keep, DoNotKeep)
- barrier — field showing which barrier this blob falls under (S — under soft barrier, H — under hard barrier; actually H never happens because blobs are synchronously deleted from the table when a hard barrier is set)

Given the potentially large table size, only part of it is shown on the monitoring page. To search for a specific blob, you can fill in the "seek" field by entering the BlobId of the desired blob, then specify the number of rows of interest before and after this blob and click the "Show" button.

refcount

The refcount table contains two columns: "blob id" and "refcount". Blob id is the identifier of the stored blob written on behalf of the blob depot to storage. Refcount is the number of references to this blob from the data table (from the value chain column).

The TotalStoredDataSize metric is formed from the sum of sizes of all blobs in this table, each of which is counted exactly once, without considering the refcount field.

2181038092	[72075186224037894:1:612:5:385:75:0]	
2181038116	[72075186224037894:1:618:25:225:75:0]	

The table contains three columns: "group id", "blob id" and "in flight". Group id is the number of the group where the no longer needed blob is stored. Blob id is the identifier of the blob itself. In flight is a sign that the blob is still going through a transaction, only after which it can be passed to the garbage collector.

The TotalStoredTrashSize and InFlightTrashSize metrics are formed from this table by summing blob sizes without the in flight flag and with it, respectively.

barriers

The barriers table contains information about client barriers that were passed to the blob depot. It consists of columns "tablet id" (tablet number), "channel" (channel number for which the barrier is written), as well as barrier values: "soft" and "hard". The value has the format `gen:counter => collect_gen:collect_step`, where gen is the tablet generation number in which this barrier was set, counter is the sequential number of the garbage collection command, `collect_gen:collect_step` is the barrier value (all blobs whose generation and step within the generation are less than or equal to the specified barrier are deleted).

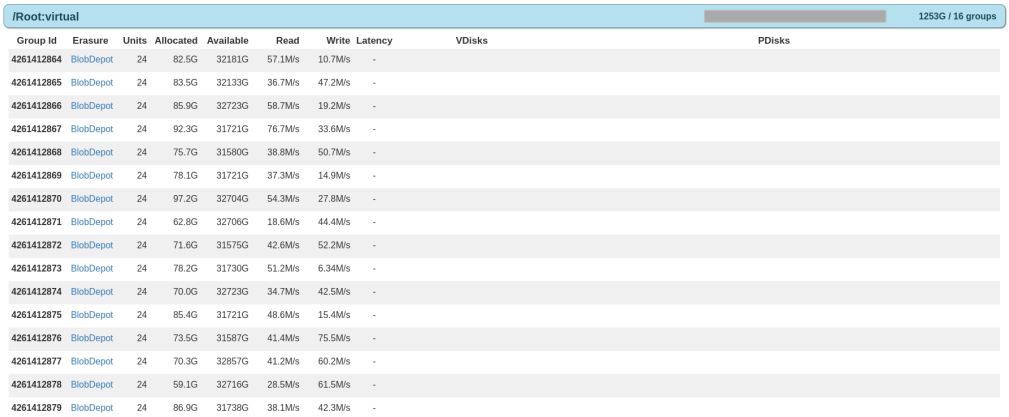
The storage table shows statistics on stored data for each group where the blob depot stores data. This table contains the following columns:

- group id — number of the group where data is stored
- bytes stored in current generation — volume of data written to this group in the current tablet generation (only useful data is counted, excluding garbage)
- bytes stored total — volume of all data saved by this blob depot to the specified group
- status flag — color status flags of the group
- free space share — group occupancy indicator (value 0 corresponds to a group completely filled by space, 1 — completely free)



Internal Viewer

On the Internal viewer monitoring page shown below, blob depots can be seen in the Storage sections and as BD tablets.

In the Nodes section, BD tablets running on different system nodes are visible:

In the Storage section, you can see virtual groups that work through blob depot. They can be distinguished by the link with the text BlobDepot in the Erasure column. The link in this column leads to the tablet monitoring page. Otherwise, virtual groups are displayed the same way, except that they have no PDisk and VDisk. However, decommissioned groups will look the same as virtual ones, but have PDisk and VDisk until decommission is complete.

Event Log

The blob depot tablet writes events to the log with the following component names:

- `BLOB_DEPOT` — blob depot tablet component.
- `BLOB_DEPOT_AGENT` — blob depot agent component.
- `BLOB_DEPOT_TRACE` — special component for debug tracing of all data-related events.

BLOB_DEPOT and BLOB_DEPOT_AGENT are output as structured records that have fields allowing identification of the blob depot and the group it serves. For BLOB_DEPOT this is the Id field and it has the format {TabletId:GroupId}:Generation, where TabletId is the blob depot tablet number, GroupId is the group number it serves, Generation is the generation in which the running blob depot writes messages to the log. For BLOB_DEPOT_AGENT this field is called AgentId and has the format {TabletId:GroupId}.

At DEBUG level, most occurring events will be logged, both on the tablet side and on the agent side. This mode is used for debugging and is not recommended in production environments due to the large number of generated events.

Charts

Each blob depot tablet provides the following charts:

Chart	Type	Description
TotalStoredDataSize	simple	Amount of saved user data net (if there are multiple references to one blob, it is counted once).
TotalStoredTrashSize	simple	Amount of bytes in garbage data that is no longer needed but has not yet been passed to garbage collection.
InFlightTrashSize	simple	Amount of garbage bytes that are still waiting for write confirmation to the local database (they cannot even start being collected yet).
BytesToDecommit	simple	Amount of data bytes remaining to be decommissioned (if this blob depot is operating in group decommission mode).
Puts/Incoming	cumulative	Rate of incoming write requests (in pieces per unit time).

Puts/Ok	cumulative	Number of successfully executed write requests.
Puts/Error	cumulative	Number of write requests completed with an error.
Decommit/GetBytes	cumulative	Data read rate during decommission.
Decommit/PutOkBytes	cumulative	Data write rate during decommission (only successfully executed writes are counted).

Group Decommissioning

Physical groups are a valuable resource in the cluster: groups can be created, but they cannot be deleted without deleting the database that uses them, since there is no mechanism for guaranteed eviction of tablet data from the group. At the same time, the number of physical groups is determined by the cluster size, and groups cannot be moved from one tenant's pool to another tenant's pool due to the use of different encryption keys for different tenants.

This can lead to a situation where there are not enough resources to create a new group to expand an existing database or create a new database, and it is also impossible to delete an old group to free up resources, since it may contain data.

To solve this problem, you can create a virtual group with channels on top of the remaining groups in the pool, copy data from the physical group to it, and then free up the resources occupied by the physical group. This task is solved by the group decommissioning process.

Group decommissioning allows removing redundant VDisks from PDisks while preserving the data of this group. This mode is implemented by creating a blob depot that starts serving the decommissioned group instead of DS proxy. In parallel, the blob depot copies data from the physical decommissioned group. As soon as all data is copied, the physical VDisks are deleted and resources are freed, while all data from the decommissioned group is distributed across other groups.

The decommissioning process is completely transparent to tablets and users and consists of several stages:

1. Creating a blob depot tablet and distributing the group configuration to block writes to the physical group disks.
2. Copying lock metadata from the physical group. After this moment, the decommissioned group becomes available for work. Before the lock copying moment, working with the group is impossible. However, this process takes a very short time, so it is practically invisible to the client. Requests arriving at this moment are queued and wait for the stage to complete.
3. Copying barrier metadata from the physical group.
4. Copying blob metadata from the physical group.
5. Copying blob data from the physical group.
6. Deleting VDisks of the physical group.

It is worth noting once again that from the moment of blocking writes to the physical group until the moment of reading all locks, work with the group is suspended. The suspension time under normal operation is fractions of a second.

How to Launch

To start decommissioning, a BS_CONTROLLER command is executed, in which you need to specify the list of groups to be decommissioned, as well as the number of the Hive tablet that will manage the blob depots of the decommissioned groups. You can also specify a list of pools where the blob depot will store its data. If this list is not specified, BS_CONTROLLER automatically selects the same pools where the decommissioned groups are located for data storage, and the number of data channels is made equal to the number of physical groups in these pools (but no more than 250).

```
dstool -e ... --direct group decommit --group-ids 2181038080 --database=/Root/db1 --wait
```

Command line parameters:

- `--wait` — wait for the decommission to start; if a startup error occurs, the error is displayed on the screen and the decommission is canceled automatically (only when this option is specified).
- `--group-ids` GROUP_ID — GROUP_ID list of groups for which decommissioning can be performed.
- `--database=DB` — specify the tenant in which decommissioning should be done (or the domain, if decommission is performed for groups within the domain).
- `--log-channel-sp=POOL_NAME` — name of the pool where channel 0 of the blob depot tablet will be placed.
- `--snapshot-channel-sp=POOL_NAME` — name of the pool where channel 1 of the blob depot tablet will be placed; if not specified, the value from `--log-channel-sp` is used.
- `--data-channel-sp=POOL_NAME[*COUNT]` — name of the pool where data channels are placed; if the `COUNT` parameter is specified (after the asterisk), `COUNT` data channels are created in the specified pool.

If neither `--log-channel-sp` , nor `--snapshot-channel-sp` , nor `--data-channel-sp` are specified, then the storage pool to which the decommissioned group belongs is automatically found, and the zero and first channels of the blob depot are created in it, as well as N data channels, where N is the number of remaining physical groups in this pool.

How to Check that Everything is Running

You can view the decommissioning result similarly to creating virtual groups. For decommissioned groups, an additional DecommitStatus field appears, which can take one of the following values:

- `NONE` — decommissioning is not performed for the specified group
- `PENDING` — group decommissioning is expected but not yet performed (blob depot is being created)
- `IN_PROGRESS` — group decommissioning is in progress (all writes already go to the blob depot, reads go to the blob depot and the old group)
- `DONE` — decommissioning is completely finished

```
$ dstool --cluster=$CLUSTER --direct group list --virtual-groups-only

```

How to Assess Progress

To assess the time and progress of decommissioning, charts are provided that allow you to understand:

- whether decommissioning is in progress (Decommit/GetBytes)
- whether data writing is happening (Decommit/PutOkBytes)
- how much data remains to be decommissioned (BytesToDecommit)

If everything is executed successfully, the Decommit/GetBytes rate approximately corresponds to Decommit/PutOkBytes. Minor discrepancies are acceptable due to the fact that decommissioned data may become outdated and be deleted by the tablet that stores data in it.

To estimate the remaining decommissioning time, it is sufficient to divide BytesToDecommit by the average Decommit/PutOkBytes rate.

Deploying YDB with Federated Query functionality

Warning

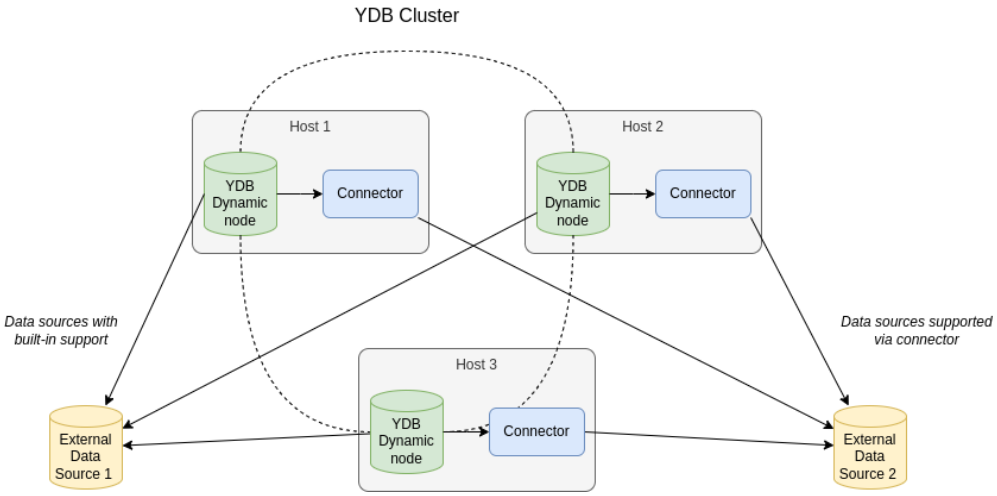
This functionality is in the "Experimental" mode.

General Installation Scheme

YDB can perform federated queries to external sources, for example, object storages or relational DBMS, without the need to move the data from external sources directly into YDB. This section describes the changes that are required in the configuration of YDB and the surrounding infrastructure to enable federated queries.

Note

A special microservice called connector must be deployed to access some of data sources. Check the list of supported sources to determine if you need to install a connector.



The YDB cluster and external data sources in a production installation should be deployed on different physical or virtual servers, including clouds. If access to a specific source requires a connector, it should be deployed on the same servers as the dynamic nodes of YDB. In other words, each `ydbd` process running in dynamic node mode should have one local connector process.

The following requirements must be met:

- The external data source must be accessible over the network to queries from YDB database nodes or from the connector, if present.
- The connector must be accessible over the network from YDB database nodes.

Tip

The easiest way to make the connector accessible from YDB nodes is to run them on the same set of hosts.

Note

Currently, we do not support deploying the connector in Kubernetes, but we plan to add it shortly.

Step-by-Step Guide

1. Follow the steps in the dynamic node YDB deployment guide up to and including preparing the configuration files.
2. If a connector must be deployed to access the desired source, do so according to the instructions.
3. If a connector needs to be deployed to access your desired source, add the `generic` subsection to the `query_service_config` section of the YDB configuration file as shown below. Specify the network address of the connector in the `connector.endpoint.host` and `connector.endpoint.port` fields (default values are `localhost` and `2130`). When co-locating the connector and the YDB dynamic node on the same server, encrypted connections between them are *not required*. If necessary, you can enable encryption by setting `connector.use_ssl` to `true` and specifying the path to the CA certificate that is used to sign the connector's TLS keys in `connector.ssl_ca_crt`:

```
query_service_config:
    generic:
        connector:
            endpoint:
                host: localhost                # hostname where the connector is deployed
                port: 2130                     # port number for the connector's listening socket
            use_ssl: false                     # flag to enable encrypted connections
            ssl_ca_crt: "/opt/ydb/certs/ca.crt" # (optional) path to the CA certificate
        default_settings:
            - name: DateTimeFormat
              value: string
            - name: UsePredicatePushdown
              value: "true"
```

4. Add the following `feature_flags` section to the YDB configuration file:

```
feature_flags:
    enable_external_data_sources: true
    enable_script_execution_operations: true
```

5. Continue deploying YDB database nodes. See the instructions.

Deploying Connectors to External Data Sources

> **Warning**
>
> This functionality is in "Experimental" mode.

Connectors are special microservices providing YDB with a universal abstraction for accessing external data sources. Connectors act as extension points for the YDB federated query processing system. This guide will discuss the specifics of deploying connectors in an on-premise environment.

fq-connector-go

The `fq-connector-go` connector is implemented in Go; its source code is hosted on GitHub. It provides access to the following data sources:

- ClickHouse
- Greenplum
- Microsoft SQL Server
- MySQL
- PostgreSQL
- YDB

The connector can be installed using a binary distribution or a Docker image.

Running from a Binary Distribution

Use binary distributions to install the connector on a physical or virtual Linux server without container virtualization.

1. On the releases page of the connector, select the latest release and download the archive for your platform and architecture. The following command downloads version `v0.2.4` of the connector for the Linux platform and `amd64` architecture:

   ```
   mkdir /tmp/connector && cd /tmp/connector
   wget https://github.com/ydb-platform/fq-connector-go/releases/download/v0.2.4/fq-connector-go-v0.2.4-lin
   ux-amd64.tar.gz
   tar -xzf fq-connector-go-v0.2.4-linux-amd64.tar.gz
   ```

2. If YDB nodes have not yet been deployed on the server, create directories for storing executable and configuration files:

   ```
   sudo mkdir -p /opt/ydb/bin /opt/ydb/cfg
   ```

3. Place the extracted executable and configuration files of the connector into the newly created directories:

   ```
   sudo cp fq-connector-go /opt/ydb/bin
   sudo cp fq-connector-go.yaml /opt/ydb/cfg
   ```

4. In the recommended usage mode, the connector is deployed on the same servers as the dynamic nodes of YDB, so encryption of network connections between them *is not required*. However, if you need to enable encryption, prepare a pair of TLS keys and specify the paths to the public and private keys in the `connector_server.tls.cert` and `connector_server.tls.key` fields of the `fq-connector-go.yaml` configuration file:

   ```
   connector_server:
     # ...
     tls:
       cert: "/opt/ydb/certs/fq-connector-go.crt"
       key: "/opt/ydb/certs/fq-connector-go.key"
   ```

5. If external data sources use TLS, the connector will need a root or intermediate Certificate Authority (CA) certificate that signed the sources' certificates to establish encrypted connections. Linux servers usually have some CA root certificates pre-installed. For Ubuntu OS, the list of supported CAs can be displayed with the following command:

   ```
   awk -v cmd='openssl x509 -noout -subject' '/BEGIN/{close(cmd)};{print | cmd}' < /etc/ssl/certs/ca-certif
   icates.crt
   ```

   If the server lacks the required CA certificate, copy it to a special system directory and update the certificates list:

   ```
   sudo cp root_ca.crt /usr/local/share/ca-certificates/
   sudo update-ca-certificates
   ```

6. You can start the service manually or using `systemd`.

   Manually

   Start the service from the console with the following command:

   ```
   /opt/ydb/bin/fq-connector-go server -c /opt/ydb/cfg/fq-connector-go.yaml
   ```

   Using systemd

   Along with the binary distribution, fq-connector-go includes a sample configuration file (unit) for the `systemd` initialization system. Copy the unit to the `/etc/systemd/system` directory, enable, and start the service:

```
cd /tmp/connector
sudo cp fq-connector-go.service /etc/systemd/system/
sudo systemctl enable fq-connector-go.service
sudo systemctl start fq-connector-go.service
```

If successful, the service should enter the `active (running)` state. Check it with the following command:

```
sudo systemctl status fq-connector-go
● fq-connector-go.service - YDB FQ Connector Go
    Loaded: loaded (/etc/systemd/system/fq-connector-go.service; enabled; vendor preset: enabled)
    Active: active (running) since Thu 2024-02-29 17:51:42 MSK; 2s ago
```

Service logs can be read using the command:

```
sudo journalctl -u fq-connector-go.service
```

Running in Docker

1. To run the connector, use the official Docker image. It already contains the service's configuration file. Start the service with default settings using the following command:

   ```
   docker run -d \
       --name=fq-connector-go \
       -p 2130:2130 \
       ghcr.io/ydb-platform/fq-connector-go:latest
   ```

   A listening socket of the GRPC service connector will start on port 2130 of your host's public network interface. Subsequently, the YDB server must connect to this network address.
2. If configuration changes are needed, prepare the configuration file based on the sample and mount it to the container:

   ```
   docker run -d \
       --name=fq-connector-go \
       -p 2130:2130 \
       -v /path/to/config.yaml:/opt/ydb/cfg/fq-connector-go.yaml
       ghcr.io/ydb-platform/fq-connector-go:latest
   ```

3. In the recommended usage mode, the connector is deployed on the same servers as the dynamic nodes of YDB, so encryption of network connections between them *is not required*. However, if you need to enable encryption between YDB and the connector, prepare a pair of TLS keys and specify the paths to the public and private keys in the `connector_server.tls.cert` and `connector_server.tls.key` fields of the configuration file:

   ```
   connector_server:
     # ...
     tls:
       cert: "/opt/ydb/certs/fq-connector-go.crt"
       key: "/opt/ydb/certs/fq-connector-go.key"
   ```

   When starting the container, mount the directory with the TLS key pair inside it so that they are accessible to the `fq-connector-go` process at the paths specified in the configuration file:

   ```
   docker run -d \
       --name=fq-connector-go \
       -p 2130:2130 \
       -v /path/to/config.yaml:/opt/ydb/cfg/fq-connector-go.yaml
       -v /path/to/keys/:/opt/ydb/certs/
       ghcr.io/ydb-platform/fq-connector-go:latest
   ```

4. If external data sources use TLS, the connector will need a root or intermediate Certificate Authority (CA) certificate that signed the sources' certificates to establish encrypted connections. The Docker image for the connector is based on the Alpine Linux distribution image, which already contains some CA certificates. Check for the required CA in the pre-installed list with the following command:

   ```
   docker run -it --rm ghcr.io/ydb-platform/fq-connector-go sh
   # then in the console inside the container:
   apk add openssl
   awk -v cmd='openssl x509 -noout -subject' ' /BEGIN/{close(cmd)};{print | cmd}' < /etc/ssl/certs/ca-certi
   ficates.crt
   ```

   If the source TLS keys are issued by a CA that is not included in the trusted list, add the CA certificate to the system paths of the container with the connector. For example, build a custom Docker image based on the existing one. Prepare the following `Dockerfile`:

   ```
   FROM ghcr.io/ydb-platform/fq-connector-go:latest

   USER root

   RUN apk --no-cache add ca-certificates openssl
   COPY root_ca.crt /usr/local/share/ca-certificates
   RUN update-ca-certificates
   ```

Place the `Dockerfile` and the CA root certificate in one folder, navigate to it, and build the image with the following command:

```
docker build -t fq-connector-go_custom_ca .
```

The new `fq-connector-go_custom_ca` image can be used to deploy the service using the above commands.

Configuration

A current example of the `fq-connector-go` service configuration file can be found in the repository.

Parameter	Description
`connector_server`	Required section. Contains the settings of the main GPRC server that accesses the data.
`connector_server.endpoint.host`	Hostname or IP address on which the service's listening socket runs.
`connector_server.endpoint.port`	Port number on which the service's listening socket runs.
`connector_server.tls`	Optional section. Filled if TLS connections are required for the main GRPC service `fq-connector-go`. By default, the service runs without TLS.
`connector_server.tls.key`	Full path to the private encryption key.
`connector_server.tls.cert`	Full path to the public encryption key.
`logger`	Optional section. It contains logging settings.
`logger.log_level`	Logging level. Valid values: `TRACE`, `DEBUG`, `INFO`, `WARN`, `ERROR`, `FATAL`. Default value: `INFO`.
`logger.enable_sql_query_logging`	For data sources supporting SQL, query logging is enabled. Valid values: `true`, `false`. **IMPORTANT**: Enabling this option may result in printing confidential user data in the logs. Default value: `false`.
`paging`	Optional section. It contains settings for the algorithm of splitting the data stream extracted from the source into Arrow blocks. For each request, a queue of blocks prepared for sending to YDB is created in the connector. Arrow block allocation contributes significantly to the memory consumption of the `fq-connector-go` process. The minimum memory required for the connector's operation can be roughly estimated by the formula , where is the number of concurrent requests, is the `paging.bytes_per_page` parameter, and is the `paging.prefetch_queue_capacity` parameter.
`paging.bytes_per_page`	Maximum number of bytes in one block. Recommended values range from 4 to 8 MiB, and the maximum is 48 MiB. Default value: 4 MiB.
`paging.prefetch_queue_capacity`	Number of pre-read data blocks stored in the connector's address space until YDB requests the next data block. In some scenarios, larger values of this setting can increase throughput but will also lead to higher memory consumption by the process. Recommended values - at least 2. Default value: 2.

YDB Enterprise Manager

YDB Enterprise Manager (hereinafter referred to as YDB EM) is a tool for centralized management of YDB clusters through a web interface and API.

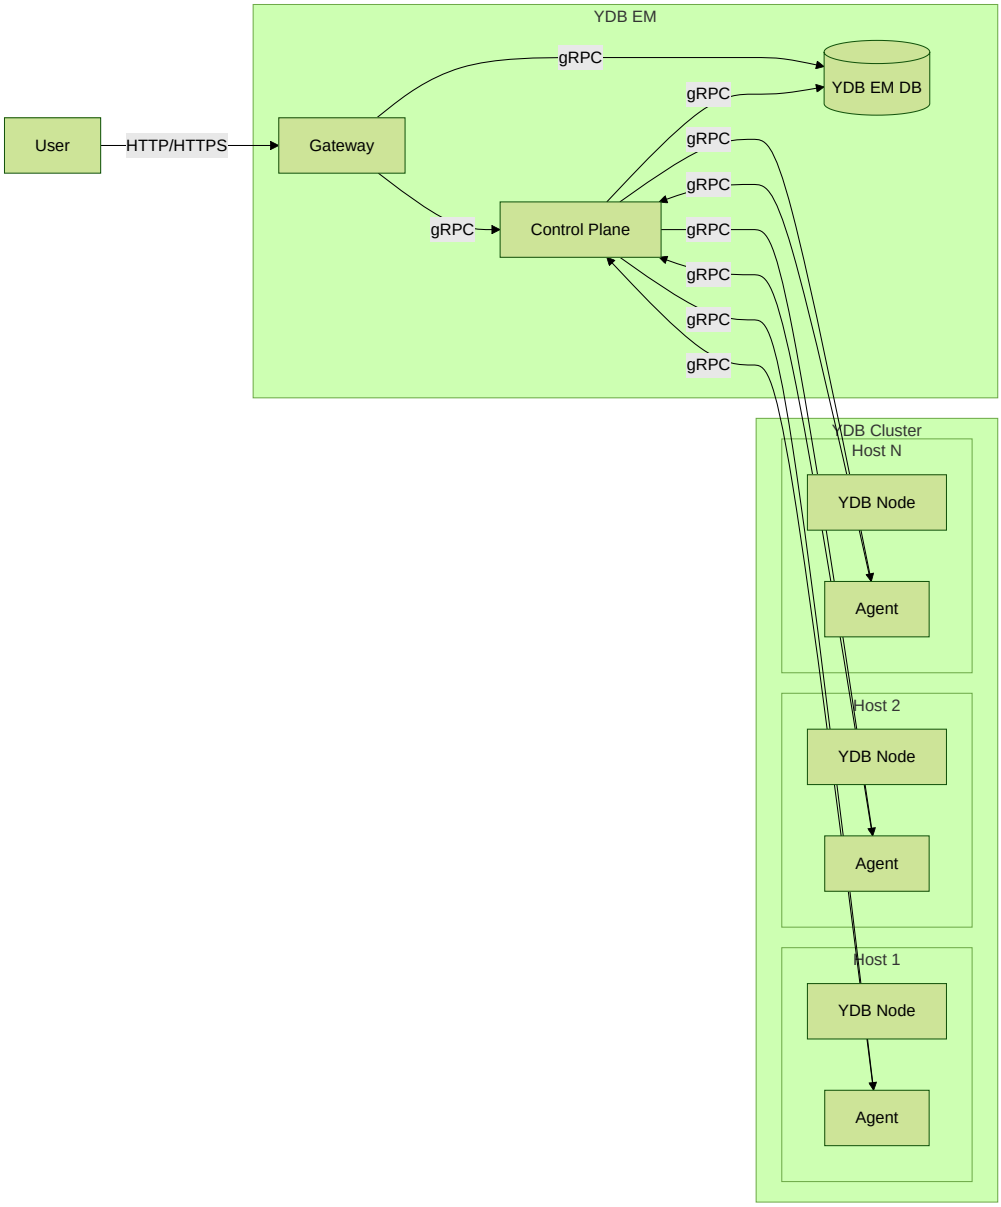
> **Note**
>
> Deploying YDB clusters is possible without YDB EM — using Ansible, Kubernetes, or manually. YDB EM provides a convenient web interface on top of existing clusters.

Purpose

YDB EM connects to existing YDB clusters and provides a graphical interface and API for the following tasks:

- centralized access to databases and YDB clusters from a single interface;
- managing dynamic nodes of a cluster — starting, stopping, and scaling;
- managing databases — creating, deleting, and modifying parameters;
- monitoring cluster and node status;
- managing resources (CPU, RAM) allocated to dynamic nodes;
- advisor — diagnostics and recommendations for resolving the most common issues;
- advanced SQL editor for running queries against databases;
- AI assistant for working with YDB.

> **Warning**
>
> YDB EM does not deploy YDB clusters. Before using YDB EM, the cluster must be deployed using one of the deployment options.



Architecture

YDB EM consists of three components:

- **Gateway** — web interface and API backend. Accepts requests from users (via a browser or API) and communicates with the Control Plane and the YDB EM database.
- **Control Plane (CP)** — coordinates cluster management. Receives commands from Gateway, stores configuration in the YDB EM database, and dispatches tasks to agents.
- **Agent** — runs on each YDB cluster host where dynamic nodes operate. The agent executes Control Plane commands: starts and stops YDB node processes, monitors their state, and reports information about available host resources.

To store its own metadata (cluster configuration, node state), YDB EM uses a YDB database — it can reside in the same cluster that EM manages.

Interaction diagram

The user interacts with Gateway through a browser or API. Gateway forwards requests to the Control Plane, which coordinates the work of agents on cluster hosts. Agents manage YDB node processes and report host status.

Key topics

- Initial deployment of YDB EM
- Configuring S3 backups for YDB EM

Initial deployment of YDB EM

This guide describes the process of initial deployment of YDB Enterprise Manager (hereinafter referred to as YDB EM) using Ansible. Upon completion, you will have a running YDB EM instance connected to an existing YDB cluster.

Before you start

Requirements

To deploy YDB EM, you need:

1. **A running YDB cluster**. YDB EM connects to an existing cluster to manage its resources; EM cannot operate without a cluster. A service database for storing YDB EM metadata will be automatically created in this cluster. For more information on deploying a cluster, see YDB Deployment Options.
2. **YDB database connection parameters** for the database that will be used to store YDB EM metadata:
   - Endpoint (for example, `grpcs://ydb-node01.ru-central1.internal:2135`).
   - Username and password for obtaining an authorization token. The user must have permissions to modify the schema, write, and read data. If the YDB cluster is configured for LDAP authentication, use an account from the corresponding directory.
3. **A host for Gateway and Control Plane components** — a single server (physical or virtual) where the YDB EM server components will be installed. This can be any of the YDB cluster hosts or a separate machine.
4. **Ansible** on the control machine (from which the installation will be performed). ansible-core 2.14–2.18 is recommended; for more details, see Deploying a YDB cluster with Ansible.
5. **SSH access** from the control machine to all servers where YDB EM components will be installed (the Gateway/CP host and cluster hosts for agents).

Network requirements

The network configuration must allow TCP connections on the following ports (default values):

Source	Destination	Port	Protocol	Purpose
User	Gateway	8789	HTTP/HTTPS	Web interface and API
Gateway, Agent	Control Plane	8787	gRPC	Management commands
Gateway, Control Plane	YDB	2135	gRPC	Connection to YDB EM DB

Downloading the package

Download the YDB EM package to the control machine (from which the installation via Ansible will be performed). Check the latest release information for the current version number and archive link:

Version	Link
`<VERSION>`	`https://binaries.ydbem.website.yandexcloud.net/builds/<VERSION>/ydb-em-<VERSION>-stable-linux-amd64.tar.xz`

Extract the downloaded archive into a working directory (replace `<VERSION>` with the actual version):

```
tar -xf ydb-em-<VERSION>-stable-linux-amd64.tar.xz
```

Package contents:

File	Description
`bin/ydb-em-gateway`	Gateway binary
`bin/ydb-em-cp`	Control Plane binary
`bin/ydb-em-agent`	Agent binary
`collections/ydb_platform-ydb-*.tar.gz`	Ansible collection for YDB
`collections/ydb_platform-ydb_em-*.tar.gz`	Ansible collection for YDB EM
`examples.tar.gz`	Ansible configuration templates (inventory and playbooks)
`install.sh`	Automatic installation script

Installing Ansible collections

Install the Ansible collection for YDB if it is not already installed:

```
ansible-galaxy collection install collections/ydb_platform-ydb-*.tar.gz
```

Install the Ansible collection for YDB EM:

```
ansible-galaxy collection install collections/ydb_platform-ydb_em-*.tar.gz
```

Note

Ansible collection versions are included in the YDB EM package. Use the files from the `collections/` directory of your package.

Preparing the configuration

Extracting configuration templates

The YDB EM package includes ready-made Ansible configuration templates — inventory files, playbooks, and directories for placing binaries and certificates. Extract this archive:

```
tar -xf examples.tar.gz
```

This will create the `examples/` directory, which will be used as the working directory for the installation.

Placing files

1. Copy the binary files from the `bin/` directory of the package to the `examples/files/` directory:

   ```
   cp bin/ydb-em-gateway bin/ydb-em-cp bin/ydb-em-agent examples/files/
   ```

2. Place TLS certificates in the `examples/files/certs/` directory. Use the same certificates as for the YDB cluster nodes (CA certificate, node certificates, and keys):

   ```
   cp /path/to/your/certs/* examples/files/certs/
   ```

Configuring the Ansible inventory

Ansible uses inventory files to describe target servers and their parameters. The YDB EM configuration is split into several files:

- `examples/inventory/50-inventory.yaml` — common parameters: SSH connection, YDB connection, Control Plane settings.
- `examples/inventory/90-inventory.yaml` — server descriptions (which hosts are used for which components).
- `examples/inventory/99-inventory-vault.yaml` — sensitive data (passwords).

Configuring hosts

Open the file `examples/inventory/90-inventory.yaml` and configure two host groups.

Group `ydb_em` — hosts for YDB EM server components (Gateway and Control Plane). A single host is sufficient — it can be any of the YDB cluster hosts or a separate server:

```
ydb_em:
  hosts:
    ydb-node01.ru-central1.internal:
```

Group `ydbd_dynamic` — YDB cluster hosts where the Agent will be installed. An Agent is needed on every host that runs YDB dynamic nodes — YDB EM manages node processes through these agents. Typically, all cluster hosts should be included:

```
ydb:
  children:
    ydbd_dynamic:
      hosts:
        ydb-node01.ru-central1.internal:
            ydb_em_agent_cpu: 4
            ydb_em_agent_memory: 8
            location: db-dc-1
        ydb-node02.ru-central1.internal:
            ydb_em_agent_cpu: 4
            ydb_em_agent_memory: 16
            location: db-dc-2
        ydb-node03.ru-central1.internal:
            location: db-dc-3
    ydb_em:
      hosts:
        ydb-node01.ru-central1.internal:
```

For each host in the `ydbd_dynamic` group, you can specify additional parameters. If parameters are not specified, default values will be used. Resource settings can be adjusted later through the YDB EM web interface.

Parameter	Description
`ydb_em_agent_cpu`	Number of CPUs available for nodes on the host
`ydb_em_agent_memory`	Amount of RAM (in gigabytes) available for nodes on the host
`ydb_em_agent_name`	Host name used by the agent
`location`	Host location (availability zone)

> **Warning**
>
> YDB binaries must be installed on all hosts in the `ydbd_dynamic` group before deploying YDB EM. For more details, see Deploying a YDB cluster with Ansible.

Configuring SSH connection

In the file `examples/inventory/50-inventory.yaml`, verify the SSH connection parameters from the control machine to the target servers:

```
# Remote user with sudo privileges
ansible_user: ansible

# Settings for connecting through a Bastion/Jump host (JUMP_IP)
# ansible_ssh_common_args: "-o ProxyJump=ansible@{{ lookup('env','JUMP_IP') }} -o UserKnownHostsFile=/dev/nul
l -o StrictHostKeyChecking=no"

# Common SSH settings
ansible_ssh_common_args: "-o UserKnownHostsFile=/dev/null -o StrictHostKeyChecking=no"

# Private key for connection
ansible_ssh_private_key_file: "~/.ssh/id_ed25519"
```

Warning

The `UserKnownHostsFile=/dev/null` and `StrictHostKeyChecking=no` parameters disable SSH host key verification, making the connection vulnerable to man-in-the-middle (MITM) attacks. This configuration is only acceptable for test environments. In production environments, it is recommended to use host key verification by specifying the path to a real `known_hosts` file:

```
ansible_ssh_common_args: "-o StrictHostKeyChecking=yes"
```

Note

If a Bastion/Jump host is used to access the servers, uncomment and configure the corresponding `ansible_ssh_common_args` line.

Configuring the YDB database connection

In the file `examples/inventory/50-inventory.yaml`, specify the connection parameters for the YDB database that will be used to store YDB EM metadata:

```
# YDB connection endpoint
ydb_em_db_connection_endpoint: "grpcs://ydb-node01.ru-central1.internal:2135"
# Root domain
ydb_em_db_connection_db_root: "/Root"
# Database name
ydb_em_db_connection_db: "db"
# YDB user
ydb_user: root
```

The YDB user password is set in the file `examples/inventory/99-inventory-vault.yaml`:

```
all:
  children:
    ydb:
      vars:
        ydb_password: <password>
```

Tip

To protect sensitive data, it is recommended to encrypt the `99-inventory-vault.yaml` file using Ansible Vault:

```
ansible-vault encrypt examples/inventory/99-inventory-vault.yaml
```

Configuring the Control Plane connection

In the file `examples/inventory/50-inventory.yaml`, specify the YDB EM Control Plane connection endpoint:

```
# The endpoint must point to a host from the ydb_em group
ydb_em_cp_connection_endpoint: "grpcs://ydb-node01.ru-central1.internal:8787"
```

This parameter is used in the configuration of **Gateway** and **Agent** for connecting to the **Control Plane**.

Note

For high availability, you can specify a load balancer address (for example, an L3/L4 load balancer or DNS-based balancing) instead of a direct host address.

Running the installation

After completing the configuration, navigate to the `examples` directory and run the installation using one of the following methods:

Automatic installation

Run the automatic installation script:

```
cd examples
./install.sh
```

The script will automatically perform all the necessary steps to deploy YDB EM components.

Manual Ansible run

You can also run the installation manually by executing the Ansible playbook:

```
ansible-playbook ydb_platform.ydb_em.initial_setup
```

> **Note**
>
> If the `99-inventory-vault.yaml` file is encrypted with Ansible Vault, add the `--ask-vault-pass` flag:
>
> ```
> ansible-playbook ydb_platform.ydb_em.initial_setup --ask-vault-pass
> ```

Verifying the installation

After the installation completes successfully, open the YDB EM web interface in a browser:

```
https://<FQDN of the host from the ydb_em group>:8789/ui/clusters
```

For example:

```
https://ydb-node01.ru-central1.internal:8789/ui/clusters
```

The web interface should display a page with a list of YDB clusters.

Troubleshooting

Cannot connect to the web interface

1. Make sure port `8789` is accessible from your machine:

   ```
   curl -k https://<FQDN>:8789/ui/clusters
   ```

2. Check the status of the YDB EM Gateway service on the target host:

   ```
   sudo systemctl status ydb-em-gateway
   ```

3. Check the service logs:

   ```
   sudo journalctl -u ydb-em-gateway -n 100
   ```

Agent cannot connect to Control Plane

1. Make sure port `8787` is accessible between the cluster nodes and the Control Plane host.
2. Check the status of the YDB EM Agent service on the node:

   ```
   sudo systemctl status ydb-em-agent
   ```

3. Verify the correctness of TLS certificates and the Control Plane endpoint in the agent configuration.

YDB database connection errors

1. Make sure the endpoint, database name, username, and password are specified correctly.
2. Check network accessibility of port `2135` on the YDB node from the YDB EM host.
3. Check the YDB EM Control Plane logs:

   ```
   sudo journalctl -u ydb-em-cp -n 100
   ```

Configuring S3 backups for YDB EM

This guide describes how to configure database backups to an S3-compatible storage through YDB Enterprise Manager (YDB EM). Backups are configured in the Control Plane configuration file. In the examples below, the path to this file is shown as `<ydb-em-cp-config.yaml>`.

S3 backup configuration consists of three parts:

- `backup_targets` — where to store backups;
- `secret_key` — which master key is used to encrypt S3 access keys;
- `locations[].default_backup_config` — when to run backups and how long to retain them.

> **Note**
>
> This article describes automated backup configuration through YDB EM. For general information about backup options in YDB, see Backup concepts and Backup and recovery.

Configuring S3 storage

Add the `backup_targets` block to the Control Plane configuration:

```
backup_targets:
  - target_id: "target-em"
    tags:
      locations:
        - "em"
    settings:
      s3:
        endpoint: s3.example.net
        bucket: ydb-em-backups
        access_key: "<encrypted access key>"
        secret_key: "<encrypted secret key>"
        compression: "zstd"
```

Parameter	Description
`target_id`	Unique backup target ID.
`tags.locations`	List of `location_id` values this target applies to. A database is backed up to this target if its `location_id` is included in the list. For YDB EM, this is usually `em`, matching `locations[].database_location_id` and `meta_location_id`.
`settings.s3.endpoint`	S3-compatible storage endpoint.
`settings.s3.bucket`	Bucket name for backups.
`settings.s3.scheme`	Connection protocol: `1` for HTTP, `2` for HTTPS. If omitted, HTTPS is used.
`settings.s3.access_key`	Encrypted S3 access key.
`settings.s3.secret_key`	Encrypted S3 secret key.
`settings.s3.compression`	Compression algorithm for exported data. The default is `zstd`. Remove this parameter if compression is not required.

A **location** is a logical group of databases in YDB EM that each database belongs to through its `location_id`. Typically, a location corresponds to a single placement zone of databases — for example, a data center or availability zone where they run — but a location can also be used for logical separation, such as by environment (`prod` , `test`). For example, if databases are deployed across two data centers, you can assign them different locations and send backups from each data center to its own S3 storage. A typical YDB EM installation uses a single location with the value `em`, which matches the `locations[].database_location_id` and `meta_location_id` fields in the Control Plane configuration.

`tags.locations` is useful when one Control Plane manages databases from several locations and different locations must use different backup storage targets. The worker selects a target by the database `location_id`: if the database `location_id` is included in `tags.locations`, this target is used for backups. For example, this lets you send backups from different zones or environments to different S3 buckets.

> **Note**
>
> Instead of binding a target to `location_id`, you can use `explicit_backup_targets` with `by_database_path` or `by_cloud_id` rules if a specific database or cloud must be assigned to a specific target.

Configuring the master key

At the top level of the configuration file, specify the path to the master key file:

```
secret_key: configs/em/secret_key
```

This master key is used to encrypt and decrypt `settings.s3.access_key` and `settings.s3.secret_key` values. The master key file must be available to Control Plane processes at the path specified in the `secret_key` parameter.

> **Warning**
>
> Do not store `access_key` and `secret_key` in the configuration as plaintext. YDB EM expects encrypted values and decrypts them at runtime.

Encrypting S3 access keys

Encrypt the S3 access keys with the same master key specified in the `secret_key` parameter. Use the `ydb-em-cp` Control Plane binary, which is included in the YDB EM package as `bin/ydb-em-cp` and is placed on the Control Plane host during initial deployment:

```
ydb-em-cp admin crypto encrypt --body '<plaintext access key>' --cfg-file <ydb-em-cp-config.yaml>
ydb-em-cp admin crypto encrypt --body '<plaintext secret key>' --cfg-file <ydb-em-cp-config.yaml>
```

Copy the resulting encrypted strings to `settings.s3.access_key` and `settings.s3.secret_key`.

To check that a value can be decrypted with the same master key, run:

```
ydb-em-cp admin crypto decrypt --body '<encrypted value>' --cfg-file <ydb-em-cp-config.yaml>
```

Configuring schedule and retention

The target defines where backups are stored. The schedule and retention period are configured separately in `locations[].default_backup_config`. This is the default backup configuration for databases in the specified location. If an individual backup configuration is set for a specific database in YDB EM, it can differ from these defaults.

```
locations:
  - database_location_id: em
    default_backup_config:
      backup_settings:
        - name: daily
          type: SYSTEM
          backup_schedule:
            daily_backup_schedule:
              execute_time:
                hours: 20
          backup_time_to_live: "604800s"
```

Parameter	Description
`backup_settings[].name`	Backup setting name.
`backup_settings[].type`	Backup setting type. Use `SYSTEM` for a system schedule.
`backup_schedule.daily_backup_schedule.execute_time.hours`	Hour of the daily backup start time in UTC.
`backup_time_to_live`	Backup retention period in seconds. For example, `604800s` means 7 days.

Applying the configuration

To apply the settings:

1. Place the updated configuration file in the Control Plane working directory. For example, for an installation under `/opt/ydb-em`, this can be `/opt/ydb-em/ydb-em-cp/cfg/config.yaml`.
2. Make sure the master key file specified in `secret_key` is available to Control Plane processes.
3. Check that `settings.s3.access_key` and `settings.s3.secret_key` are encrypted with the same master key.
4. Restart the Control Plane service:

   ```
   sudo systemctl restart ydb-em-cp
   ```

After restart, Control Plane resolves the target by `location_id` according to the schedule, configures the S3 storage, and starts data export to the specified bucket.

Checklist

Before starting backups, check that:

- `backup_targets[].tags.locations` contains the `location_id` values of the databases that require backups;
- `endpoint`, `bucket`, and `scheme` point to the correct S3 storage;
- `access_key` and `secret_key` are encrypted with `ydb-em-cp admin crypto encrypt`;
- the top-level `secret_key` parameter points to the correct master key file;
- `locations[].default_backup_config` defines the schedule and retention period;
- the updated configuration file is placed in the Control Plane working directory;
- the Control Plane service is restarted after the configuration change.

Observability overview

This section contains descriptions of tools for monitoring the YDB cluster.

Main subsections:

- Setting Up YDB Cluster Monitoring
- Logging in YDB
- Minidumps (built-in Google Breakpad)
- Tracing in YDB
- Cluster System Views
- Alerting
- Diagnostics of an isolated cluster

Setting Up YDB Cluster Monitoring

Accessing metrics via the web interface

This page explains how to set up monitoring for a YDB cluster.

YDB provides numerous system state metrics. Instant metric values can be viewed in the web interface:

```
http://<ydb-server-address>:<ydb-port>/counters/
```

where:

- `<ydb-server-address>` – YDB server address.

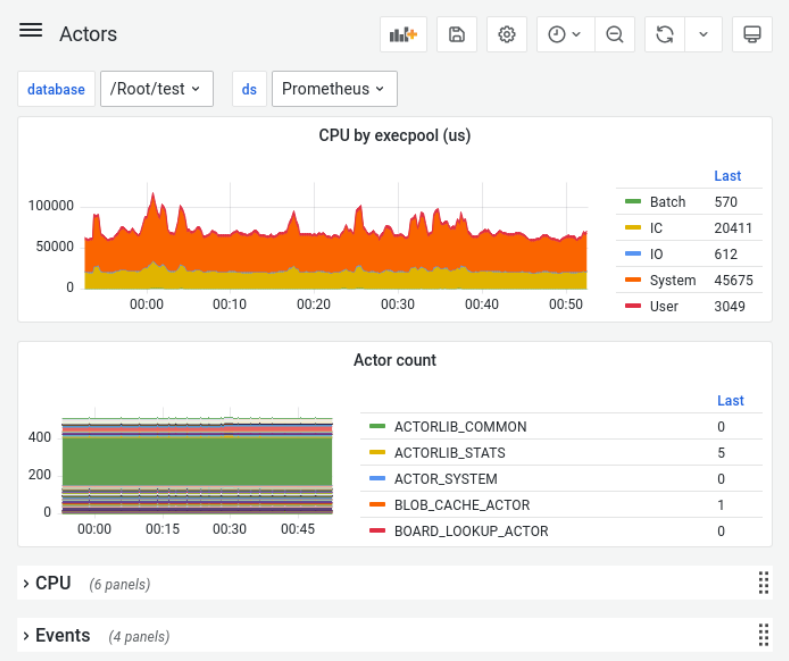
  For a local single-node YDB cluster started using the Quick start instructions, use the address `localhost`.
- `<ydb-port>` – YDB port. Default value: 8765.

Related metrics are grouped into subgroups (for example `counters auth`). To view metric values for a specific subgroup only, navigate to a URL of the following form:

```
http://<ydb-server-address>:<ydb-port>/counters/counters=<servicename>/
```

- `<servicename>` — metric subgroup name.

For example, server hardware resource utilization data is available at the following URL:



```
http://<ydb-server-address>:<ydb-port>/counters/counters=utils
```

To collect metric values, you can use the popular open-source tool Prometheus or any other system that supports this format. YDB metric values in Prometheus format are available at URLs of the following form:

```
http://<ydb-server-address>:<ydb-port>/counters/counters=<servicename>/prometheus
```

- `<servicename>` — metric subgroup name.

Data can be visualized using any system that supports the Prometheus format, such as Grafana, Zabbix or Amazon CloudWatch:

Setting Up Monitoring with Prometheus and Grafana

To set up YDB cluster monitoring using Prometheus and Grafana:

1. Install Prometheus.
2. Edit the Prometheus configuration files:
   2.1. In the `targets` section of `ydbd-storage.yml`, specify the addresses of all YDB cluster servers and the ports of storage nodes running on the servers.

   ```
   - labels:
       container: ydb-static
     targets:
     - "ydb-s1.example.com:8765"
     - "ydb-s2.example.com:8765"
     - "ydb-s3.example.com:8765"
   ```

   For a local single-node YDB cluster, specify one address in the targets section:

```
- labels:
    container: ydb-static
  targets:
  - "localhost:8765"
```

2.2. In the `targets` section of `ydbd-database.yml`, specify the addresses of all YDB cluster servers and the ports of all database nodes running on the servers.

```
- labels:
    container: ydb-dynamic
  targets:
  - "ydb-s1.example.com:31002"
  - "ydb-s1.example.com:31012"
  - "ydb-s1.example.com:31022"
  - "ydb-s2.example.com:31002"
  - "ydb-s2.example.com:31012"
  - "ydb-s2.example.com:31022"
  - "ydb-s3.example.com:31002"
  - "ydb-s3.example.com:31012"
  - "ydb-s3.example.com:31022"
```

For a local single-node YDB cluster, specify one address in the targets section:

```
- labels:
    container: ydb-dynamic
  targets:
  - "localhost:8765"
```

2.3. If necessary, in the `tls_config` section of `prometheus_ydb.yml`, specify the Certificate Authority (CA) certificate that signed the other TLS certificates of the YDB cluster:

```
scheme: https
tls_config:
    ca_file: '<ydb-ca-file>'
```

3. Start Prometheus using `prometheus_ydb.yml` as a configuration file.
4. Install and start Grafana.
5. Create a data source with type `prometheus` in Grafana and connect it to the running Prometheus instance.
6. Upload YDB dashboards to Grafana.

   You can upload dashboards using the Grafana UI Import tool or run the script. Note that the script uses basic authentication in Grafana. For other cases, modify the script.

   See the Grafana dashboards reference.

Logging in YDB

Each YDB component writes messages of different levels to logs. These can be used to detect critical problems or understand the causes of issues.

Logging Setup

Logging configuration for individual components can be done in YDB UI.

Currently, there are two options for starting YDB logging: manually and using systemd.

Manually

For convenience, YDB provides standard mechanisms for collecting logs and metrics.
Logging is performed to standard `stdout` and `stderr` channels and can be redirected using popular solutions.

Using Systemd

By default, logs are written to `journald` and can be retrieved using `journalctl -u ydbd-storage`. For database nodes, change the systemd unit name appropriately.

Minidumps (built-in Google Breakpad)

The `ydbd` nodes in YDB can collect **minidumps** when the process crashes, using the built-in Google Breakpad. A minidump is a compact snapshot of the process state (stack, registers, list of loaded modules) at the moment of a crash caused by an unhandled signal (`SIGSEGV` , `SIGABRT` , `SIGFPE` , and others).

Unlike a system core dump, a minidump:

- takes up significantly less space;
- is collected by its own signal handler and does not depend on the host's `ulimit` and `core_pattern` settings;
- can be automatically passed to an external script for post-processing (uploading, symbolization, alerting).

> **Note**
>
> Minidump collection works on Linux only. On other platforms (for example, macOS) `ydbd` runs, but the built-in Breakpad is not part of the build and minidumps are not collected.

Enabling minidump collection

By default, minidump collection is disabled. To enable it, specify the directory where dumps will be written. This can be done in two ways: through environment variables or through `ydbd server` command-line options. Command-line options take precedence over environment variables.

If the directory is not set by either method, the built-in Breakpad is not activated and does not install signal handlers.

> **Note**
>
> The specified directory must exist before the process starts; YDB does not create it automatically. If the directory is missing at crash time, the minidump will not be written.

Environment variables

Variable	Purpose
`BREAKPAD_MINIDUMPS_PATH`	directory for writing minidumps; setting this variable enables minidump collection at process startup
`BREAKPAD_MINIDUMPS_SCRIPT`	path to the minidump post-processing script

Command-line options

The options are added to the `ydbd server` command:

Option	Purpose
`--breakpad-minidumps-path PATH`	directory for writing minidumps
`--breakpad-minidumps-script SCRIPT`	path to the minidump post-processing script

Startup example:

```
ydbd server \
    --breakpad-minidumps-path /var/log/ydb/minidumps \
    --breakpad-minidumps-script /usr/local/bin/process-minidump.sh \
    ...
```

Post-processing script

If a post-processing script is set, it is run immediately after the minidump is written. The script is called with the following arguments:

Argument	Value
`$1`	`true` or `false` — whether the minidump was written successfully
`$2`	path to the minidump file (empty string if writing failed)

The `ydbd` process environment is not passed to the script, so any parameters it needs must be hardcoded in the script itself or derived from the arguments.

> **Warning**
>
> The script is launched from the crashed process's signal handler via `fork` / `exec` . The signal handler blocks until the script exits, so the script should complete quickly. Heavy processing (uploading the dump, symbolization, alerting) should be delegated to background processes that the script spawns before exiting.

Example of a script that only moves the dump to an archive directory:

```
#!/bin/sh
# $1 — succeeded (true|false), $2 — path to the minidump
if [ "$1" = "true" ]; then
    mv "$2" /var/log/ydb/minidumps/archive/
fi
```

Analyzing minidumps

A minidump does not contain symbols: to obtain a human-readable stack, you need the symbols of the same `ydbd` build artifact. The standard Google Breakpad tools (`minidump_stackwalk` and `.sym` files) produced from the symbols of the corresponding build are used for the analysis.

Cluster System Views

For internal introspection of cluster state, users can query special service views (system views). These views are available from the cluster root directory and use the system path prefix `.sys`.

Cloud database users typically do not have access to cluster system views, as the cloud team is responsible for their maintenance and timely diagnostics.

In the descriptions of available fields below, the **Key** column contains the primary key field index of the corresponding view.

> **Note**
>
> Similar system views exist for what happens inside a specific database; they are described in a separate article for developers.

Access control

The ability to flexibly configure the access rights to system views allows for precise separation of access to service information and user data.

Typical access control scenarios

- **Access only to system views:**
  If your infrastructure has users or services that need to monitor the state of the cluster or database — for example, database administrators — but do not require access to user data, it is recommended to grant these users read-only permissions for the `.sys` directory.
- **Access only to data:**
  When you need to hide information about service and system objects from individual users or groups (for example, analysts who do not need access to internal diagnostics), it is sufficient to grant read-only permissions for the corresponding directory containing user data. In this case, there is no need to grant permissions for the `.sys` directory or the database root — this ensures that users will not see and will not be able to query system views.

You can also assign different permissions to individual system views — both for specific users and for groups. This approach enables flexible implementation of the principle of least privilege and control over different levels of access to service information for various roles and tasks.

Distributed Storage

Information about the distributed storage operation is contained in several interconnected views, each responsible for describing its own entity:

- PDisk
- VSlot
- Group
- Storage Pool

Additionally, there is a separate view that shows statistics on the usage of group numbers in different storage pools and the growth capabilities of these pools.

ds_pdisks

Field	Type	Key	Value
NodeId	Uint32	0	Identifier of the node on which PDisk is running
PDiskId	Uint32	1	PDisk identifier (unique within the node)
Type	String		Media type (`ROT`, `SSD`, `NVME`)
Kind	Uint64		User-defined numeric identifier needed to group disks with the same media type into different subgroups
Path	String		Path to the block device inside the machine
Guid	Uint64		Unique identifier randomly generated when adding a disk to the system, designed to prevent data loss in case disks are swapped
BoxId	Uint64		Identifier of the Box that includes this PDisk
SharedWithOs	Bool		Presence of the "SharedWithOs" label, set manually when creating PDisk. Can be used for filtering disks when creating new groups.
ReadCentric	Bool		Presence of the "ReadCentric" label, set manually when creating PDisk. Can be used for filtering disks when creating new groups.
AvailableSize	Uint64		Number of bytes available for allocation on PDisk
TotalSize	Uint64		Total number of bytes on PDisk
Status	String		PDisk operating mode that affects its participation in group allocation (`ACTIVE`, `INACTIVE`, `BROKEN`, `FAULTY`, `TO_BE_REMOVED`)
StatusChangeTimestamp	Timestamp		Time when `Status` last changed; if `NULL`, `Status` has not changed since PDisk creation
ExpectedSlotCount	Uint32		Maximum number of VSlots that can be created on this PDisk
NumActiveSlots	Uint32		Number of currently occupied VSlots

DecommitStatus	String		Status of PDisk decommissioning (`DECOMMIT_NONE` , `DECOMMIT_PENDING` , `DECOMMIT_IMMINENT` , `DECOMMIT_REJECTED`)

ds_vslots

Field	Type	Key	Value
NodeId	Uint32	0	Identifier of the node on which VSlot is running
PDiskId	Uint32	1	PDisk identifier within the node on which VSlot is running
VSlotId	Uint32	2	VSlot identifier within PDisk
GroupId	Uint32		Storage group number that includes this VSlot
GroupGeneration	Uint32		Storage group configuration generation that includes this VSlot
FailRealm	Uint32		Relative fail realm number of VSlot within the storage group
FailDomain	Uint32		Relative fail domain number of VSlot within the fail realm
VDisk	Uint32		Relative VSlot number within the fail domain
AllocatedSize	Uint64		Number of bytes that VSlot occupies on PDisk
AvailableSize	Uint64		Number of bytes available for allocation to this VSlot
Status	String		State of the running VDisk in this VSlot (`INIT_PENDING` , `REPLICATING` , `READY` , `ERROR`)
Kind	String		Preset VDisk operating mode setting (`Default` , `Log` , ...)

Note that the tuple `(NodeId, PDiskId)` forms a foreign key to the `ds_pdisks` view, and `(GroupId)` to the `ds_groups` view.

ds_groups

Field	Type	Key	Value
GroupId	Uint32	0	Storage group number in the cluster
Generation	Uint32		Storage group configuration generation
ErasureSpecies	String		Redundancy encoding mode for the group (`block-4-2` , `mirror-3-dc` , `mirror-3of4` , ...)
BoxId	Uint64		Identifier of the Box in which this group was created
StoragePoolId	Uint64		Storage pool identifier within the Box where this group operates
EncryptionMode	Uint32		Presence of data encryption in the group and encryption algorithm if enabled
LifeCyclePhase	Uint32		Presence of an expired encryption key if encryption is enabled
AllocatedSize	Uint64		Amount of allocated data bytes in the group (converted to user bytes, i.e., before redundancy)
AvailableSize	Uint64		Amount of user data bytes available for allocation (also before redundancy)
SeenOperational	Bool		Boolean flag showing whether the group was in operational state after its creation
PutTabletLogLatency	Interval		90th percentile of `PutTabletLog` request execution time
PutUserDataLatency	Interval		90th percentile of `PutUserData` request execution time
GetFastLatency	Interval		90th percentile of `GetFast` request execution time
OperatingStatus	String		Group status based on latest VDisk reports only (`UNKNOWN` , `FULL` , `PARTIAL` , `DEGRADED` , `DISINTEGRATED`)
ExpectedStatus	String		Status based not only on operational report, but on PDisk status and plans too (`UNKNOWN` , `FULL` , `PARTIAL` , `DEGRADED` , `DISINTEGRATED`)

In this view, the tuple `(BoxId, StoragePoolId)` forms a foreign key to the `ds_storage_pools` view.

ds_storage_pools

Field	Type	Key	Value
BoxId	Uint64	0	Identifier of the Box that includes this storage pool
StoragePoolId	Uint64	1	Storage pool identifier within the Box
Name	String		User-defined storage pool name (used for linking tablets and storage pools)
Generation	Uint64		Storage pool configuration generation (number of changes)
ErasureSpecies	String		Redundancy encoding mode for all groups within this storage pool
VDiskKind	String		Preset operating mode setting for all VDisks in this storage pool
Kind	String		User-defined string description of pool purpose, can also be used for filtering

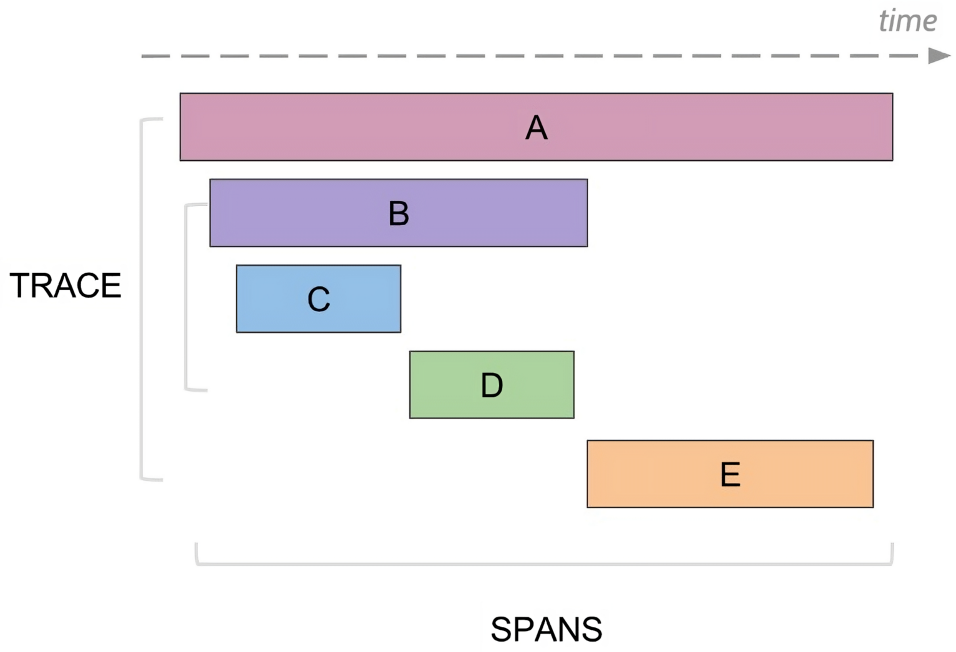
NumGroups	Uint32		Number of groups within this storage pool
EncryptionMode	Uint32		Data encryption setting for all groups (similar to `ds_groups.EncryptionMode`)
SchemeshardId	Uint64		SchemeShard identifier of the schema object to which this storage pool belongs (currently always `NULL`)
PathId	Uint64		Schema object node identifier within the specified SchemeShard to which this storage pool belongs

ds_storage_stats

Unlike other views showing physical entities, `ds_storage_stats` shows aggregated storage information.

Field	Type	Key	Value
BoxId	Uint64	0	Box identifier for which statistics are calculated
PDiskFilter	String	1	String description of filters selecting PDisk for group creation (e.g., by media type)
ErasureSpecies	String	2	Redundancy encoding mode for which statistics are collected
CurrentGroupsCreated	Uint32		Number of created groups with specified characteristics
CurrentAllocatedSize	Uint64		Total occupied space across all groups included in `CurrentGroupsCreated`
CurrentAvailableSize	Uint64		Total space available for allocation across all groups included in `CurrentGroupsCreated`
AvailableGroupsToCreate	Uint32		Number of groups with specified characteristics that can be created considering reserve needs
AvailableSizeToCreate	Uint64		Number of available bytes that would result from creating all groups from `AvailableGroupsToCreate`

Note that `AvailableGroupsToCreate` shows the maximum number of groups that can be created if no other types of groups are created. Thus, when expanding one storage pool, the `AvailableGroupsToCreate` numbers in several statistics rows may change.



Note

Accessing system views is more of an analytical workload. Frequent access to them in large databases will significantly consume system resources. The recommended load is no more than 1-2 RPS.

Tracing in YDB

> **Note**
>
> The OpenTelemetry website describes the concept of tracing in detail in the Observability Primer article.

Tracing is a tool that allows you to view the detailed path of a request through a distributed system. A set of spans describes the path of a single request (trace). A span is a time segment usually associated with the execution time of a specific operation (e.g., writing information to disk or executing a transaction). Spans form a tree, often with the subtree of a span as its detail, but this is not always the case.

To aggregate disparate spans into traces, they are sent to a *collector*. This service aggregates and stores received spans for subsequent trace analysis. YDB does not include this service; the administrator must set it up independently. Typically, Jaeger is used as a collector.

Minimal configuration

To enable tracing in YDB, add the following section to the configuration:

```
tracing_config:
  backend:
    opentelemetry:
      collector_url: grpc://example.com:4317
      service_name: ydb
  external_throttling:
    - max_traces_per_minute: 10
```

Here, the `collector_url` field sets the URL of an OTLP-compatible span collector. More details on the backend section can be found in the relevant section.

With this configuration, no requests are sampled, and no more than ten requests per minute with an external trace-id are traced by each cluster node.

Section descriptions

Backend

Example section

```
tracing_config:
  # ...
  backend:
    opentelemetry:
      collector_url: grpc://example.com:4317
      service_name: ydb
```

Description

This section describes the span collector. Currently, the only option is `opentelemetry`. Spans are pushed from the cluster node to the collector, requiring the collector to be OTLP compatible.

In the `opentelemetry` section:

- `collector_url` — the URL of the span collector. The scheme can be either `grpc://` for an insecure connection or `grpcs://` for a TLS connection.
- `service_name` — the name under which all spans will be marked.

Both parameters are mandatory.

Uploader

Example section

```
tracing_config:
  # ...
  uploader:
    max_exported_spans_per_second: 30
    max_spans_in_batch: 100
    max_bytes_in_batch: 10485760 # 10 MiB
    max_export_requests_inflight: 3
    max_batch_accumulation_milliseconds: 5000
    span_export_timeout_seconds: 120
```

Description

The uploader is a cluster node component responsible for sending spans to the collector. To avoid overloading the span collector, the uploader will not send more than `max_exported_spans_per_second` spans per second on average.

For optimization, the uploader sends spans in batches. Each batch contains no more than `max_spans_in_batch` spans with a total serialized size of no more than `max_bytes_in_batch` bytes. Each batch accumulates for no more than `max_batch_accumulation_milliseconds` milliseconds. Batches can be sent in parallel, with the maximum number of simultaneously sent batches controlled by the `max_export_requests_inflight` parameter. If more than `span_export_timeout_seconds` seconds have passed since the uploader received the span, the uploader may delete it to send fresher spans.

Default values:

- `max_exported_spans_per_second = inf` (no limits)
- `max_spans_in_batch = 150`
- `max_bytes_in_batch = 20000000`
- `max_batch_accumulation_milliseconds = 1000`
- `span_export_timeout_seconds = inf` (no spans are deleted by the uploader)
- `max_export_requests_inflight = 1`

The `uploader` section may be completely absent, in which case each parameter will use its default value.

> **Note**
>
> The uploader is a node-local component. Therefore, the described limits apply to each node separately, not to the entire cluster.

External throttling

Example section

```
tracing_config:
  # ...
  external_throttling:
    - scope:
        database: /Root/db1
      max_traces_per_minute: 60
      max_traces_burst: 3
```

Description

YDB supports the transmission of external trace-ids to build a coherent request trace. The method for transmitting an external trace-id is described on the Passing external trace-id to YDB page. To avoid overloading the collector, YDB has a mechanism to limit the number of externally traced requests. The limits are described in this section and are a sequence of rules. Each rule contains:

- `scope` – a set of selectors for filtering the request.
- `max_traces_per_minute` – the maximum average number of requests per minute traced by this rule. A positive integer is expected.
- `max_traces_burst` – the maximum burst of externally traced requests. A non-negative integer is expected.

The only mandatory parameter is `max_traces_per_minute`.

A detailed description of these options is provided in the Rule semantics section.

The `external_throttling` section is not mandatory; if it is absent, all trace-ids in requests are **ignored** (no external traces are continued).

This section can be modified without restarting the node using the dynamic configuration mechanism.

Sampling

Example section

```
tracing_config:
  # ...
  sampling:
    - fraction: 0.01
      level: 10
      max_traces_per_minute: 5
      max_traces_burst: 2
    - scope:
        request_types:
          - KeyValue.ExecuteTransaction
          - KeyValue.Read
      fraction: 0.1
      level: 15
      max_traces_per_minute: 5
      max_traces_burst: 2
```

Description

For diagnosing system issues, looking at a sample request trace can be useful regardless of whether users trace their requests or not. For this purpose, YDB has a request sampling mechanism. For a sampled request, a random trace-id is generated. This section controls request sampling in a format similar to `external_throttling`. Each rule has two additional fields:

- `fraction` – the fraction of requests sampled by this rule. A floating-point number between 0 and 1 is expected.
- `level` — the detail level of the trace. An integer from 0 to 15 is expected. This parameter is described in more detail in the Detail levels section.

Both fields are mandatory.

The `sampling` section is not mandatory; no requests will be sampled if it is absent.

This section can be modified without restarting the node using the dynamic configuration mechanism.

Rule semantics

Selectors

Each rule includes an optional `scope` field with a set of selectors that determine which requests the rule applies to. Currently, the supported selectors are:

- `request_types`

  Accepts a list of request types. A request matches this selector if its type is in the list.

Possible values

- KeyValue.CreateVolume
- KeyValue.DropVolume
- KeyValue.AlterVolume
- KeyValue.DescribeVolume
- KeyValue.ListLocalPartitions
- KeyValue.AcquireLock
- KeyValue.ExecuteTransaction
- KeyValue.Read
- KeyValue.ReadRange
- KeyValue.ListRange
- KeyValue.GetStorageChannelStatus
- Table.CreateSession
- Table.KeepAlive
- Table.AlterTable
- Table.CreateTable
- Table.DropTable
- Table.DescribeTable
- Table.CopyTable
- Table.CopyTables
- Table.RenameTables
- Table.ExplainDataQuery
- Table.ExecuteSchemeQuery
- Table.BeginTransaction
- Table.DescribeTableOptions
- Table.DeleteSession
- Table.CommitTransaction
- Table.RollbackTransaction
- Table.PrepareDataQuery
- Table.ExecuteDataQuery
- Table.BulkUpsert
- Table.StreamExecuteScanQuery
- Table.StreamReadTable
- Table.ReadRows
- Query.ExecuteQuery

- Query.ExecuteScript
- Query.FetchScriptResults
- Query.CreateSession
- Query.DeleteSession
- Query.AttachSession
- Query.BeginTransaction
- Query.CommitTransaction
- Query.RollbackTransaction
- Discovery.WhoAmI
- Discovery.NodeRegistration
- Discovery.ListEndpoints

> **Note**
>
> Tracing is supported not only for the request types listed above. This list includes request types that are supported by the `request_types` selector.

> **Warning**
>
> Note that the QueryService API is experimental and may change in the future.

- `database`

  Filters requests to the specified database.

A request matches a rule if it matches all selectors. `scope` can be absent, which is equivalent to an empty set of selectors, and all requests will fall under this rule.

Rate limiting

The `max_traces_per_minute` and `max_traces_burst` parameters limit the number of requests. In the case of sampling, they limit the number of requests sampled by this rule. In the case of external throttling, they limit the number of external traces that enter the system.

A variation of the leaky bucket is used for rate limiting with a bucket size equal to `max_traces_burst + 1`. For example, if `max_traces_per_minute = 60` and `max_traces_burst = 0`, then with a flow of 10,000 requests per minute, one request will be traced every second. If `max_traces_burst = 20`, then with the same request flow, the first 21 requests will be traced, and then one request per second will be traced.

> **Warning**
>
> The limits on the number of traced requests are local to the cluster node. For example, if each cluster node has a rule specifying `max_traces_per_minute = 1`, then no more than one request per minute will be traced **from each cluster node** by this rule.

Detail levels

As with logs, diagnosing most system issues does not require the most detailed trace. Therefore, in YDB, each span has its own level described by an integer from 0 to 15 inclusive. Each rule in the `sampling` section must include the detail level of the generated trace (`level`); spans with a level less than or equal to `level` will be included in it.

The YDB architecture section describes the system's division into 5 layers:

Layer	Components
1	gRPC Proxies
2	Query Processor
3	Distributes Transactions
4	Tablet, System tablet
5	Distributed Storage

Each layer has seven detail levels:

Level	Value
`Off`	No tracing
`TopLevel`	Lowest detail, no more than two spans per request to the component
`Basic`	Spans of main component operations
`Detailed`	Highest detail applicable for diagnosing problems in production
`Diagnostic`	Detailed debugging information for developers
`Trace`	Very detailed debugging information

The table below shows the distribution of system layer detail levels by trace detail levels:

Trace detail level	gRPC Proxies	Query Processor	Distributed Transactions	Tablets	Distributed Storage
0	`TopLevel`	`Off`	`Off`	`Off`	`Off`
1	`TopLevel`	**`TopLevel`**	`Off`	`Off`	`Off`
2	`TopLevel`	`TopLevel`	**`TopLevel`**	`Off`	`Off`
3	`TopLevel`	`TopLevel`	`TopLevel`	**`TopLevel`**	`Off`
4	`TopLevel`	`TopLevel`	`TopLevel`	`TopLevel`	**`TopLevel`**
5	**`Basic`**	`TopLevel`	`TopLevel`	`TopLevel`	`TopLevel`
6	`Basic`	**`Basic`**	`TopLevel`	`TopLevel`	`TopLevel`
7	`Basic`	`Basic`	**`Basic`**	`TopLevel`	`TopLevel`
8	`Basic`	`Basic`	`Basic`	**`Basic`**	`TopLevel`
9	`Basic`	`Basic`	`Basic`	`Basic`	**`Basic`**
10	**`Detailed`**	**`Detailed`**	`Basic`	`Basic`	`Basic`
11	`Detailed`	`Detailed`	**`Detailed`**	`Basic`	`Basic`
12	`Detailed`	`Detailed`	`Detailed`	**`Detailed`**	`Basic`
13	`Detailed`	`Detailed`	`Detailed`	`Detailed`	**`Detailed`**
14	**`Diagnostic`**	**`Diagnostic`**	**`Diagnostic`**	**`Diagnostic`**	**`Diagnostic`**
15	**`Trace`**	**`Trace`**	**`Trace`**	**`Trace`**	**`Trace`**

Rules

External throttling

The semantics of each rule are as follows: it allocates a quota for the number of requests in this category. For example, if the `external_throttling` section looks like this:

```
tracing_config:
  external_throttling:
    - max_traces_per_minute: 60
    - scope:
        request_types:
          - KeyValue.ReadRange
      max_traces_per_minute: 20
```

With a sufficient flow of requests with an external trace-id, at least 60 requests per minute and at least 20 `KeyValue.ReadRange` type requests per minute will be traced. A total of up to 80 requests per minute will be traced.

The algorithm is as follows: for a request with an external trace-id, the rules that apply to this request are determined. The request consumes the quota of all rules that still have it. The request is not traced only if none of the rules have any quota left.

Sampling

The semantics of the rule for sampling are similar: with a sufficiently low flow of requests in this category, at least a `fraction` of the requests with at least `level` detail will be sampled.

The algorithm is similar: the set of rules that apply to this request is determined for a request without an external trace-id (either due to its initial absence or due to a previous decision not to trace this request). The request consumes the quota of all rules that still have it and that have randomly "decided" to sample it. It is not sampled if no rule decides to sample the request (all rules that "decided" to sample the request have no quota left). Otherwise, the detail level is determined as the maximum among the rules into whose quota the request fell.

For example, with the following `sampling` configuration:

```
tracing_config:
  sampling:
    - scope:
        database: /Root/db1
      fraction: 0.5
      level: 5
      max_traces_per_minute: 100
    - scope:
        database: /Root/db1
      fraction: 0.01
      level: 15
      max_traces_per_minute: 5
```

With a sufficiently low flow of requests to the `/Root/db1` database, the following will be sampled:

- 1% of requests with a detail level of 15
- 49.5% of requests with a detail level of 5

With a sufficiently high flow of requests to the `/Root/db1` database, the following will be sampled:

- 5 requests per minute with a detail level of 15
- between 95 and 100 requests per minute with a detail level of 5

Alerting

Alerting is a mechanism for automatic notifications that informs administrators or DevOps engineers about events that require their attention or intervention.

Use it to monitor critical database parameters in real time (such as overall system health, CPU utilization, authentication errors, and disk space usage) and to respond quickly to failures, errors, or load above acceptable thresholds.

This page describes configurable alerting rules and how they work in YDB.

Alerting in YDB with Prometheus Alerting Rules

Prometheus Alerting Rules are a set of rules written in YAML that define conditions for generating alerts. The rules use PromQL (Prometheus Query Language) and let you detect issues automatically from collected metrics. For example, you can configure a rule that fires when CPU load exceeds 70% or when disk usage is above 60%.

Before You Begin

- Set up a Prometheus server. For installation, see the Prometheus documentation.
- Get familiar with recording rules.
- Configure notifications so that alerts are delivered to your preferred channels. For configuration, see the Alertmanager documentation.

Key rule parameters:

```
- alert: YDBAuthTicketErrors  # Alert name
  expr: auth_TicketsErrors > 2  # Condition that triggers the alert
  for: 1m  # Time the condition must hold before the alert fires
  ...
```

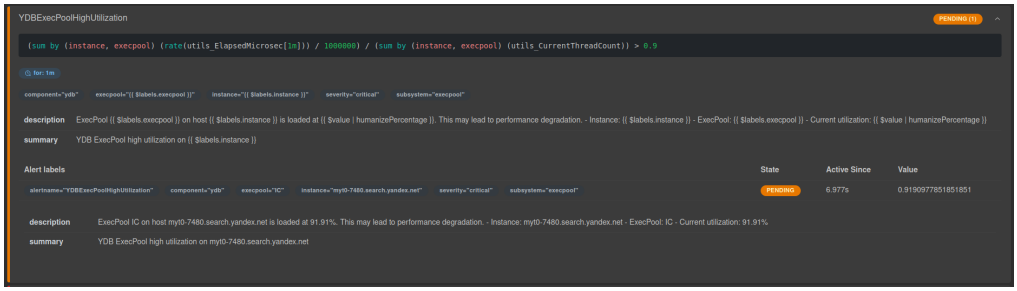
- **Where are they stored?** Rules are usually defined in separate files (for example, `rules.yml`) and loaded into the Prometheus configuration.
- **How are they evaluated?** The Prometheus server periodically (by default every 1–2 minutes) evaluates the `expr` expressions in the rules. If the condition is true for the duration specified in `for`, an alert is generated.

Alert states:

- **Pending:** The alert condition (`expr`) is satisfied (the expression evaluates to `true`), but the `for` duration has not elapsed yet.
- **Firing:** The condition has remained true for the full `for` duration; the alert is active.
- **Resolved:** The condition no longer holds; the alert is closed.

For details on the system and rule structure, see the official Prometheus documentation.

Recommended Alerting Rules for Every Cluster



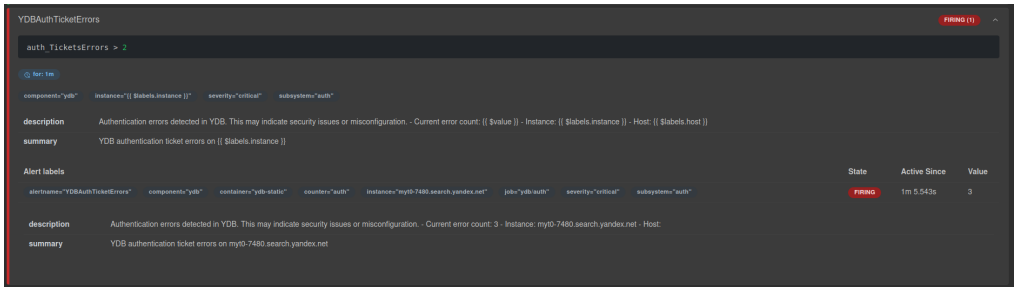
YDB ExecPool High Utilization

Description: This rule monitors resource pool utilization in YDB. It fires when utilization exceeds 90%, which can lead to performance degradation and higher query latency.
What to do: Analyze the load. The alert message includes the name of the pool where the threshold is exceeded. For diagnosing CPU-related issues, see CPU bottleneck.

> **Note**
>
> If you change the alert configuration, update the `for` parameter together with the `utils_ElapsedMicrosec` window so that their values stay consistent.

```
- alert: YDBExecPoolHighUtilization
  expr: |
    (
      sum by (instance, execpool) (
        rate(utils_ElapsedMicrosec[1m])
      ) / 1000000
    ) / (
      sum by(instance, execpool) (
        utils_CurrentThreadCount
      )
    ) > 0.9
  for: 1m
  labels:
    severity: critical
    component: ydb
    subsystem: execpool
    instance: "{{ $labels.instance }}"
    execpool: "{{ $labels.execpool }}"
  annotations:
    summary: "YDB ExecPool high utilization on {{ $labels.instance }}"
    description: |
      ExecPool {{ $labels.execpool }} on host {{ $labels.instance }}
      is loaded at {{ $value | humanizePercentage }}.
      This may lead to performance degradation.
      - Instance: {{ $labels.instance }}
      - ExecPool: {{ $labels.execpool }}
      - Current utilization: {{ $value | humanizePercentage }}
```

Example of a firing alert:



YDB Authentication Errors

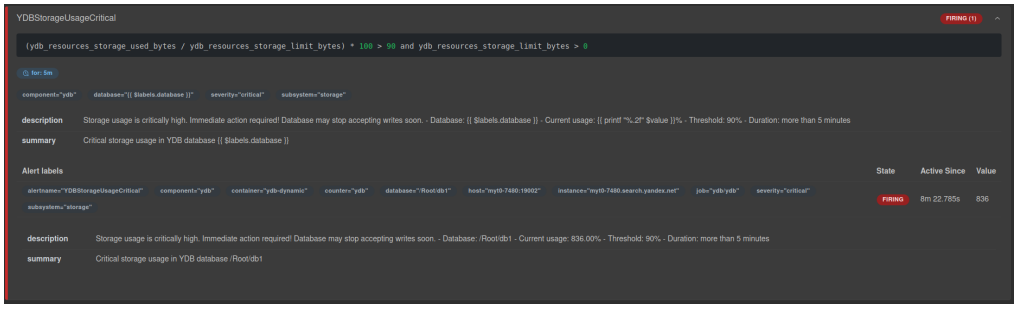
Description: This rule tracks authentication errors in YDB. It fires when more than 2 errors occur within the `for` period. This may indicate incorrect credentials, security misconfiguration, or a system configuration issue.
What to do: Search Logging in YDB for authentication errors and identify the cause.

```
- alert: YDBAuthTicketErrors
  expr: auth_TicketsErrors > 2
  for: 1m
  labels:
    severity: critical
    component: ydb
    subsystem: auth
    instance: "{{ $labels.instance }}"
  annotations:
    summary: "YDB authentication ticket errors on {{ $labels.instance }}"
    description: |
      Authentication errors detected in YDB.
      This may indicate security issues or misconfiguration.
      - Current error count: {{ $value }}
      - Instance: {{ $labels.instance }}
      - Host: {{ $labels.host }}
```

Example of a firing alert:

YDB Storage Usage

Description: This rule monitors disk space usage. It fires when storage utilization reaches critical levels. Configure two thresholds: a warning at 80% usage and a critical alert at 90%.
What to do: Determine why the database has grown beyond the expected size. Remove unneeded data (for example, old logs) or increase the database size limit if appropriate. For diagnosing disk space issues, see Disk space.



Warning Storage Usage (80%)

```
- alert: YDBStorageUsageWarning
  expr: |
    (ydb_resources_storage_used_bytes / ydb_resources_storage_limit_bytes) * 100 > 80
    and ydb_resources_storage_limit_bytes > 0
  for: 5m
  labels:
    severity: warning
    component: ydb
    subsystem: storage
    database: "{{ $labels.database }}"
  annotations:
    summary: "High storage usage in YDB database {{ $labels.database }}"
    description: |
      Storage usage is above warning threshold.
      Consider cleaning up old data or increasing storage capacity.
      - Database: {{ $labels.database }}
      - Current usage: {{ printf "%.2f" $value }}%
      - Threshold: 80%
      - Duration: more than 5 minutes
```

Critical Storage Usage (90%)

```
- alert: YDBStorageUsageCritical
  expr: |
    (ydb_resources_storage_used_bytes / ydb_resources_storage_limit_bytes) * 100 > 90
    and ydb_resources_storage_limit_bytes > 0
  for: 5m
  labels:
    severity: critical
    component: ydb
    subsystem: storage
    database: "{{ $labels.database }}"
  annotations:
    summary: "Critical storage usage in YDB database {{ $labels.database }}"
    description: |
      Storage usage is critically high. Immediate action required!
      Database may stop accepting writes soon.
      - Database: {{ $labels.database }}
      - Current usage: {{ printf "%.2f" $value }}%
      - Threshold: 90%
      - Duration: more than 5 minutes
```

Example of a firing alert:

Full Configuration File

A full configuration file with all of the rules above is available on GitHub.

Configuration Recommendations

- **Thresholds:** Adjust the thresholds in the `expr` parameter to match your SLAs and load profile.
- **Pending duration:** Increase the `for` parameter for less critical alerts to reduce false positives.

Diagnostics of an isolated cluster

If a cluster is hidden behind network barriers, direct monitoring of its state is impossible. In such cases, to identify problems in the cluster's internal environment, you can use the mechanism of saving its state to a file.

Collecting diagnostic information

To collect diagnostic information, use the command:

```
ydb [global options...] admin cluster diagnostics collect \
  --duration 200 \
  --period 15 \
  --output diagnostics.tar
```

Command parameters

- `--duration` — the number of seconds during which cluster information will be collected.
- `--period` — the interval in seconds between metric collections.
- `--output` — the path and file name in `.tar` format, where all collected cluster information will be written.
- `--no-sanitize` — allows you to get a full report by disabling the sanitization of user table names, columns, and queries (which are stripped by default).

The command writes the internal state of cluster nodes to the specified file over a given period. Every `period` seconds, metrics are collected from each cluster node and written to the file.

Archive contents

The resulting file is an archive and contains:

- Metrics collected from cluster nodes.
- Cluster information.

All data is written in JSON format in a human-readable form.

Cluster information

Cluster information includes:

- Health Check report.
- Queries to the cluster partition tables `/Root/.sys` and their responses.
- Current configuration of cluster subsystems.
- Current state of cluster nodes.

Backup and recovery

YDB is initially designed for data safety in case of hardware failures: redundancy options are available for different numbers of availability zones, racks, hosts, disks, and other components (see cluster operating modes). This reduces the risk of data loss due to hardware failures.

However, data can be lost or corrupted **logically**: errors or malicious actions can lead to mass deletion/corruption of data by operations legitimate for the DBMS. In such cases, cluster fault tolerance does not replace a **separate copy** of data outside the cluster.

Backup is used to protect against such scenarios and allows restoring data from a backup. It is recommended to store copies on a separate medium or in cloud object storage (for example, via export to files or export to S3).

YDB provides several solutions for performing backup and recovery. For conceptual information and comparison of backup methods, see backup concepts.

- Backup to files and recovery using the YDB CLI.
- Backup to S3-compatible storage and recovery using the YDB CLI.
- Backup of system tablets to the local file system of cluster hosts.

YDB CLI

Files

The following commands are used for backup to files:

- `ydb admin cluster dump` — for backing up cluster metadata
- `ydb admin database dump` — for backing up the database
- `ydb tools dump` — for backing up individual schema objects or directories

Learn more about these commands in Exporting data to the file system.

The following commands are used for restoration from a file backup:

- `ydb admin cluster restore` — for restoring cluster metadata from a backup
- `ydb admin database restore` — for restoring the database from a backup
- `ydb tools restore` — for restoring individual schema objects or directories from a backup

Learn more about these commands in Importing data from the file system.

S3-compatible storage

To perform backup to an S3-compatible storage (for example, AWS S3), the `ydb export s3` command is used. Follow the link to the YDB CLI reference for information about this command.

To perform restoration from a backup created in an S3-compatible storage, the `ydb import s3` command is used. Follow the link to the YDB CLI reference for information about this command.

NFS

To perform backup to NFS on hosts where YDB is running, the `ydb export nfs` command is used. Follow the link to the YDB CLI reference for information about this command.

To perform restoration from a backup created in NFS on hosts where YDB is running, the `ydb import nfs` command is used. Follow the link to the YDB CLI reference for information about this command.

For more details on configuring NFS for backup and recovery, see the recipe Backup and recovery via NFS.

> **Note**
>
> The speed of backup and restore operations to/from S3-compatible storage or NFS is tuned to minimize the impact on user load. To control the operation speed, configure limits for the corresponding queue of the resource broker.

> **Note**
>
> When performing an export, a directory named `export_*` is created in the root directory of the database, where `*` is the numeric part of the export identifier. This directory contains tables that hold a consistent snapshot of the exported data at the time the export started. After the backup operation completes successfully, the `export_*` directory along with its contents is deleted.

Backup collections

Backup collections provide incremental backup and point-in-time recovery for production workloads. For conceptual information and architecture details, see Backup collections.

Backup collections are recommended for production environments with a regular backup schedule and large datasets where incremental changes are significantly smaller than the total volume. For simpler scenarios (one-time migrations, development environments, small databases), consider using export/import or dump/restore.

For step-by-step instructions on configuring and using backup collections, see:

- Backup collections — architecture, concepts, and limitations
- Recipes for backup collections — typical scenarios and examples

Backup of system tablets

The system tablet backup mechanism provides incremental copying of cluster metadata to the local file system of the cluster hosts.

For conceptual information and how it works, see Backup concepts.

For step-by-step instructions on enabling and restoring, see Recipes for system tablet backup.

Initial Synchronization for Asynchronous Replication Using Backup and Restore

With this initial synchronization method, the source data is transferred to the target from a backup in S3-compatible storage. Asynchronous replication then applies accumulated changes and continues synchronizing the databases. Applications can keep writing to the source during the transfer.

This method uses server-side backup and restore operations to transfer large datasets. With an initial CDC scan, all source data passes through changefeeds, and a separate backup is not required. For differences in resource and operational costs, see the comparison of initial synchronization methods.

Prerequisites

In this example, the `original_table` table in the `/Root/source` database is transferred to the `replica_table` table in the `/Root/target` database. The `my_replication` replication instance is created on the target. The commands use the `source` and `target` YDB CLI profiles to connect to the respective databases.

Before you begin:

- Configure the profiles and check connectivity to both databases using the `scheme ls` command.
- Set up permissions for asynchronous replication, export on the source, and import on the target. The user creating the replication instance must be able to alter the restored tables to attach them as replicas.
- On the target, create a secret named `source_token` containing the token that replication will use to connect to the source.
- Prepare the `mybucket` bucket and S3 authentication. The examples use the `storage.yandexcloud.net` endpoint and read access keys from environment variables or the `~/.aws/credentials` file. The endpoint must be accessible from the servers of both databases: the source writes the backup, and the target reads it.
- Choose an unused prefix, `replication-bootstrap`, in the bucket. Do not modify the exported files until the import is complete.
- Make sure that `replica_table` does not exist on the target. The `import s3` command creates the table together with its data and does not overwrite existing tables. Use `scheme ls` to check the path.

Keep the set of replicated tables, their columns, and their indexes unchanged during initial synchronization. The table schemas in the backup must match the source schemas when replication starts.

> **Warning**
>
> Before creating replication, choose the availability period for unacknowledged changes. With `AVAILABILITY_PERIOD = 'UNLIMITED'`, changes are retained until their processing is acknowledged; provide enough space for them to accumulate in the source. With a finite period, plan the export, import, and processing of accumulated changes so that replication can acknowledge their processing before this period expires. The `PAUSED` state does not stop messages from aging.

1. Create Replication Without an Initial Scan

On the target, run a CREATE ASYNC REPLICATION statement with `INITIAL_SCAN = FALSE`. You can run the YQL statements in this guide using the `sql` command with the `target` profile.

```
CREATE ASYNC REPLICATION my_replication
FOR original_table AS replica_table
WITH (
    CONNECTION_STRING = 'grpcs://source.example.com:2135/?database=/Root/source',
    TOKEN_SECRET_PATH = 'source_token',
    INITIAL_SCAN = FALSE,
    AVAILABILITY_PERIOD = 'UNLIMITED'
);
```

The `source.example.com:2135` address in the example is the source endpoint. The `CONNECTION_STRING` and `TOKEN_SECRET_PATH` parameters specify the connection that the target will use to create and read changefeeds.

The example explicitly selects the `'UNLIMITED'` availability period, which is also the default. For a finite period, specify a positive value of type `Interval`, for example, `AVAILABILITY_PERIOD = Interval('PT48H')`. This parameter cannot be changed using `ALTER ASYNC REPLICATION` after creation.

Replication is created in the `PAUSED` state and prepares changefeeds in the source without exporting the initial data. The `replica_table` table is not created or attached to replication yet. The import operation will create it.

2. Wait for the Changefeeds to Be Ready

Changefeeds are created asynchronously. Before starting the export, check that they are ready for all replicated tables, including index implementation tables if they are part of the replication.

Get the replication description in JSON format:

```
ydb -p target scheme describe my_replication --format proto-json-base64
```

Check the following fields:

- `paused`: replication is waiting to be started after the import. This field alone does not confirm that the changefeeds are ready.
- `items`: the list of objects with their `source_path` and `destination_path` paths. Wait until all expected objects appear.
- `source_changefeed_name` for each object: the changefeed name. Names are assigned automatically; do not set them manually.

For `original_table`, check the changefeed state on the source:

```
ydb -p source scheme describe original_table --format proto-json-base64
```

In the `changefeeds` array, find the changefeed with the name from `source_changefeed_name`. Its `state` field must be `STATE_ENABLED`.

For an item corresponding to a synchronous or unique index, `source_path` points to the index. Its implementation table is located at `source_path/indexImplTable`. Check the `changefeeds` array in the description of that table.

Also use `scheme describe` to check the changefeed topic settings: the presence of the `replicationConsumer` consumer, its availability policy, and the `RetentionPeriod` value. The changefeed path depends on the object:

Object	Changefeed path
Table	`source_path/source_changefeed_name`
Index implementation table	`source_path/indexImplTable/source_changefeed_name`

Use the field values from the replication description in these paths. To check the settings, run:

```
ydb -p source scheme describe <changefeed-path>
```

Where:

- `<changefeed-path>`: the changefeed path, for example, `/Root/source/original_table/stream-name`. Replace `stream-name` with the name from the replication description.

In the consumer table, check the following for `replicationConsumer`:

- With `AVAILABILITY_PERIOD = 'UNLIMITED'`, the `Important` field must be `Yes`.
- With a finite period, the `Important` field must be `No`, and `Availability period` must match the selected interval.

Repeat the checks for every object in `items`. Unacknowledged messages are protected by the consumer policy, so `RetentionPeriod` alone does not determine the availability of accumulated changes. For more information, see Storing Changes in the Source.

Warning

Start the export only after all changefeeds are ready. If the backup is created earlier, replication may miss changes made between the backup and the creation of the changefeeds. You cannot use an arbitrary pre-existing backup for this procedure.

3. Export the Source Data

Start an export to S3 using the source profile:

```
ydb -p source export s3 \
  --s3-endpoint storage.yandexcloud.net \
  --bucket mybucket \
  --destination-prefix replication-bootstrap \
  --include original_table \
  --include-index-data true
```

The table export is stored under the `replication-bootstrap/original_table` prefix. The `--include-index-data true` option also saves index table data if the source table has indexes. This data will be loaded from the backup during the import.

For multiple tables, specify `--include` for each table in a single export operation: the server creates a consistent copy of the tables. The exported objects must match the set of replication objects.

The command returns a server-side operation ID. Wait for the operation to complete successfully using `operation get`:

```
ydb -p source operation get <export-operation-id>
```

Where:

- `<export-operation-id>`: the ID returned when you started the export.

Proceed to the import only when the table output shows `ready = true`, `status = SUCCESS`, and `progress = Done`. Successfully starting the export command does not mean that the export has finished.

Applications can continue changing the source data. Changefeeds retain these changes according to the selected `AVAILABILITY_PERIOD`, including while replication is in the `PAUSED` state.

4. Import the Data into the Target

After the export succeeds, start an import from S3 using the target profile:

```
ydb -p target import s3 \
  --s3-endpoint storage.yandexcloud.net \
  --bucket mybucket \
  --item src=replication-bootstrap/original_table,dst=replica_table \
  --index-population-mode import
```

The `--item` option maps the table prefix in the backup to the `replica_table` target path specified in `CREATE ASYNC REPLICATION`. The `--index-population-mode import` mode loads the index data saved in the previous step. For multiple tables, specify a separate `--item` for each pair of paths.

Wait for the operation to complete successfully using `operation get`:

```
ydb -p target operation get <import-operation-id>
```

Where:

- `<import-operation-id>`: the ID returned when you started the import.

Make sure that `ready = true`, `status = SUCCESS`, and `progress = Done`. Check the created table:

```
ydb -p target scheme describe replica_table
```

Until replication starts, the restored table is a regular table. Do not write application data to it: these writes are not synchronized with the source and may be overwritten when changes are applied.

5. Start Change Data Replication

After all table imports are complete, run ALTER ASYNC REPLICATION on the target:

```
ALTER ASYNC REPLICATION my_replication SET (STATE = 'STANDBY');
```

The target checks that the restored table schemas match the source schemas and attaches the tables as replica objects. The check covers the primary key, columns, their types, column families, and indexes. Attached tables become read-only, and replication starts applying accumulated changes.

Synchronous secondary indexes, including unique indexes, are supported. Restored vector indexes are deleted when tables are attached to replication. For more information, see Restrictions.

Records are read from the changefeeds created before the export. They may include changes already reflected in the backup. Until the accumulated records have been processed, the target data may change and does not yet match the current source state.

Check the state and lag:

```
ydb -p target scheme describe my_replication --stats
```

After replication starts, the `paused` field in the description is replaced by `running`. Statistics include lag for replication and individual objects. Wait until the accumulated changes have been processed; a missing lag value does not mean zero lag. The value may be unavailable if a consumer stops, loses its session, or does not report fresh statistics. For more information, see Change Data Replication.

Replication then continues transferring new changes. If the transfer is part of an application migration, follow the separate procedure for completing asynchronous replication before switching writes to the target.

Errors and Retries

- If an export or import fails, check its status and error description using `operation get`. Keep replication in the `PAUSED` state until all table imports succeed. When retrying an import, remember that target tables must not exist; a failed operation does not confirm that no objects were created.
- If starting replication fails, get its JSON description and check the `error` field. In particular, check that all target tables exist, their schemas match, and permissions are sufficient. Do not import over tables already attached as replicas.
- If required CDC records have been deleted because their retention period expired, continuing to read cannot ensure data completeness. Repeat initial synchronization with new changefeeds and a new backup.
- Restarting the replication controller preserves the `PAUSED` state; it does not replace an explicit transition to `STANDBY`. If a CLI session is interrupted, check previously started server-side operations by their IDs before starting new ones.

For more information about temporary and critical errors, see Error Handling During Asynchronous Replication.

YDB for Application Developers / Software Engineers

This section of YDB documentation covers everything you need to know to develop applications interacting with YDB.

Main resources:

- Getting started with YDB as an Application Developer / Software Engineer
- Example applications working with YDB
- Generate code from YQL (sqlc-ydb)
- YQL Tutorial - Overview
- Choosing a primary key for:
  - Row-oriented tables
  - Column-oriented tables
- Secondary indexes
- Uploading data to YDB
- Paginated output
- Using timeouts
- System database views
- Change Data Capture
- Custom attributes in tables
- Reference:
  - YQL - Overview
  - Reference for YDB SDK
  - YDB CLI
  - Kafka API

If you're interested in developing YDB core or satellite projects, refer to the documentation for contributors.

Getting started with YDB as an Application Developer / Software Engineer

First of all, you'll need to obtain access to a YDB cluster. Follow the quickstart instructions to get a basic local instance. Later on, you can work with your DevOps team to build a production-ready cluster or leverage one of the cloud service providers that offer a managed YDB service.

The second step is designing a data schema for an application you will build from scratch or adapt the schema of an existing application if you're migrating from another database management system.

In parallel with designing the schema, you need to set up your development environment for interaction with YDB. There are a few main aspects to it, explored below.

Choosing API

Choose the YDB API you want to use; there are several options:

- The recommended way for mainstream programming languages is using a YDB SDK. They provide high-level APIs and implement best practices on working with YDB. YDB SDKs are available for several popular languages and strive for feature parity, but not all are feature-complete. Refer to the SDK feature comparison table to check if the SDK for the programming language you had in mind will fit your needs or to choose a programming language with better feature coverage if you're flexible.
- If you are interested in YDB topics feature, it is worth noting that they also provide Kafka-compatible API. Follow that link if this use case is relevant.
- As a last resort, YDB's native API is based on the gRPC protocol, which has an ecosystem around it, including code generation of clients. YDB's gRPC specs are hosted on GitHub and you could leverage them in your application. The generated clients are low-level and will require extra work to handle aspects like retries and timeouts properly, so go this route only if other options above aren't possible and you know what you're doing.

Install prerequisites

Choose the specific programming language you'll be using. Install the respective YDB SDK.

Additionally, you'd want to set up at least one of the available ways to run ad-hoc queries for debugging purposes. Choose at least one according to your preferences:

- YDB CLI
- YDB UI
- Any SQL IDE that supports JDBC

Start coding

For YDB SDK route

- Go through YQL tutorial to get familiar with YDB's SQL dialect.
- Explore example applications to see how working with SDK's looks like.
- Check out SDK recipies for typical SDK use cases, which you can refer to later.
- Learn how to handle YDB SDK errors.
- Leverage your IDE capabilities to navigate the SDK code.

Testing

To write tests on applications working with YDB:

- For functional tests, you can mock YDB's responses using a suitable testing framework for your chosen programming language.
- For integrational tests, you can launch a single-node YDB instance in your CI/CD environment with either a Docker image or executable similarly to how it is done in the Quickstart article. It is recommended to test against a few versions of YDB: the one you have in production to check for issues you can encounter when updating your application and the newer versions to identify the potential issues of upgrading YDB early on.
- For performance tests, you'd want to use a cluster deployed according to instructions for production use as single-node won't yield realistic results. You can run ydb workload if you want to see how your YDB cluster performs in generic scenarios even before writing any application code. Then you can use the source code of the library behind this tool as an example of how to write your own performance tests with YDB. It'd be great if you could contribute an anonymized version of your workload to upstream so it can be included in performance testing of YDB itself.

What's next

The above should be enough to start developing applications that interact with YDB. Along the way use YQL and YDB SDK reference documentation and other resources in this documentation section.

In case of any issues, feel free to discuss them in YDB Discord.

Streaming queries

Practical aspects of working with streaming queries:

- Local and external topics — accessing topics of the current and another database in YQL queries
- Typical patterns — minimal examples for a quick start
- Writing to tables — how streaming queries allow writing data to YDB tables in real time.
- Data enrichment — ways to enrich data in a stream using reference data.
- Data formats for reading/writing topics — supported data formats when working with topics, examples of their use.
- Data delivery guarantees — level of guarantees, observed anomalies in window aggregation, and recommendations.
- Checkpoints — a mechanism for saving the state of stream processing to ensure fault tolerance and recovery capability.
- Watermarks — a mechanism for tracking time progress in a data stream.

See also

- Recipes for working with streaming queries
- Streaming queries overview

Typical streaming query patterns

This section contains minimal examples of streaming queries for the most common scenarios. First, a basic pattern for reading data from a topic is described, followed by variants of full data processing: data processing and writing results to a topic in JSON format, to a topic as a string, and to a table. Each example can be used as a starting point for your own tasks.

The examples below use local and external topics. Notation:

- `ext_source` — a pre-created `external data source`
- `input_topic` — the topic from which data is read
- `output_topic` — the topic where results are written
- `output_table` — the YDB table where results are written

Reading data from a topic

Reading structured messages is done using `SELECT ... FROM ... WITH (FORMAT, SCHEMA)`. The `WITH` block specifies the input data format and schema — which fields are expected in each message and their types.

The following fragment is used inside CREATE STREAMING QUERY in the `DO BEGIN ... END DO` block:

```
SELECT
    Id,
    Name
FROM
    topic_name  -- local topic; for external: ext_source.topic_name
WITH (
    FORMAT = json_each_row,
    SCHEMA = (
        Id Uint64 NOT NULL,
        Name Utf8 NOT NULL
    )
);
```

For more details on formats: Data formats for reading/writing from topics.

This pattern is used in all subsequent examples.

Writing to a topic (JSON)

The query reads events from the input topic, forms a JSON object from individual fields, and writes the result to the output topic. The `AsStruct` function creates a structure from the specified fields, `Yson::From` converts it to Yson, `Yson::SerializeJson` serializes it to a JSON string, and `ToBytes` converts it to the `String` type, which is required for writing to the topic.

```
CREATE STREAMING QUERY write_json_example AS
DO BEGIN

INSERT INTO ext_source.output_topic -- or local topic output_topic
SELECT
    -- Building JSON from individual fields
    ToBytes(Unwrap(Yson::SerializeJson(Yson::From(
        AsStruct(Id AS id, Name AS name)
    ))))
FROM
    input_topic -- or external topic ext_source.input_topic
WITH (
    FORMAT = json_each_row,  -- Input data format
    SCHEMA = (               -- Input data schema
        Id Uint64 NOT NULL,
        Name Utf8 NOT NULL
    )
);

END DO
```

For more details on functions:

- AsStruct
- Yson::From
- Yson::SerializeJson
- Unwrap
- ToBytes.

Writing to a topic (string)

The query reads events from the input topic and writes one field as a string to the output topic. To write strings to a topic, `SELECT` must return a single column of type `String` or `Utf8`.

```
CREATE STREAMING QUERY write_utf8_example AS
DO BEGIN

INSERT INTO output_topic -- or external topic ext_source.output_topic
SELECT
    Name
FROM
    ext_source.input_topic -- or local topic input_topic
WITH (
    FORMAT = json_each_row,  -- Input data format
    SCHEMA = (               -- Input data schema
        Id Uint64 NOT NULL,
        Name Utf8 NOT NULL
    )
);

END DO
```

For more details on write formats: Formats for writing data.

Writing to a table

The query reads events from the topic and writes them to the `output_table` table. The table must be created in advance with a schema matching the selected columns.

> **Warning**
>
> Writing to tables in streaming queries is supported **only in UPSERT mode**. The `INSERT INTO` operation is not supported, because during reprocessing of events (the at-least-once guarantee) it would lead to duplicate rows. With `UPSERT`, if a row with such a primary key already exists, it will be updated; otherwise, a new row will be inserted, and `INSERT INTO` will fail with an error.

```
CREATE STREAMING QUERY write_table_example AS
DO BEGIN

-- Writing to table (only UPSERT, INSERT not supported)
UPSERT INTO output_table
SELECT
    Id,
    Name
FROM
    ext_source.input_topic -- or local topic input_topic
WITH (
    FORMAT = json_each_row,  -- Input data format
    SCHEMA = (               -- Input data schema
        Id Uint64 NOT NULL,
        Name Utf8 NOT NULL
    )
);

END DO
```

- Quick start: reading and writing to topics

Writing to tables

Writing to tables lets you save the results of a streaming query for later analysis with regular SQL queries. For example, you can aggregate events from a stream and save the results to a table.

For writing, UPSERT INTO is used — inserting a new row or updating an existing one by primary key. The UPSERT operation is idempotent by primary key: rewriting the same row results in an update, not duplication. This is important because streaming queries provide the at-least-once guarantee — when recovering from a checkpoint, some events may be processed again.

Alert

Not supported:

- The INSERT INTO command — use UPSERT INTO. INSERT INTO is not used because reprocessing events (at-least-once guarantee) would lead to duplicate rows.
- Writing to YDB tables located in external databases. In the current version, writing is only possible to local tables.

Example

The query reads events from a topic and writes them to the `output_table` table. The `Ts` field is converted from a string to the `Timestamp` type using `CAST`, and Unwrap removes the optionality of the result.

```
CREATE STREAMING QUERY query_with_table_write AS
DO BEGIN

-- Reading from a topic and writing to a table
UPSERT INTO
    output_table
SELECT
    -- Converting a string to Timestamp
    Unwrap(CAST(Ts AS Timestamp)) AS Ts,
    Country,
    Count
FROM
    -- Reading events from a topic
    input_topic
WITH (
    -- Data format in a topic
    FORMAT = json_each_row,
    -- Data schema
    SCHEMA = (
        Ts String NOT NULL,
        Count Uint64 NOT NULL,
        Country Utf8 NOT NULL
    )
);

END DO
```

Limitations

In a single streaming query:

- You cannot use the same table for stream enrichment using `JOIN` and for writing the query result.
- You cannot write to the same table multiple times.

Data enrichment

Data enrichment is adding additional information from a reference to events in a stream. For example, an event contains only an identifier, and the reference allows adding a name or other attributes to it. You can use data from a local table or from an S3 object storage as a reference.

In streaming queries, the reference is connected using the `JOIN` construct. The stream must be on the left, the reference on the right.

> **Warning**
>
> The reference is fully loaded into memory when the query starts. If the data in the reference has changed, to get the current version of the reference, you need to restart the query — delete it using DROP STREAMING QUERY and recreate it using CREATE STREAMING QUERY.

Data enrichment from local and external topics is possible.

In the examples below:

- `ext_source` — a pre-created external data source for topics in another YDB database
- `input_topic` and `output_topic` — topics in the current or external YDB database

Streaming queries for data enrichment

The queries in the examples below read events from the input topic, attach the service name from the reference by `ServiceId` to each event, and write the result to the output topic.

For more details on the functions used in the queries:

- TableRow
- Yson::From
- Yson::SerializeJson
- Unwrap
- ToBytes.

Enrichment from a local table

In this example, the reference is stored in the table `services_dict` in the current database.

Create a streaming query that performs enrichment:

```
CREATE STREAMING QUERY query_with_table_join AS
DO BEGIN

-- Reading events from input topic
$topic_data = SELECT
    *
FROM
    ext_source.input_topic -- or local topic input_topic
WITH (
    FORMAT = json_each_row,
    SCHEMA = (
        Time String NOT NULL,
        ServiceId Uint32 NOT NULL,
        Message String NOT NULL
    )
);

-- Joining reference to stream by ServiceId
$joined_data = SELECT
    s.Name AS Name,
    t.*
FROM
    $topic_data AS t
LEFT JOIN
    services_dict AS s
ON
    t.ServiceId = s.ServiceId;

-- Writing to the output topic (JSON)
INSERT INTO
    output_topic -- or external topic ext_source.output_topic
SELECT
    ToBytes(Unwrap(Yson::SerializeJson(Yson::From(TableRow()))))
FROM
    $joined_data;

END DO
```

Enrichment from S3

The reference is stored in S3 and connected via an external data source.

Create an additional external data source to read the reference from S3:

```
-- S3 data source for reading reference
CREATE EXTERNAL DATA SOURCE s3_source WITH (
    SOURCE_TYPE = "ObjectStorage",
    LOCATION = "<s3_endpoint>",
    AUTH_METHOD = "NONE"
);
```

Where:

- `<s3_endpoint>` — the S3 storage URL, for example `https://storage.yandexcloud.net/<bucket>/` for Yandex Cloud.

Create a streaming query that performs enrichment:

```
CREATE STREAMING QUERY query_with_join AS
DO BEGIN

-- Reading events from input topic
$topic_data = SELECT
    *
FROM
    input_topic -- or external topic ext_source.input_topic
WITH (
    FORMAT = json_each_row,
    SCHEMA = (
        Time String NOT NULL,
        ServiceId Uint32 NOT NULL,
        Message String NOT NULL
    )
);

-- Reading service reference from S3
$s3_data = SELECT
    *
FROM
    s3_source.`file.csv`
WITH (
    FORMAT = csv_with_names,
    SCHEMA = (
        ServiceId Uint32,
        Name Utf8
    )
);

-- Joining reference to stream by ServiceId
$joined_data = SELECT
    s.Name AS Name,
    t.*
FROM
    $topic_data AS t
LEFT JOIN
    $s3_data AS s
ON
    t.ServiceId = s.ServiceId;

-- Write result to output topic in JSON format
INSERT INTO
    ext_source.output_topic -- or local topic output_topic
SELECT
    ToBytes(Unwrap(Yson::SerializeJson(Yson::From(TableRow()))))
FROM
    $joined_data;

END DO
```

For more details on data formats (`json_each_row`, `csv_with_names`, etc.): Data formats for reading/writing from topics.

Data formats for reading/writing from topics

This section describes the data formats of streaming queries supported in YDB when reading from topics, and the list of supported YQL types for each data format.

Supported data formats

YDB supports built-in data formats (predefined by default) and custom formats (configured by the user for specific tasks).

Below is the list of data formats built into YDB:

- `csv_with_names`
- `tsv_with_names`
- `json_list`
- `json_each_row`
- `json_as_string`
- `parquet`
- `raw`

Examples of parsing data in custom formats.

In the examples on this page, `input_topic` and `output_topic` are topics in the current database, and `output_table` is a YDB table. For topics in another database, see local and external topics.

Formats for writing data

When writing to a topic, `SELECT` must return a single column of type `String`, `Utf8`, `Json`, or `Yson`. The column cannot be `Optional`.

Writing a single column:

```
CREATE STREAMING QUERY write_string_example AS
DO BEGIN

    INSERT INTO output_topic
    SELECT
        CAST(Data AS String)
    FROM
        input_topic
    WITH (
        FORMAT = raw,
        SCHEMA = (
            Data String
        )
    );

END DO
```

To write multiple columns, serialize them into JSON:

```
CREATE STREAMING QUERY write_json_example AS
DO BEGIN

    INSERT INTO output_topic
    SELECT
        ToBytes(Unwrap(Yson::SerializeJson(Yson::From(TableRow()))))
    FROM
        input_topic
    WITH (
        FORMAT = json_each_row,
        SCHEMA = (
            Id Uint64 NOT NULL,
            Name Utf8 NOT NULL
        )
    );

END DO
```

For more details on functions: TableRow, Yson::From, Yson::SerializeJson, Unwrap, ToBytes.

If a single streaming query writes to multiple topics, all output topics must be different.

Formats for reading data

csv_with_names format

This format is based on the CSV format. Data is placed in columns separated by commas, with column names in the first row.

Example data (in a single message):

```
Year,Manufacturer,Model,Price
1997,Man_1,Model_1,3000.00
1999,Man_2,Model_2,4900.00
```

Example query:

```
CREATE STREAMING QUERY csv_example AS
DO BEGIN

    UPSERT INTO output_table
    SELECT
        *
    FROM
        input_topic
    WITH (
        FORMAT = csv_with_names,
        SCHEMA = (
            Year Int32 NOT NULL,
            Manufacturer String NOT NULL,
            Model String NOT NULL,
            Price Double NOT NULL
        )
    );

END DO
```

tsv_with_names format

This format is based on the TSV format. Data is placed in columns separated by tab characters (code `0x9`), with column names in the first row.

Example data (in a single message):

```
Year    Manufacturer    Model   Price
1997    Man_1   Model_1    3000.00
1999    Man_2   Model_2    4900.00
```

Example query:

```
CREATE STREAMING QUERY tsv_example AS
DO BEGIN

    UPSERT INTO output_table
    SELECT
        *
    FROM
        input_topic
    WITH (
        FORMAT = tsv_with_names,
        SCHEMA = (
            Year Int32 NOT NULL,
            Manufacturer String NOT NULL,
            Model String NOT NULL,
            Price Double NOT NULL
        )
    );

END DO
```

json_list format

This format is based on the JSON representation of data. In this format, each message must be a JSON array of objects.

Example of valid data (as a list of JSON objects):

```
[
    { "Year": 1997, "Manufacturer": "Man_1", "Model": "Model_1", "Price": 3000.0 },
    { "Year": 1999, "Manufacturer": "Man_2", "Model": "Model_2", "Price": 4900.00 }
]
```

Example of invalid data (each message contains a separate JSON object, but these objects are not combined into a list):

```
{ "Year": 1997, "Manufacturer": "Man_1", "Model": "Model_1", "Price": 3000.0 }
{ "Year": 1999, "Manufacturer": "Man_2", "Model": "Model_2", "Price": 4900.00 }
```

Example query:

```
CREATE STREAMING QUERY json_list_example AS
DO BEGIN

    UPSERT INTO output_table
    SELECT
        *
    FROM
        input_topic
    WITH (
        FORMAT = json_list,
        SCHEMA = (
            Year Int32 NOT NULL,
            Manufacturer String NOT NULL,
            Model String NOT NULL,
            Price Double NOT NULL
        )
    );

END DO
```

json_each_row format

This format is based on the JSON representation of data. In this format, each message must be a JSON object. This format is used when transferring data through streaming systems, such as Apache Kafka or YDB Topics.
Multiple separate JSONs in a single message are not supported; a JSON list is also not supported.

Example of valid data (in a single message):

```
{ "Year": 1997, "Manufacturer": "Man_1", "Model": "Model_1", "Price": 3000.0 }
```

Example of invalid data:

```
{ "Year": 1997, "Manufacturer": "Man_1", "Model": "Model_1", "Price": 3000.0 }
{ "Year": 1999, "Manufacturer": "Man_2", "Model": "Model_2", "Price": 4900.00 }
```

Example query:

```
CREATE STREAMING QUERY json_each_row_example AS
DO BEGIN

    UPSERT INTO output_table
    SELECT
        *
    FROM
        input_topic
    WITH (
        FORMAT = json_each_row,
        SCHEMA = (
            Year Int32 NOT NULL,
            Manufacturer Utf8 NOT NULL,
            Model Utf8 NOT NULL,
            Price Double NOT NULL
        )
    );

END DO
```

json_as_string format

This format is based on the JSON representation of data.

In this format, each message must contain:

- An object in valid JSON representation on each separate line of the file.
- Objects in valid JSON representation combined into a list.

The `json_as_string` format does not split the input JSON document into fields, but represents each message as a single JSON object (or a single line). This format is convenient when the list of fields is not the same across all rows and can vary.

Example of valid data:

```
{ "Year": 1997, "Attrs": { "Manufacturer": "Man_1", "Model": "Model_1" }, "Price": 3000.0 }
{ "Year": 1999, "Attrs": { "Manufacturer": "Man_2", "Model": "Model_2" }, "Price": 4900.00 }
```

In this format, the schema of the read data must consist of only one column with one of the allowed data types; see below for details.

Example query:

```
CREATE STREAMING QUERY json_as_string_example AS
DO BEGIN

    INSERT INTO output_topic
    SELECT
        *
    FROM
        input_topic
    WITH (
        FORMAT = json_as_string,
        SCHEMA = (
            Data Json
        )
    );

END DO
```

parquet format

This format allows reading the contents of messages in Apache Parquet format.

Example query:

```
CREATE STREAMING QUERY parquet_example AS
DO BEGIN

    UPSERT INTO output_table
    SELECT
        *
    FROM
        input_topic
    WITH (
        FORMAT = parquet,
        SCHEMA = (
            Year Int32 NOT NULL,
            Manufacturer Utf8 NOT NULL,
            Model Utf8 NOT NULL,
            Price Double NOT NULL
        )
    );

END DO
```

raw format

This format allows reading the contents of messages as-is, in "raw" form. Data read in this way can be processed using YQL. Default schema: `SCHEMA(Data String)`.

Example query:

```
CREATE STREAMING QUERY raw_example AS
DO BEGIN

    INSERT INTO output_topic
    SELECT
        *
    FROM
        input_topic
    WITH (
        FORMAT = raw,
        SCHEMA = (
            Data String
        )
    );

END DO
```

Supported data types

Table of all supported types in the query schema:

Type	csv_with_names	tsv_with_names	json_list	json_each_row	json_as_string	parquet	raw
`Int8`, `Int16`, `Int32`, `Int64`, `Uint8`, `Uint16`, `Uint32`, `Uint64`, `Float`, `Double`	✓	✓	✓	✓	✓	✓	
`Bool`	✓	✓	✓	✓		✓	
`DyNumber`							
`String`, `Utf8`	✓	✓	✓	✓	✓	✓	✓

`Json`					✓		✓
`JsonDocument`							
`Yson`							
`Uuid`				✓			
`Date`, `Datetime`, `Timestamp`, `TzDate`, `TzDateTime`, `TzTimestamp`							
`Interval`							
`Date32`, `Datetime64`, `Timestamp64`, `Interval64`, `TzDate32`, `TzDateTime64`, `TzTimestamp64`							
`Optional<T>`	✓	✓	✓	✓	✓	✓	✓

Examples of parsing data in custom formats

Parsing JSON with built-in functions

Example data:

```
{"key": 1997, "value": "42"}
```

Example query:

```
CREATE STREAMING QUERY json_builtins_example AS
DO BEGIN

    INSERT INTO output_topic
    SELECT
        JSON_VALUE(Data, "$.key") AS Key,
        JSON_VALUE(Data, "$.value") AS Value
    FROM
        input_topic
    WITH (
        FORMAT = raw,
        SCHEMA = (
            Data Json
        )
    );

END DO
```

For more details about functions: JSON_VALUE.

Parsing JSON with the Yson library

Example data (Change Data Capture format):

```
{"update":{"volume":10,"product":"bWlsaw=="},"key":[6],"ts":[1765192622420,1844674407370955161 5]}
```

Example query:

```
CREATE STREAMING QUERY json_yson_example AS
DO BEGIN

    $input = SELECT
        Yson::ConvertTo(
            Data, Struct<
                update: Struct<volume: Uint64>,
                key: List<Uint64>,
                ts: List<Uint64>
            >
        )
    FROM
        input_topic
    WITH (
        FORMAT = json_as_string,
        SCHEMA = (
            Data Json
        )
    );

    INSERT INTO output_topic
    SELECT
        ts[0] AS Ts,
        update.volume AS Volume
    FROM
        $input
    FLATTEN COLUMNS;

END DO
```

For more information about functions:

- Yson::ConvertTo
- FLATTEN COLUMNS.

Parsing DSV (TSKV)

Example data:

```
name=Elena  uid=95792365232151958
name=Denis  uid=78086244452810046
name=Mikhail    uid=70609792906901286
```

Example query:

```
CREATE STREAMING QUERY dsv_example AS
DO BEGIN

    $input = SELECT
        Dsv::Parse(Data, "\t") AS Data
    FROM
        input_topic
    FLATTEN LIST BY (
        String::SplitToList(Data, "\n", TRUE AS SkipEmpty) AS Data
    );

    INSERT INTO output_topic
    SELECT
        DictLookup(Data, "name") AS Name,
        DictLookup(Data, "uid") AS Uid
    FROM
        $input;

END DO
```

For more information about functions:

- String::SplitToList
- DictLookup
- FLATTEN LIST BY.

Data delivery guarantees

Delivery guarantees determine how many times each event from the input topic will be processed by a streaming query. Understanding the system's guarantees is critical when designing data processing pipelines.

> **Note**
>
> We are constantly working on developing streaming processing mechanisms. In future versions, the guarantees provided will be improved.

Data processing guarantees (dataplane):

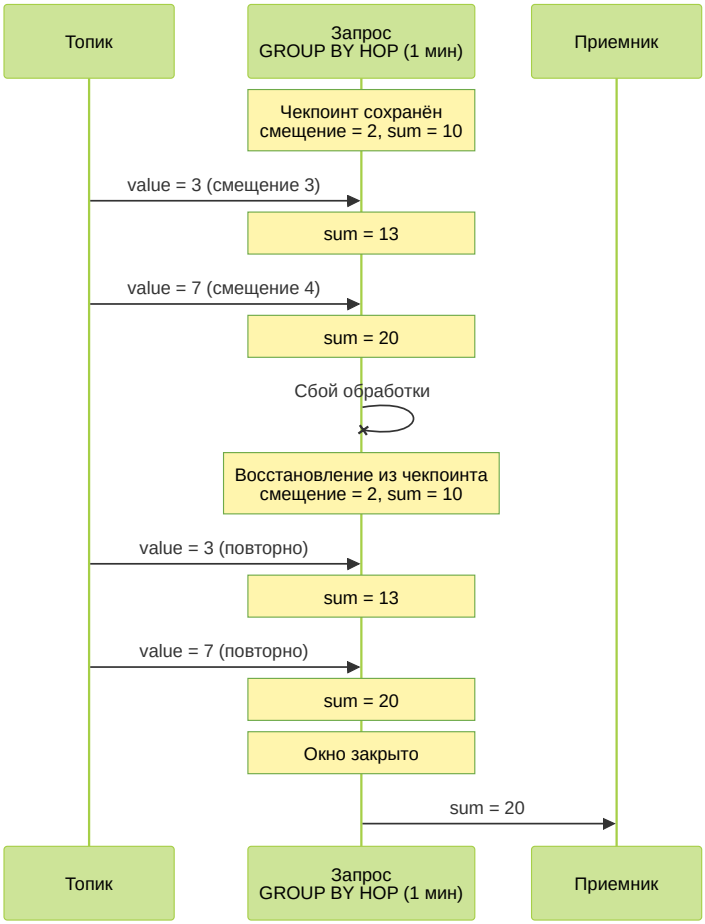
- at-least-once — for all query types, each event is processed at least once.

Anomalies when modifying queries (control plane):

- Event loss when recreating a query — when recreating a query via DROP + CREATE, some events that arrived between deletion and creation will be skipped.
- Partial first aggregation window — when a query starts, the first aggregation window contains incomplete data.

Checkpoints and recovery

YDB periodically saves a checkpoint — a snapshot of the query state containing:



- offsets in input topics — positions up to which events have been read and processed;
- aggregation states — intermediate results of operations, for example accumulated values in GROUP BY HOP.

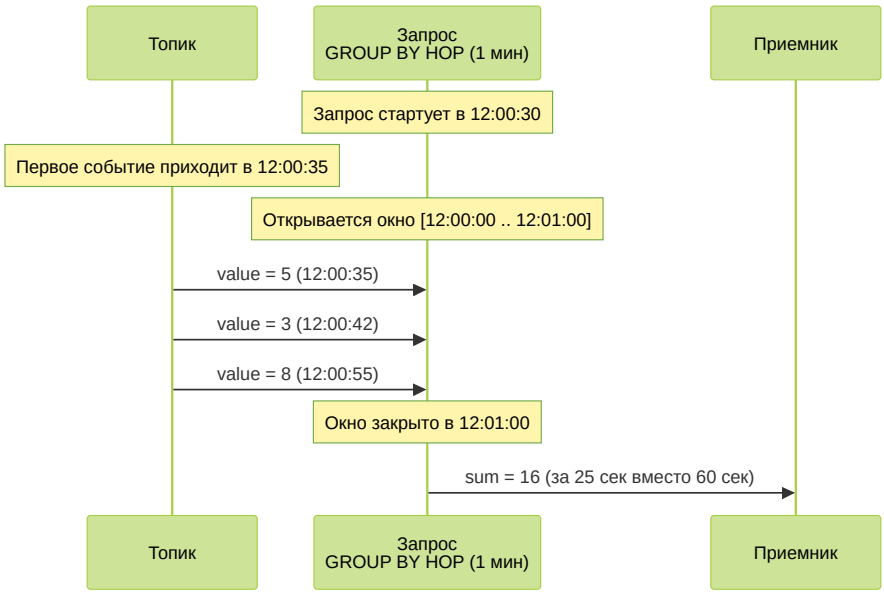
YDB stores read offsets in its own checkpoints, rather than relying on the offsets of a consumer in an external system.

During recovery, the query rolls back to the last checkpoint: it resumes reading from the saved offsets and restores the aggregation states. Events that arrived between the checkpoint and the failure will be reprocessed. For more details on the checkpoint mechanism, see the Checkpoints section.

Data processing guarantees (dataplane) — at-least-once

If a failure occurs during stream processing (compute node restart, network outage, timeout), YDB automatically restores the query from the last checkpoint. The at-least-once guarantee is provided for all types of streaming queries — each event will be processed at least once. The query resumes reading from the saved offset and resends the processing results. This applies to all types of queries: queries without aggregation (filtering, enrichment, transformation) and queries with window aggregation.

When writing the result to a table via UPSERT, reprocessing does not lead to duplication: UPSERT updates the existing row by primary key. Data is not lost, and duplicates do not accumulate.



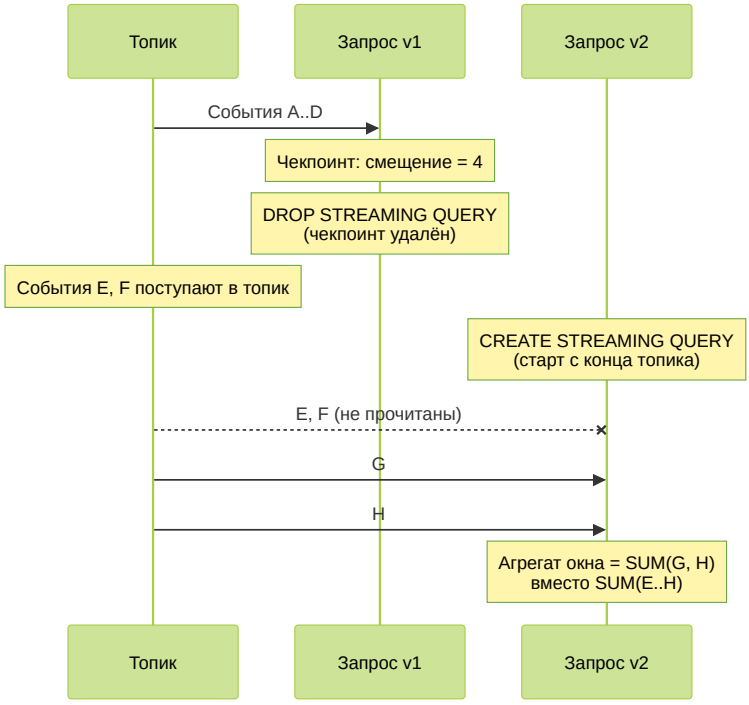
When writing the result to an output topic, reprocessing leads to duplicates: the same events will be written to the topic more than once. The consumer of the output topic must account for this and, if necessary, perform deduplication on its own.

Guarantees when modifying a query (control plane)

Currently, changing the query text without stopping it is not supported. To update a query, a combination of DROP and CREATE commands is used; in this case, the `at-least-once` guarantee is not met: some events may be skipped. The scenarios where this occurs are described below.

Partial results of the first window when starting a query

Time windows (GROUP BY HOP) calculate their boundaries based on absolute (wall-clock) time. Window boundaries are aligned to multiples of intervals from the start of the epoch: for example, with a 1-minute window, boundaries always occur at 12:00:00, 12:01:00, 12:02:00, etc., regardless of when the query was started. If the query starts at 12:00:30, it falls into the already running window [12:00:00 .. 12:01:00], but data only starts arriving at 12:00:30. As a result, the aggregate of the first window is computed from 30 seconds of data instead of a full minute.



This is expected behavior on the first start — all subsequent windows will receive data for the full interval, which is important to consider when recreating a query.

Event loss when recreating a query

To change the query text, the combination of commands DROP + CREATE is used. When `DROP`, the checkpoint is deleted along with the query, since YDB uses internal storage of read offsets from the source, these offsets are deleted along with the query. The new query does not have a saved position and starts reading from the end of the topic. All events that arrived in the topic between the deletion of the old query and the start of the new one will not be read.

A similar situation occurs if the data pointed to by the offset in the checkpoint has already been deleted from the topic by TTL.

For queries with window aggregation, the first windows after recreation will contain data gaps and understated aggregates.

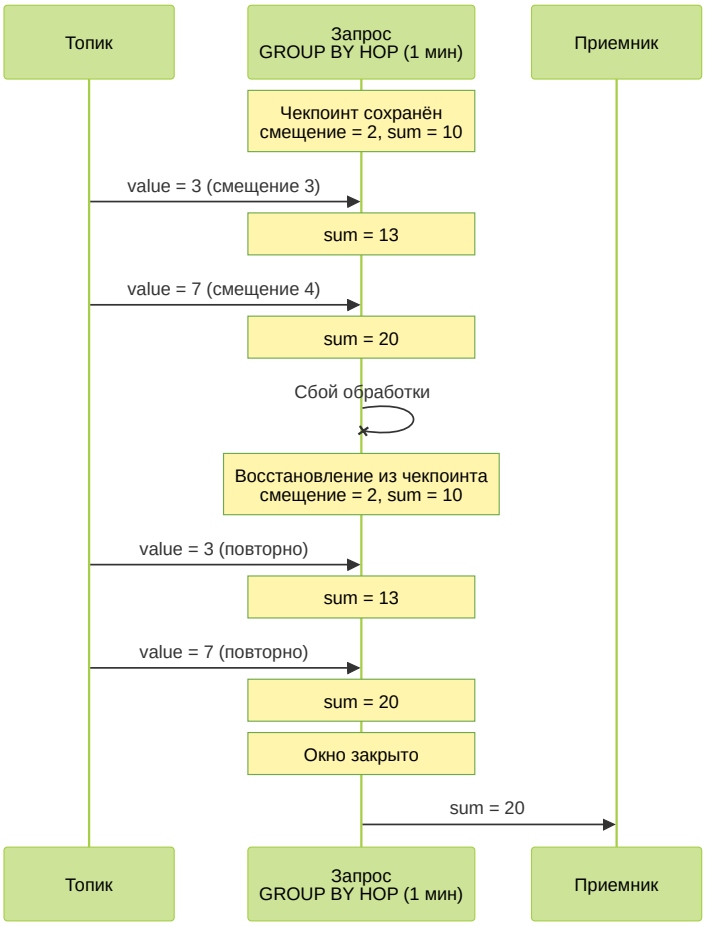
See also

- Streaming queries — general description of streaming queries.
- Checkpoints — checkpoint mechanism that ensures recovery after failures.
- Writing to tables — writing to tables and UPSERT idempotence.

Checkpoints

A **checkpoint** is persisted state of a running streaming query, used to recover processing after failures. YDB periodically checkpoints all running streaming queries.

Checkpoint contents



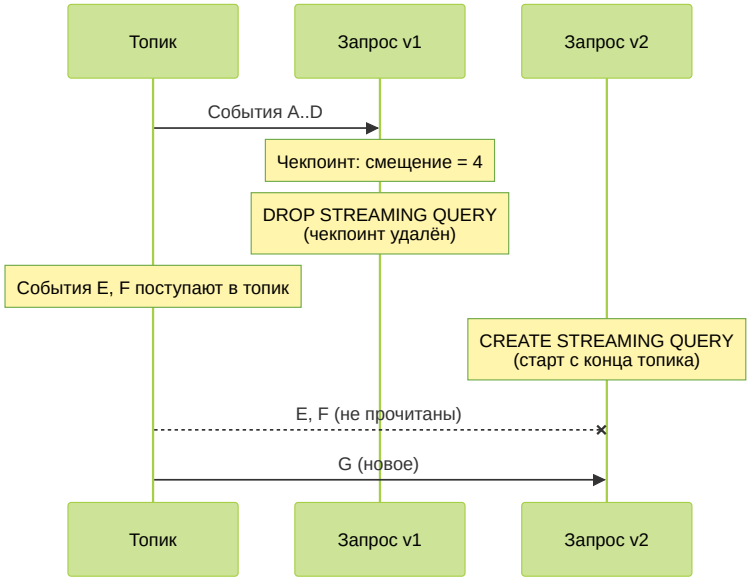
A checkpoint contains:

- Offsets in input topics — positions up to which events were read and processed;
- Aggregation state — intermediate results such as accumulators for GROUP BY HOP.

YDB stores read offsets in its own checkpoints and does not rely on external consumer offsets. When a query is removed (DROP STREAMING QUERY), offsets are removed with the checkpoint — external systems are not aware how far the query read in the topic.

Recovery after failure

When processing fails (compute node restart, network interruption, timeout), the query restarts automatically and restores state from the latest checkpoint: it resumes reading from saved offsets and restores aggregation state.



Events that arrived between the last checkpoint and the failure are processed again. That provides at-least-once delivery — each event is processed at least once.

Saving and selecting checkpoints for recovery is automatic. Old checkpoints are removed after a new one is saved successfully.

Checkpoint deleted when recreating a query

When you delete a query (DROP STREAMING QUERY), its checkpoint is deleted with it. Because offsets live only in the checkpoint, a new query (CREATE STREAMING QUERY) has no saved position and starts reading from the end of the topic. Events that arrived between deleting the old query and starting the new one are not read.

The same happens if data referenced by an offset in the checkpoint has already been removed from the topic due to TTL.

For how this affects delivery guarantees, see Event loss when recreating a query.

Disabling checkpoints

To reduce overhead, you can disable checkpointing with pragma `ydb.DisableCheckpoints`.

> **Warning**
>
> With checkpoints disabled there are no consistency guarantees across user or internal restarts. Use only for debugging.

```
CREATE STREAMING QUERY query_without_checkpoints AS
DO BEGIN

PRAGMA ydb.DisableCheckpoints = "TRUE";

INSERT INTO
    output_topic
SELECT
    *
FROM
    input_topic;

END DO
```

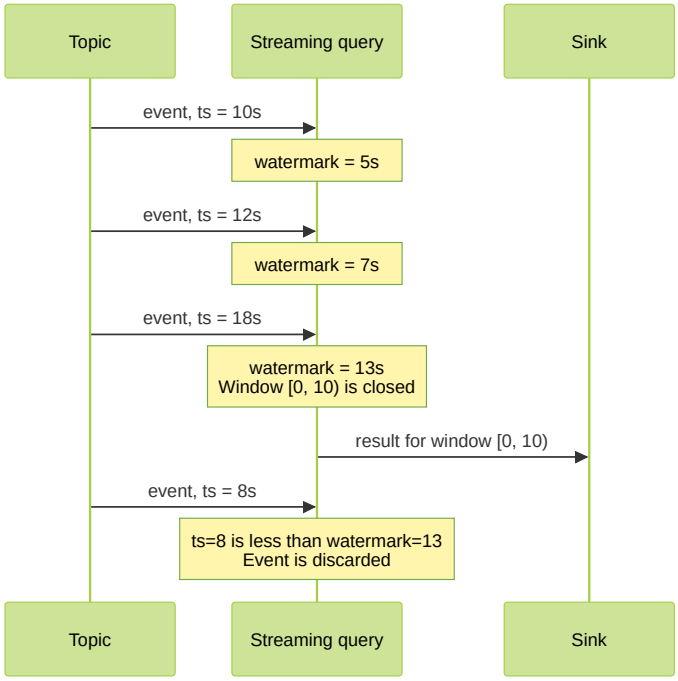
Watermarks

Watermark — a monotonically increasing lower bound on event times in the stream (more about the concept: Watermarks). This section describes the configuration of watermarks in streaming queries YDB.



Event time

In stream processing, each event has a timestamp that the system uses to track the progress of time in the stream. In the current implementation, the only source of event time is the write time of the event to the topic, available via the system column `__ydb_write_time`.

> **Note**
>
> Support for arbitrary expressions to extract time from event data (for example, the `event.created_at` field) is planned in future versions.

Usage

Watermark is used by operations that depend on the progress of event time in the stream. In YDB, such operations include window aggregation HoppingWindow — it defines sliding time windows that group events. When a watermark is received, `HoppingWindow` closes all windows that are fully covered by this value.

Watermark computation

When the system receives an event, it updates the watermark — **advancing** it forward along the time axis. The watermark is calculated as `maximum observed event time − delay`, where `delay` is the lag value specified in the `WATERMARK` expression (for example, `Interval("PT5S")` in `WATERMARK = __ydb_write_time - Interval("PT5S")`).

Events in a stream may arrive out of chronological order: an event with timestamp 10:00:03 may be processed after an event with timestamp 10:00:05. Reasons: clock skew in a distributed system, network delays, uneven load on topic partitions.

The `delay` parameter sets the allowable time margin for events arriving with a delay. For example, with `delay` of 5 seconds, an event with time 00:00:48 will be accepted even if events with time 00:00:50 have already arrived: the watermark has not yet reached 00:00:48. If the same event arrives later, when the watermark has already advanced past 00:00:48, it will be considered late and discarded.

On the trade-off between accuracy and result delivery latency: Accuracy vs. Latency Trade-off.

Idle partitions

If the input topic contains multiple partitions, each of them advances the watermark independently. The overall query watermark does not advance ahead of the slowest partition: windows are not closed until at least one partition has reached the corresponding point in time.

If one of the partitions stops receiving data, its watermark stops advancing. Such a partition is called idle. As long as the idle partition is taken into account when computing the overall watermark, it also stops advancing, and results are not emitted despite data arriving from other partitions.

To avoid this blocking, an idle partition is excluded from the common watermark calculation after a configurable timeout period (the `WATERMARK_IDLE_TIMEOUT` parameter; for details, see the Configuration section).

Configuration

Watermarks are enabled and configured in the WITH section when reading from a topic.

Configuration parameters:

- `WATERMARK` — expression for calculating the watermark. Currently, only the write time to a topic with a constant delay is supported. Format: `__ydb_write_time - Interval("<delay>")`, where `<delay>` is specified in ISO 8601 format.
- `WATERMARK_GRANULARITY` — watermark generation frequency. The smaller it is, the higher the CPU consumption by the query and the lower the response latency. Only relevant for streaming queries. Specified in ISO 8601 format. Default value — 1

second.

- `WATERMARK_IDLE_TIMEOUT` — period after which an idle partition will be excluded from the combined watermark calculation. Only relevant for streaming queries. Specified in ISO 8601 format. Default value — 5 seconds.

> **Warning**
>
> When using HoppingWindow, the first parameter (time extractor) and the time source in the WATERMARK expression must match. In the current implementation, both must use `__ydb_write_time`.

Example

Below is an example of a streaming query with watermark and window aggregation. The query reads events from a topic, filters them by the `pass` field, and aggregates the `payload` values in windows of 10 seconds with a 5-second step. The watermark is configured with a 5-second lag.

Input data

```
{"pass": 1, "payload": "a"} // record time: 1970-01-01T00:00:40Z
{"pass": 1, "payload": "b"} // record time: 1970-01-01T00:00:42Z
{"pass": 0, "payload": "c"} // record time: 1970-01-01T00:00:50Z
{"pass": 1, "payload": "d"} // record time: 1970-01-01T00:00:40Z
```

Query

```
CREATE STREAMING QUERY example AS
DO BEGIN
    $input = (
        SELECT
            t.*,
            __ydb_write_time AS ts
        FROM
            Input
        WITH (
            FORMAT = json_each_row,
            SCHEMA = (
                pass Int64,
                payload String
            ),
            WATERMARK = __ydb_write_time - Interval("PT5S")
        ) AS t
    );

    $output = (
        SELECT
            AGGREGATE_LIST(payload) AS result,
            CAST(HOP_END() AS String) AS ts
        FROM
            $input
        WHERE pass > 0
        GROUP BY
            HoppingWindow(ts, "PT5S", "PT10S")
    );

    INSERT INTO Output
    SELECT
        ToBytes(Unwrap(Yson2::SerializeJson(Yson::From(TableRow()))))
    FROM $output;
END DO;
```

Where:

- `CREATE STREAMING QUERY` — creates a named streaming query.
- `__ydb_write_time` is a system column containing the time the event was written to the topic.
- `FORMAT = json_each_row` — data format in a topic, each line contains a separate JSON object.
- `WATERMARK = __ydb_write_time - Interval("PT5S")` is a watermark with a 5-second lag. `Interval("PT5S")` sets the interval in ISO 8601 format.
- `AGGREGATE_LIST` — aggregate function that collects values into a list.
- `HOP_END()` returns the timestamp of the end of the current window.
- `HoppingWindow(ts, "PT5S", "PT10S")` — window function with a step of 5 seconds and a window size of 10 seconds.

Result

```
{"result": ["a", "b"], "ts": "1970-01-01T00:00:45.000000Z"}
```

Explanation

1. The first event (`"a"` , record time 40s) passes the filter (`pass > 0`) and enters windows `[35; 45)` and `[40; 50)`. Watermark advances to 35s and does not close any window.
2. The second event (`"b"` , record time 42s) similarly falls into windows `[35; 45)` and `[40; 50)`. The watermark advances to 37s.
3. The third event (`"c"` , record time 50s) is discarded by the filter (`pass = 0`). Despite this, the event still advances the watermark to 45s. The watermark closes window `[35; 45)` — result `["a", "b"]` is output.

4. The fourth event (`"d"`, record time 40s) does not advance the watermark: it is already at the 45s mark. The event passes the filter but is discarded as late — its record time (40s) is less than the current watermark (45s). Although window `[40; 50)` is still open, the watermark has already promised that no events with time < 45s will arrive, so `d` is not counted in any of its windows.

Example applications working with YDB

This section outlines the implementation of example applications, all designed to perform similar functions, using the YDB SDKs across various programming languages. Each app is developed to demonstrate how a respective SDK can be utilized in a specific language.

- C++
- C# (.NET)
- Go
- Java
- JavaScript
- Python
- Rust

> **Note**
>
> Refer to YDB SDK reference documentation for more details.

A test app performs the following steps:

Initializing a database connection

To interact with YDB, create instances of the driver, client, and session:

- The YDB driver facilitates interaction between the app and YDB nodes at the transport layer. It must be initialized before creating a client or session and must persist throughout the YDB access lifecycle.
- The YDB client operates on top of the YDB driver and enables the handling of entities and transactions.
- The YDB session, which is part of the YDB client context, contains information about executed transactions and prepared queries.

C++ | C# (.NET) | Go | Java | JavaScript | PHP | Python | Rust

Creating tables

Create tables to be used in operations on a test app. This step results in the creation of database tables for the series directory data model:

- `Series`
- `Seasons`
- `Episodes`

After the tables are created, a method for retrieving information about data schema objects is called, and the result of its execution is displayed.

C++ | C# (.NET) | Go | Java | JavaScript | PHP | Python | Rust

Adding data

Add data to the created tables using the `UPSERT` statement in YQL. A data update request is sent to the server as a single request with transaction auto-commit mode enabled.

C++ | C# (.NET) | Go | Java | JavaScript | PHP | Python | Rust

Retrieving data

Retrieve data using a `SELECT` statement in YQL. Handle the retrieved data selection in the app.

C++ | C# (.NET) | Go | Java | JavaScript | PHP | Python | Rust

Parameterized queries

Query data using parameters. This query execution method is preferable because it allows the server to reuse the query execution plan for subsequent calls and protects against vulnerabilities such as SQL injection.

C++ | C# (.NET) | Go | Java | JavaScript | PHP | Python | Rust

Multistep transactions

Multiple statements can be executed within a single multistep transaction. Client-side code can run between query steps. Using a transaction ensures that queries executed in its context are consistent with each other.

C++ | C# (.NET) | Go | Java | JavaScript | PHP | Python

Managing transactions

Transactions are managed through TCL `Begin` and `Commit` calls.

In most cases, instead of explicitly using `Begin` and `Commit` calls, it's better to use transaction control parameters in execute calls. This allows to avoid additional requests to YDB server and thus run queries more efficiently.

C++ | C# (.NET) | Go | Java | JavaScript | PHP | Python | Rust

Error handling

For more information about error handling, see Error handling in the API.

Example app in C++

This page contains a detailed description of the code of a test app that is available as part of the YDB C++SDK.

Initializing a database connection

To interact with YDB, create instances of the driver, client, and session:

- The YDB driver facilitates interaction between the app and YDB nodes at the transport layer. It must be initialized before creating a client or session and must persist throughout the YDB access lifecycle.
- The YDB client operates on top of the YDB driver and enables the handling of entities and transactions.
- The YDB session, which is part of the YDB client context, contains information about executed transactions and prepared queries.

App code snippet for driver initialization:

```
    auto connectionParams = TConnectionsParams()
        .SetEndpoint(endpoint)
        .SetDatabase(database)
        .SetAuthToken(GetEnv("YDB_TOKEN"));

    TDriver driver(connectionParams);
```

App code snippet for creating a client:

```
    TClient client(driver);
```

Creating tables

Create tables to be used in operations on a test app. This step results in the creation of database tables for the series directory data model:

- `Series`
- `Seasons`
- `Episodes`

After the tables are created, a method for retrieving information about data schema objects is called, and the result of its execution is displayed.

```
    //! Creates sample tables with the ExecuteQuery method
    ThrowOnError(client.RetryQuerySync([](TSession session) {
        auto query = Sprintf(R"(
            CREATE TABLE series (
                series_id Uint64,
                title Utf8,
                series_info Utf8,
                release_date Uint64,
                PRIMARY KEY (series_id)
            );
        )");
        return session.ExecuteQuery(query, TTxControl::NoTx()).GetValueSync();
    }));
```

Adding data

Add data to the created tables using the `UPSERT` statement in YQL. A data update request is sent to the server as a single request with transaction auto-commit mode enabled.

Code snippet for data insert/update:

```
//! Shows basic usage of mutating operations.
void UpsertSimple(TQueryClient client) {
    ThrowOnError(client.RetryQuerySync([](TSession session) {
        auto query = Sprintf(R"(
            UPSERT INTO episodes (series_id, season_id, episode_id, title) VALUES
                (2, 6, 1, "TBD");
        )");

        return session.ExecuteQuery(query,
            TTxControl::BeginTx(TTxSettings::SerializableRW()).CommitTx()).GetValueSync();
    }));
}
```

`PRAGMA TablePathPrefix` adds a specified prefix to the table paths. It uses standard filesystem path concatenation, meaning it supports parent folder referencing and does not require a trailing slash. For example:

```
PRAGMA TablePathPrefix = "/cluster/database";
SELECT * FROM episodes;
```

For more information about `PRAGMA` in YQL, refer to the YQL documentation.

Retrieving data

Retrieve data using a `SELECT` statement in YQL. Handle the retrieved data selection in the app.

To execute YQL queries, use the `ExecuteQuery` method.
The SDK lets you explicitly control the execution of transactions and configure the transaction execution mode using the `TTxControl` class.

In the code snippet below, the transaction settings are defined using the `TTxControl::BeginTx` method. With `TTxSettings`, set the `SerializableRW` transaction execution mode. When all the queries in the transaction are completed, the transaction is automatically completed by explicitly setting `CommitTx()`. The `query` described using the YQL syntax is passed to the `ExecuteQuery` method for execution.

```
void SelectSimple(TQueryClient client) {
    TMaybe<TResultSet> resultSet;
    ThrowOnError(client.RetryQuerySync([&resultSet](TSession session) {
        auto query = Sprintf(R"(
            SELECT series_id, title, CAST(release_date AS Date) AS release_date
            FROM series
            WHERE series_id = 1;
        )");

        auto txControl =
            // Begin a new transaction with SerializableRW mode
            TTxControl::BeginTx(TTxSettings::SerializableRW())
            // Commit the transaction at the end of the query
            .CommitTx();

        auto result = session.ExecuteQuery(query, txControl).GetValueSync();
        if (!result.IsSuccess()) {
            return result;
        }
        resultSet = result.GetResultSet(0);
        return result;
    }));
```

Processing execution results

The `TResultSetParser` class is used for processing query execution results.

The code snippet below shows how to process query results using the `parser` object:

```
    TResultSetParser parser(*resultSet);
    while (parser.TryNextRow()) {
        Cout << "> SelectSimple:" << Endl << "Series"
            << ", Id: " << parser.ColumnParser("series_id").GetOptionalUint64()
            << ", Title: " << parser.ColumnParser("title").GetOptionalUtf8()
            << ", Release date: " << parser.ColumnParser("release_date").GetOptionalDate()->FormatLocalTime
("%Y-%m-%d")
            << Endl;
    }
}
```

The given code snippet prints the following text to the console at startup:

```
> SelectSimple:
series, Id: 1, title: IT Crowd, Release date: 2006-02-03
```

Parameterized queries

Query data using parameters. This query execution method is preferable because it allows the server to reuse the query execution plan for subsequent calls and protects against vulnerabilities such as SQL injection.

The code snippet shows the use of parameterized queries and the `TParamsBuilder` to generate parameters and pass them to the `ExecuteQuery` method:

```
void SelectWithParams(TQueryClient client) {
    TMaybe<TResultSet> resultSet;
    ThrowOnError(client.RetryQuerySync([&resultSet](TSession session) {
        ui64 seriesId = 2;
        ui64 seasonId = 3;
        auto query = Sprintf(R"(
            DECLARE $seriesId AS Uint64;
            DECLARE $seasonId AS Uint64;

            SELECT sa.title AS season_title, sr.title AS series_title
            FROM seasons AS sa
            INNER JOIN series AS sr
            ON sa.series_id = sr.series_id
            WHERE sa.series_id = $seriesId AND sa.season_id = $seasonId;
        )");

        auto params = TParamsBuilder()
            .AddParam("$seriesId")
                .Uint64(seriesId)
                .Build()
            .AddParam("$seasonId")
                .Uint64(seasonId)
                .Build()
            .Build();

        auto result = session.ExecuteQuery(
            query,
            TTxControl::BeginTx(TTxSettings::SerializableRW()).CommitTx(),
            params).GetValueSync();

        if (!result.IsSuccess()) {
            return result;
        }
        resultSet = result.GetResultSet(0);
        return result;
    }));

    TResultSetParser parser(*resultSet);
    if (parser.TryNextRow()) {
        Cout << "> SelectWithParams:" << Endl << "Season"
            << ", Title: " << parser.ColumnParser("season_title").GetOptionalUtf8()
            << ", Series title: " << parser.ColumnParser("series_title").GetOptionalUtf8()
            << Endl;
    }
}
```

The given code snippet prints the following text to the console at startup:

```
> SelectWithParams:
Season, title: Season 3, series title: Silicon Valley
```

Stream queries

Making a stream query that results in a data stream. Streaming lets you read an unlimited number of rows and amount of data.

> **Warning**
>
> Do not use the `StreamExecuteQuery` method without wrapping the call with `RetryQuery` or `RetryQuerySync`.

```
void StreamQuerySelect(TQueryClient client) {
    Cout << "> StreamQuery:" << Endl;

    ThrowOnError(client.RetryQuerySync([](TQueryClient client) -> TStatus {
        auto query = Sprintf(R"(
            DECLARE $series AS List<UInt64>;

            SELECT series_id, season_id, title, CAST(first_aired AS Date) AS first_aired
            FROM seasons
            WHERE series_id IN $series
            ORDER BY season_id;
        )");

        auto paramsBuilder = TParamsBuilder();
        auto& listParams = paramsBuilder
                                .AddParam("$series")
                                .BeginList();

        for (auto x : {1, 10}) {
            listParams.AddListItem().Uint64(x);
        }

        auto parameters = listParams
                               .EndList()
                               .Build()
                               .Build();

        // Executes stream query
        auto resultStreamQuery = client.StreamExecuteQuery(query, TTxControl::NoTx(), parameters).GetValueSyn
c();

        if (!resultStreamQuery.IsSuccess()) {
            return resultStreamQuery;
        }

        // Iterates over results
        bool eos = false;

        while (!eos) {
            auto streamPart = resultStreamQuery.ReadNext().ExtractValueSync();

            if (!streamPart.IsSuccess()) {
                eos = true;
                if (!streamPart.EOS()) {
                    return streamPart;
                }
                continue;
            }

            // It is possible for lines to be duplicated in the output stream due to an external retrier
            if (streamPart.HasResultSet()) {
                auto rs = streamPart.ExtractResultSet();
                TResultSetParser parser(rs);
                while (parser.TryNextRow()) {
                    Cout << "Season"
                            << ", SeriesId: " << parser.ColumnParser("series_id").GetOptionalUint64()
                            << ", SeasonId: " << parser.ColumnParser("season_id").GetOptionalUint64()
                            << ", Title: " << parser.ColumnParser("title").GetOptionalUtf8()
                            << ", Air date: " << parser.ColumnParser("first_aired").GetOptionalDate()->Format
LocalTime("%Y-%m-%d")
                            << Endl;
                }
            }
        }
        return TStatus(EStatus::SUCCESS, NYql::TIssues());
    }));

}
```

The given code snippet prints the following text to the console at startup (there may be duplicate lines in the output stream due to an external `RetryQuerySync`):

```
> StreamQuery:
Season, SeriesId: 1, SeasonId: 1, Title: Season 1, Air date: 2006-02-03
Season, SeriesId: 1, SeasonId: 2, Title: Season 2, Air date: 2007-08-24
Season, SeriesId: 1, SeasonId: 3, Title: Season 3, Air date: 2008-11-21
Season, SeriesId: 1, SeasonId: 4, Title: Season 4, Air date: 2010-06-25
```

Multistep transactions

Multiple statements can be executed within a single multistep transaction. Client-side code can run between query steps. Using a transaction ensures that queries executed in its context are consistent with each other.

The first step is to prepare and execute the first query:

```
//! Shows usage of transactions consisting of multiple data queries with client logic between them.
void MultiStep(TQueryClient client) {
    TMaybe<TResultSet> resultSet;
    ThrowOnError(client.RetryQuerySync([&resultSet](TSession session) {
        ui64 seriesId = 2;
        ui64 seasonId = 5;
        auto query1 = Sprintf(R"(
            DECLARE $seriesId AS Uint64;
            DECLARE $seasonId AS Uint64;

            SELECT first_aired AS from_date FROM seasons
            WHERE series_id = $seriesId AND season_id = $seasonId;
        )");

        auto params1 = TParamsBuilder()
            .AddParam("$seriesId")
                .Uint64(seriesId)
                .Build()
            .AddParam("$seasonId")
                .Uint64(seasonId)
                .Build()
            .Build();

        // Execute the first query to retrieve the required values for the client.
        // Transaction control settings do not set the CommitTx flag, allowing the transaction to remain acti
ve
        // after query execution.
        auto result = session.ExecuteQuery(
            query1,
            TTxControl::BeginTx(TTxSettings::SerializableRW()),
            params1);

        auto resultValue = result.GetValueSync();

        if (!resultValue.IsSuccess()) {
            return resultValue;
        }
```

A transaction identifier needs to be obtained to continue working within the current transaction:

```
        // Get the active transaction id
        auto txId = resultValue.GetTransaction()->GetId();

        // Processing the request result
        TResultSetParser parser(resultValue.GetResultSet(0));
        parser.TryNextRow();
        auto date = parser.ColumnParser("from_date").GetOptionalUint64();

        // Perform some client logic on returned values
        auto userFunc = [] (const TInstant fromDate) {
            return fromDate + TDuration::Days(15);
        };

        TInstant fromDate = TInstant::Days(*date);
        TInstant toDate = userFunc(fromDate);
```

The next step is to create the next query that uses the results of code execution on the client side:

```
        // Construct next query based on the results of client logic
        auto query2 = Sprintf(R"(
            DECLARE $seriesId AS Uint64;
            DECLARE $fromDate AS Uint64;
            DECLARE $toDate AS Uint64;

            SELECT season_id, episode_id, title, air_date FROM episodes
            WHERE series_id = $seriesId AND air_date >= $fromDate AND air_date <= $toDate;
        )");

        auto params2 = TParamsBuilder()
            .AddParam("$seriesId")
                .Uint64(seriesId)
                .Build()
            .AddParam("$fromDate")
                .Uint64(fromDate.Days())
                .Build()
            .AddParam("$toDate")
                .Uint64(toDate.Days())
                .Build()
            .Build();

        // Execute the second query.
        // The transaction control settings continue the active transaction (tx)
        // and commit it at the end of the second query execution.
        auto result2 = session.ExecuteQuery(
            query2,
            TTxControl::Tx(txId).CommitTx(),
            params2).GetValueSync();

        if (!result2.IsSuccess()) {
            return result2;
        }
        resultSet = result2.GetResultSet(0);
        return result2;
    })); // The end of the retried lambda

    TResultSetParser parser(*resultSet);
    Cout << "> MultiStep:" << Endl;
    while (parser.TryNextRow()) {
        auto airDate = TInstant::Days(*parser.ColumnParser("air_date").GetOptionalUint64());

        Cout << "Episode " << parser.ColumnParser("episode_id").GetOptionalUint64()
            << ", Season: " << parser.ColumnParser("season_id").GetOptionalUint64()
            << ", Title: " << parser.ColumnParser("title").GetOptionalUtf8()
            << ", Air date: " << airDate.FormatLocalTime("%a %b %d, %Y")
            << Endl;
    }
}
```

The given code snippets output the following text to the console at startup:

```
> MultiStep:
Episode 1, Season: 5, title: Grow Fast or Die Slow, Air date: Sun Mar 25, 2018
Episode 2, Season: 5, title: Reorientation, Air date: Sun Apr 01, 2018
Episode 3, Season: 5, title: Chief Operating Officer, Air date: Sun Apr 08, 2018
```

Managing transactions

Transactions are managed through TCL `Begin` and `Commit` calls.

In most cases, instead of explicitly using `Begin` and `Commit` calls, it's better to use transaction control parameters in execute calls. This allows to avoid additional requests to YDB server and thus run queries more efficiently.

Code snippet for `BeginTransaction` and `tx.Commit()` calls:

```
void ExplicitTcl(TQueryClient client) {
    // Demonstrate the use of explicit Begin and Commit transaction control calls.
    // In most cases, it's preferable to use transaction control settings within ExecuteDataQuery calls inste
ad,
    // as this avoids additional hops to the YDB cluster and allows for more efficient query execution.
    ThrowOnError(client.RetryQuerySync([](TQueryClient client) -> TStatus {
        auto airDate = TInstant::Now();
        auto session = client.GetSession().GetValueSync().GetSession();
        auto beginResult = session.BeginTransaction(TTxSettings::SerializableRW()).GetValueSync();
        if (!beginResult.IsSuccess()) {
            return beginResult;
        }

        // Get newly created transaction id
        auto tx = beginResult.GetTransaction();

        auto query = Sprintf(R"(
            DECLARE $airDate AS Date;

            UPDATE episodes SET air_date = CAST($airDate AS Uint16) WHERE title = "TBD";
        )");

        auto params = TParamsBuilder()
            .AddParam("$airDate")
                .Date(airDate)
                .Build()
            .Build();

        // Execute query.
        // Transaction control settings continues active transaction (tx)
        auto updateResult = session.ExecuteQuery(query,
            TTxControl::Tx(tx.GetId()),
            params).GetValueSync();

        if (!updateResult.IsSuccess()) {
            return updateResult;
        }
        // Commit active transaction (tx)
        return tx.Commit().GetValueSync();
    }));
}
```

Example app in C# (.NET)

This page contains a detailed description of the code of a test app that uses the YDB C# (.NET) SDK.

Initializing a database connection

To interact with YDB, create instances of the driver, client, and session:

- The YDB driver facilitates interaction between the app and YDB nodes at the transport layer. It must be initialized before creating a client or session and must persist throughout the YDB access lifecycle.
- The YDB client operates on top of the YDB driver and enables the handling of entities and transactions.
- The YDB session, which is part of the YDB client context, contains information about executed transactions and prepared queries.

App code snippet for connecting to the database:

```
using Ydb.Sdk.Ado;

await using var dataSource = new YdbDataSource("Host=localhost;Port=2136;Database=/local");
await using var connection = await dataSource.OpenConnectionAsync();
```

Creating tables

Create tables to be used in operations on a test app. This step results in the creation of database tables for the series directory data model:

- `Series`
- `Seasons`
- `Episodes`

After the tables are created, a method for retrieving information about data schema objects is called, and the result of its execution is displayed.

To create tables, use `YdbCommand` with a DDL (Data Definition Language) YQL query:

```
await using var command = new YdbCommand(connection)
{
    CommandText = @"
        CREATE TABLE series (
            series_id Uint64 NOT NULL,
            title Utf8,
            series_info Utf8,
            release_date Date,
            PRIMARY KEY (series_id)
        );

        CREATE TABLE seasons (
            series_id Uint64,
            season_id Uint64,
            title Utf8,
            first_aired Date,
            last_aired Date,
            PRIMARY KEY (series_id, season_id)
        );

        CREATE TABLE episodes (
            series_id Uint64,
            season_id Uint64,
            episode_id Uint64,
            title Utf8,
            air_date Date,
            PRIMARY KEY (series_id, season_id, episode_id)
        );"
};
await command.ExecuteNonQueryAsync();
```

Adding data

Add data to the created tables using the `UPSERT` statement in YQL. A data update request is sent to the server as a single request with transaction auto-commit mode enabled.

Parameterized queries

Query data using parameters. This query execution method is preferable because it allows the server to reuse the query execution plan for subsequent calls and protects against vulnerabilities such as SQL injection.

Code snippet for data insert/update:

```
await using var command = new YdbCommand(@"
    UPSERT INTO series (series_id, title, release_date) VALUES
        ($id, $title, $release_date);
    ", connection);
command.Parameters.Add(new YdbParameter("$id", YdbDbType.Uint64, 1UL));
command.Parameters.Add(new YdbParameter("$title", YdbDbType.Text, "NewTitle"));
command.Parameters.Add(new YdbParameter("$release_date", YdbDbType.Date, DateTime.UtcNow));
await command.ExecuteNonQueryAsync();
```

Retrieving data

Retrieve data using a `SELECT` statement in YQL. Handle the retrieved data selection in the app.

To read data with a YQL query, use the `ExecuteReaderAsync` method. Query parameters are passed through the `Parameters` collection of the `YdbCommand` object:

```
await using var command = new YdbCommand(@"
    SELECT
        series_id,
        title,
        release_date
    FROM series
    WHERE series_id = $id;
    ", connection);
command.Parameters.Add(new YdbParameter("$id", YdbDbType.Uint64, id));
await using var reader = await command.ExecuteReaderAsync();
```

Processing execution results

The query result is processed via `DbDataReader`. Example of processing the result:

```
while (await reader.ReadAsync())
{
    Console.WriteLine($"> Series, " +
        $"series_id: {reader.GetUint64(0)}, " +
        $"title: {reader.GetString(1)}, " +
        $"release_date: {reader.GetDateTime(2)}");
}
```

For sequential row reading from another query:

```
await using var command = new YdbCommand(
    "SELECT title FROM seasons ORDER BY series_id, season_id;", connection);
await using var reader = await command.ExecuteReaderAsync();
while (await reader.ReadAsync())
{
    Console.WriteLine(reader.GetString(0));
}
```

Example app in Go

This page provides a detailed description of the code for a test app that uses the YDB Go SDK.

Parameterized queries

See parameterized queries.

Downloading and starting

The instructions below assume that Git and Go are installed. Make sure to install the YDB Go SDK.

Create a working directory and use it to run the following command from the command line to clone the GitHub repository:

```
git clone https://github.com/ydb-platform/ydb-go-sdk.git
```

Next, from the same working directory, run the following command to start the test app:

Local Docker

To connect to a locally deployed YDB database according to the Docker use case, run the following command in the default configuration:

```
( export YDB_ANONYMOUS_CREDENTIALS=1 && cd ydb-go-sdk/examples && \
go run ./basic/native/query -ydb="grpc://localhost:2136/local" )
```

Any database

To run the example against any available YDB database, the endpoint and the database path need to be provide.

If authentication is enabled for the database, the authentication mode needs to be chosen and credentials (a token or a username/password pair) need to be provided.

Run the command as follows:

```
( export <auth_mode_var>="<auth_mode_value>" && cd ydb-go-sdk/examples && \
go run ./basic -ydb="<endpoint>?database=<database>" )
```

where

- `<endpoint>`: The endpoint.
- `<database>`: The database path.
- `<auth_mode_var>`: The environment variable that determines the authentication mode.
- `<auth_mode_value>` is the authentication parameter value for the selected mode.

For example:

```
( export YDB_ACCESS_TOKEN_CREDENTIALS="t1.9euelZqOnJuJlc..." && cd ydb-go-sdk/examples && \
go run ./basic -ydb="grpcs://ydb.example.com:2135/somepath/somelocation" )
```

Initializing a database connection

To interact with YDB, create instances of the driver, client, and session:

- The YDB driver facilitates interaction between the app and YDB nodes at the transport layer. It must be initialized before creating a client or session and must persist throughout the YDB access lifecycle.
- The YDB client operates on top of the YDB driver and enables the handling of entities and transactions.
- The YDB session, which is part of the YDB client context, contains information about executed transactions and prepared queries.

To work with YDB in `Go`, import the `ydb-go-sdk` driver package:

```
import (
 "context"
 "log"
 "path"

 "github.com/ydb-platform/ydb-go-sdk/v3"
 "github.com/ydb-platform/ydb-go-sdk/v3/query"
)
```

To interact with YDB, it is necessary to create a YDB driver:

```
db, err := ydb.Open(context.Background(), "grpc://localhost:2136/local")
if err != nil {
  // handle connection error
}

// You should close the driver when your application finishes its work (for example, when exiting the progra
m).
defer db.Close(context.Background())
```

The `ydb.Open` method returns a driver instance if successful. The driver performs several services, such as YDB cluster discovery and client-side load balancing.

The `ydb.Open` method takes two mandatory arguments:

- a context
- a YDB connection string

There are also many connection options available that let you override the default settings.

By default, anonymous authentication is used. To connect to the YDB cluster using a token, use the following syntax:

```
db, err := ydb.Open(context.Background(), clusterEndpoint,
 ydb.WithAccessTokenCredentials(token),
)
```

You can see the full list of auth providers in the ydb-go-sdk documentation and on the recipes page.

It is necessary to close the driver at the end of work to clean up resources.

```
defer db.Close(ctx)
```

The `db` struct is the entry point for working with YDB. To query tables, use the `db.Query()` query service:

YQL queries are executed within special objects called `query.Session`. Sessions store the execution context of queries (for example, transactions) and provide server-side load balancing among the YDB cluster nodes.

The query service client provides an API for executing queries:

- `db.Query().Do(ctx, op)` creates sessions in the background and automatically retries the provided `op func(ctx context.Context, s query.Session) error` operation if necessary. As soon as a session is ready, it is passed to the callback.
- `db.Query().DoTx(ctx, op)` automatically handles the transaction lifecycle. It provides a prepared transaction object, `query.TxActor`, to the user-defined function `op func(ctx context.Context, tx query.TxActor)` error. If the operation returns without an error (nil), the transaction commits automatically. If the operation returns an error, the transaction rolls back automatically.
- `db.Query().Exec` runs a single query that returns **no result**, with automatic retry logic on failure. This method returns nil if the execution is successful or an error otherwise.
- `db.Query().Query` executes a single query containing one or more statements that return a result. It automatically handles retries. Upon successful execution, it returns a fully materialized result (`query.Result`). All result rows are loaded into memory and available for immediate iteration. For queries returning large datasets, this may lead to an out of memory problem.
- `db.Query().QueryResultSet` executes a query that contains exactly one statement returning results (it may contain other auxiliary statements that return no results, such as `UPSERT`). Like `db.Query().Query`, it automatically retries failed operations and returns a fully materialized result set (`query.ResultSet`). Queries that return large datasets may cause an OOM error.
- `db.Query().QueryRow` runs queries expected to return exactly one row. It also automatically retries failed operations. On success, it returns a `query.Row` instance.

Creating tables

Create tables to be used in operations on a test app. This step results in the creation of database tables for the series directory data model:

- `Series`
- `Seasons`
- `Episodes`

After the tables are created, a method for retrieving information about data schema objects is called, and the result of its execution is displayed.

Example of a query with no returned result (table creation):

```
import "github.com/ydb-platform/ydb-go-sdk/v3/query"

err = db.Query().Exec(ctx, `
 CREATE TABLE IF NOT EXISTS series (
  series_id Bytes,
  title Text,
  series_info Text,
  release_date Date,
  comment Text,

  PRIMARY KEY(series_id)
 )`, query.WithTxControl(query.NoTx()),
)
if err != nil {
  // handle query execution error
}
```

Retrieving data

Retrieve data using a `SELECT` statement in YQL. Handle the retrieved data selection in the app.

To execute YQL queries and fetch results, use `query.Session` methods: `query.Session.Query`, `query.Session.QueryResultSet`, or `query.Session.QueryRow`.

The YDB SDK supports explicit transaction control via the `query.TxControl` structure:

```
readTx := query.TxControl(
 query.BeginTx(
  query.WithSnapshotReadOnly(),
 ),
 query.CommitTx(),
)
row, err := db.Query().QueryRow(ctx,`
 DECLARE $seriesID AS Uint64;
 SELECT
   series_id,
   title,
   release_date
 FROM
   series
 WHERE
   series_id = $seriesID;`,
 query.WithParameters(
  ydb.ParamsBuilder().Param("$seriesID").Uint64(1).Build(),
 ),
 query.WithTxControl(readTx),
)
if err != nil {
  // handle query execution error
}
```

You can extract row data (`query.Row`) using the following methods:

- `query.Row.ScanStruct` — scans row data into a struct based on struct field tags that match column names.
- `query.Row.ScanNamed` — scans data into variables using explicitly defined column-variable pairs.
- `query.Row.Scan` — scans data directly by column order into the provided variables.

ScanStruct

```
var info struct {
 SeriesID    string    `sql:"series_id"`
 Title       string    `sql:"title"`
 ReleaseDate time.Time `sql:"release_date"`
}
err = row.ScanStruct(&info)
if err != nil {
  // handle query execution error
}
```

ScanNamed

```
var seriesID, title string
var releaseDate time.Time
err = row.ScanNamed(query.Named("series_id", &seriesID), query.Named("title", &title), query.Named("release_d
ate", &releaseDate))
if err != nil {
  // handle query execution error
}
```

Scan

```
var seriesID, title string
var releaseDate time.Time
err = row.Scan(&seriesID, &title, &releaseDate)
if err != nil {
  // handle query execution error
}
```

Warning

If the expected query result is very large, avoid loading all data into memory using helper methods like `query.Client.Query` or `query.Client.QueryResultSet`. These methods return fully materialized results, storing all rows from the server in local client memory. Large result sets can cause an OOM problem.

Instead, use the `query.TxActor.Query` or `query.TxActor.QueryResultSet` methods on a transaction or session. These methods return iterators over results without fully materializing them upfront. The `query.Session` object is accessible via the `query.Client.Do` method, which handles automatic retries. Keep in mind that the read operation can be interrupted at any time, restarting the entire query process. Therefore, the user function passed to `Do` may run multiple times.

```
err = db.Query().Do(ctx,
 func(ctx context.Context, s query.Session) error {
  rows, err := s.QueryResultSet(ctx,`
   SELECT series_id, season_id, title, first_aired
   FROM seasons`,
  )
  if err != nil {
   return err
  }
  defer rows.Close(ctx)
  for row, err := range rows.Rows(ctx) {
   if err != nil {
    return err
   }
   var info struct {
    SeriesID    string    `sql:"series_id"`
    SeasonID    string    `sql:"season_id"`
    Title       string    `sql:"title"`
    FirstAired  time.Time `sql:"first_aired"`
   }
   err = row.ScanStruct(&info)
   if err != nil {
    return err
   }
   fmt.Printf("%+v\n", info)
  }
  return nil
 },
 query.WithIdempotent(),
)
if err != nil {
  // handle query execution error
}
```

Example app in Java

This page contains a detailed description of the code of a test app that is available as part of the YDB Java SDK Examples.

Downloading SDK Examples and running the example

The following execution scenario is based on Git and Maven.

Create a working directory and use it to run from the command line the command to clone the GitHub repository:

```
git clone https://github.com/ydb-platform/ydb-java-examples
```

Then build the SDK Examples

```
mvn package -f ./ydb-java-examples
```

Next, from the same working directory, run the following command to start the test app:

Local Docker

To connect to a locally deployed YDB database according to the Docker use case, run the following command in the default configuration:

```
YDB_ANONYMOUS_CREDENTIALS=1 java -jar ydb-java-examples/query-example/target/ydb-query-example.jar grpc://loc
alhost:2136/local
```

Any database

To run the example against any available YDB database, the endpoint and the database path need to be provide.

If authentication is enabled for the database, the authentication mode needs to be chosen and credentials (a token or a username/password pair) need to be provided.

Run the command as follows:

```
<auth_mode_var>="<auth_mode_value>" java -jar ydb-java-examples/query-example/target/ydb-query-example.jar gr
pcs://<endpoint>:<port>/<database>
```

where

- `<endpoint>`: The endpoint.
- `<database>`: The database path.
- `<auth_mode_var>`: The environment variable that determines the authentication mode.
- `<auth_mode_value>` is the authentication parameter value for the selected mode.

For example:

```
YDB_ACCESS_TOKEN_CREDENTIALS="..." java -jar ydb-java-examples/query-example/target/ydb-query-example.jar grp
cs://ydb.example.com:2135/somepath/somelocation
```

Initializing a database connection

To interact with YDB, create instances of the driver, client, and session:

- The YDB driver facilitates interaction between the app and YDB nodes at the transport layer. It must be initialized before creating a client or session and must persist throughout the YDB access lifecycle.
- The YDB client operates on top of the YDB driver and enables the handling of entities and transactions.
- The YDB session, which is part of the YDB client context, contains information about executed transactions and prepared queries.

Main driver initialization parameters

- A connection string containing details about an endpoint and database. This is the only parameter that is required.
- Authentication provider. Unless explicitly specified, an anonymous connection is used.
- Session pool settings

App code snippet for driver initialization:

```
this.transport = GrpcTransport.forConnectionString(connectionString)
        .withAuthProvider(CloudAuthHelper.getAuthProviderFromEnviron())
        .build();
this.queryClient = QueryClient.newClient(transport).build();
```

It is also [recommended] (../../../recipes/ydb-sdk/retry.md) to use the `SessionRetryContext` helper class for execution of operations with the YDB: it ensures proper retries in case the database becomes partially unavailable. Sample code to initialize the retry context:

```
this.retryCtx = SessionRetryContext.create(queryClient).build();
```

Creating tables

Create tables to be used in operations on a test app. This step results in the creation of database tables for the series directory data model:

- `Series`

- `Seasons`
- `Episodes`

After the tables are created, a method for retrieving information about data schema objects is called, and the result of its execution is displayed.

To create tables, use the `TxMode.NONE` transaction mode, which allows the execution of DDL queries:

```
private void createTables() {
    retryCtx.supplyResult(session -> session.createQuery(""
            + "CREATE TABLE series ("
            + "  series_id UInt64,"
            + "  title Text,"
            + "  series_info Text,"
            + "  release_date Date,"
            + "  PRIMARY KEY(series_id)"
            + ")", TxMode.NONE).execute()
    ).join().getStatus().expectSuccess("Can't create table series");

    retryCtx.supplyResult(session -> session.createQuery(""
            + "CREATE TABLE seasons ("
            + "  series_id UInt64,"
            + "  season_id UInt64,"
            + "  title Text,"
            + "  first_aired Date,"
            + "  last_aired Date,"
            + "  PRIMARY KEY(series_id, season_id)"
            + ")", TxMode.NONE).execute()
    ).join().getStatus().expectSuccess("Can't create table seasons");

    retryCtx.supplyResult(session -> session.createQuery(""
            + "CREATE TABLE episodes ("
            + "  series_id UInt64,"
            + "  season_id UInt64,"
            + "  episode_id UInt64,"
            + "  title Text,"
            + "  air_date Date,"
            + "  PRIMARY KEY(series_id, season_id, episode_id)"
            + ")", TxMode.NONE).execute()
    ).join().getStatus().expectSuccess("Can't create table episodes");
}
```

Adding data

Add data to the created tables using the `UPSERT` statement in YQL. A data update request is sent to the server as a single request with transaction auto-commit mode enabled.

To execute YQL queries, use the `QuerySession.createQuery()` method. It creates a new `QueryStream` object, which allows to execute a query and subscribe for receiving response data from the server. Because write requests don't expect any results, the `QueryStream.execute()` method is used without parameters; it just executes the request and waits for the stream to complete. Code snippet demonstrating this logic:

```
private void upsertSimple() {
    String query
            = "UPSERT INTO episodes (series_id, season_id, episode_id, title) "
            + "VALUES (2, 6, 1, \"TBD\");";

    // Executes data query with specified transaction control settings.
    retryCtx.supplyResult(session -> session.createQuery(query, TxMode.SERIALIZABLE_RW).execute())
        .join().getValue();
```

Retrieving data

Retrieve data using a `SELECT` statement in YQL. Handle the retrieved data selection in the app.

Direct usage of the `QueryStream` class to obtain results may not always be convenient, as it involves receiving data from the server asynchronously in the callback of the `QueryStream.execute()` method. If the number of expected rows in a result is not too large, it is more practical to use the `QueryReader` helper from the SDK, which first reads all response parts from the stream and provides them all to the user in an ordered form.

```
private void selectSimple() {
    String query
            = "SELECT series_id, title, release_date "
            + "FROM series WHERE series_id = 1;";

    // Executes data query with specified transaction control settings.
    QueryReader result = retryCtx.supplyResult(
            session -> QueryReader.readFrom(session.createQuery(query, TxMode.SERIALIZABLE_RW))
    ).join().getValue();

    logger.info("--[ SelectSimple ]--");

    ResultSetReader rs = result.getResultSet(0);
    while (rs.next()) {
        logger.info("read series with id {}, title {} and release_date {}",
                rs.getColumn("series_id").getUint64(),
                rs.getColumn("title").getText(),
                rs.getColumn("release_date").getDate()
        );
    }
}
```

As a result of the query, an object of the `QueryReader` class is generated. It may contain several sets obtained using the `getResultSet( <index> )` method. Since there was only one `SELECT` statement in the query, the result contains only one selection indexed as `0`. The given code snippet prints the following text to the console at startup:

```
12:06:36.548 INFO  App - --[ SelectSimple ]--
12:06:36.559 INFO  App - read series with id 1, title IT Crowd and release_date 2006-02-03
```

Parameterized queries

Query data using parameters. This query execution method is preferable because it allows the server to reuse the query execution plan for subsequent calls and protects against vulnerabilities such as SQL injection.

The code snippet below demonstrates how to use parameterized queries and the `Params` class to construct parameters and pass them to the `QuerySession.createQuery` method.

```
private void selectWithParams(long seriesID, long seasonID) {
    String query
            = "DECLARE $seriesId AS Uint64; "
            + "DECLARE $seasonId AS Uint64; "
            + "SELECT sa.title AS season_title, sr.title AS series_title "
            + "FROM seasons AS sa INNER JOIN series AS sr ON sa.series_id = sr.series_id "
            + "WHERE sa.series_id = $seriesId AND sa.season_id = $seasonId";

    // Begin new transaction with SerializableRW mode
    TxControl txControl = TxControl.serializableRw().setCommitTx(true);

    // Type of parameter values should be exactly the same as in DECLARE statements.
    Params params = Params.of(
            "$seriesId", PrimitiveValue.newUint64(seriesID),
            "$seasonId", PrimitiveValue.newUint64(seasonID)
    );

    DataQueryResult result = retryCtx.supplyResult(session -> session.executeDataQuery(query, txControl, para
ms))
            .join().getValue();

    logger.info("--[ SelectWithParams ] -- ");

    ResultSetReader rs = result.getResultSet(0);
    while (rs.next()) {
        logger.info("read season with title {} for series {}",
                rs.getColumn("season_title").getText(),
                rs.getColumn("series_title").getText()
        );
    }
}
```

Streaming data reads

If the expected row count in the response is large, asynchronous reading is the preferred way to process them. In this case, the `SessionRetryContext` is still used for retries because processing response parts can be interrupted at any moment, requiring the entire execution process to restart.

```
private void asyncSelectRead(long seriesID, long seasonID) {
    String query
            = "DECLARE $seriesId AS Uint64; "
            + "DECLARE $seasonId AS Uint64; "
            + "SELECT ep.title AS episode_title, sa.title AS season_title, sr.title AS series_title "
            + "FROM episodes AS ep "
            + "JOIN seasons AS sa ON sa.season_id = ep.season_id "
            + "JOIN series AS sr ON sr.series_id = sa.series_id "
            + "WHERE sa.series_id = $seriesId AND sa.season_id = $seasonId;";

    // Type of parameter values should be exactly the same as in DECLARE statements.
    Params params = Params.of(
            "$seriesId", PrimitiveValue.newUint64(seriesID),
            "$seasonId", PrimitiveValue.newUint64(seasonID)
    );

    logger.info("--[ ExecuteAsyncQueryWithParams ]--");
    retryCtx.supplyResult(session -> {
        QueryStream asyncQuery = session.createQuery(query, TxMode.SNAPSHOT_RO, params);
        return asyncQuery.execute(part -> {
            ResultSetReader rs = part.getResultSetReader();
            logger.info("read {} rows of result set {}", rs.getRowCount(), part.getResultSetIndex());
            while (rs.next()) {
                logger.info("read episode {} of {} for {}",
                        rs.getColumn("episode_title").getText(),
                        rs.getColumn("season_title").getText(),
                        rs.getColumn("series_title").getText()
                );
            }
        });
    }).join().getStatus().expectSuccess("execute query problem");
}
```

Multistep transactions

Multiple statements can be executed within a single multistep transaction. Client-side code can run between query steps. Using a transaction ensures that queries executed in its context are consistent with each other.

To ensure interoperability between the transactions and the retry context, each transaction must wholly execute inside the callback passed to `SessionRetryContext`. The callback must return after the entire transaction is completed.

Code template for running complex transactions inside `SessionRetryContext`

```
private void multiStepTransaction(long seriesID, long seasonID) {
    retryCtx.supplyStatus(session -> {
        QueryTransaction transaction = session.createNewTransaction(TxMode.SNAPSHOT_RO);

        //...

        return CompletableFuture.completedFuture(Status.SUCCESS);
    }).join().expectSuccess("multistep transaction problem");
}
```

The first step is to prepare and execute the first query:

```
    String query1
            = "DECLARE $seriesId AS Uint64; "
            + "DECLARE $seasonId AS Uint64; "
            + "SELECT MIN(first_aired) AS from_date FROM seasons "
            + "WHERE series_id = $seriesId AND season_id = $seasonId;";

    // Execute the first query to start a new transaction
    QueryReader res1 = QueryReader.readFrom(transaction.createQuery(query1, Params.of(
            "$seriesId", PrimitiveValue.newUint64(seriesID),
            "$seasonId", PrimitiveValue.newUint64(seasonID)
    ))).join().getValue();
```

After that, we can process the resulting data on the client side:

```
    // Perform some client logic on returned values
    ResultSetReader resultSet = res1.getResultSet(0);
    if (!resultSet.next()) {
        throw new RuntimeException("not found first_aired");
    }
    LocalDate fromDate = resultSet.getColumn("from_date").getDate();
    LocalDate toDate = fromDate.plusDays(15);
```

And get the current `transaction id` to continue processing within the same transaction:

```
    // Get active transaction id
    logger.info("started new transaction {}", transaction.getId());
```

The next step is to create the next query that uses the results of code execution on the client side:

```
    // Construct next query based on the results of client logic
    String query2
            = "DECLARE $seriesId AS Uint64;"
            + "DECLARE $fromDate AS Date;"
            + "DECLARE $toDate AS Date;"
            + "SELECT season_id, episode_id, title, air_date FROM episodes "
            + "WHERE series_id = $seriesId AND air_date >= $fromDate AND air_date <= $toDate;";

    // Execute the second query and commit
    QueryReader res2 = QueryReader.readFrom(transaction.createQueryWithCommit(query2, Params.of(
        "$seriesId", PrimitiveValue.newUint64(seriesID),
        "$fromDate", PrimitiveValue.newDate(fromDate),
        "$toDate", PrimitiveValue.newDate(toDate)
    ))).join().getValue();

    logger.info("--[ MultiStep ]--");
    ResultSetReader rs = res2.getResultSet(0);
    while (rs.next()) {
        logger.info("read episode {} with air date {}",
                rs.getColumn("title").getText(),
                rs.getColumn("air_date").getDate()
        );
    }
```

The given code snippets output the following text to the console at startup:

```
12:06:36.850 INFO  App - --[ MultiStep ]--
12:06:36.851 INFO  App - read episode Grow Fast or Die Slow with air date 2018-03-25
12:06:36.851 INFO  App - read episode Reorientation with air date 2018-04-01
12:06:36.851 INFO  App - read episode Chief Operating Officer with air date 2018-04-08
```

Managing transactions

Transactions are managed through TCL `Begin` and `Commit` calls.

In most cases, instead of explicitly using `Begin` and `Commit` calls, it's better to use transaction control parameters in execute calls. This allows to avoid additional requests to YDB server and thus run queries more efficiently.

Code snippet for `beginTransaction()` and `transaction.commit()` calls:

```
private void tclTransaction() {
    retryCtx.supplyResult(session -> {
        QueryTransaction transaction = session.beginTransaction(TxMode.SERIALIZABLE_RW)
            .join().getValue();

        String query
                = "DECLARE $airDate AS Date; "
                + "UPDATE episodes SET air_date = $airDate WHERE title = \"TBD\";";

        Params params = Params.of("$airDate", PrimitiveValue.newDate(Instant.now()));

        // Execute data query.
        // Transaction control settings continues active transaction (tx)
        QueryReader reader = QueryReader.readFrom(transaction.createQuery(query, params))
            .join().getValue();

        logger.info("get transaction {}", transaction.getId());

        // Commit active transaction (tx)
        return transaction.commit();
    }).join().getStatus().expectSuccess("tcl transaction problem");
}
```

Example app in JavaScript

This page provides a detailed description of the example application code that uses the YDB JavaScript SDK.

Usage examples are available in the ydb-js-sdk repository, and additional real-world scenario examples can be found in the ydb-js-examples repository.

Initializing a database connection

To interact with YDB, create instances of the driver, client, and session:

- The YDB driver facilitates interaction between the app and YDB nodes at the transport layer. It must be initialized before creating a client or session and must persist throughout the YDB access lifecycle.
- The YDB client operates on top of the YDB driver and enables the handling of entities and transactions.
- The YDB session, which is part of the YDB client context, contains information about executed transactions and prepared queries.

To work with YDB, you need to create a driver instance and a query client.

Installing the required packages:

```
npm install @ydbjs/core @ydbjs/query
```

App code snippet for driver initialization:

Using connectionString

```
import { Driver } from '@ydbjs/core'
import { query } from '@ydbjs/query'

const connectionString = 'grpc://localhost:2136/local'
const driver = new Driver(connectionString)
await driver.ready()

const sql = query(driver)
```

Using authentication

```
import { Driver } from '@ydbjs/core'
import { query } from '@ydbjs/query'
import { AnonymousCredentialsProvider } from '@ydbjs/auth'

const connectionString = 'grpc://localhost:2136/local'
const driver = new Driver(connectionString, {
  credentialsProvider: new AnonymousCredentialsProvider(),
})
await driver.ready()

const sql = query(driver)
```

Creating tables

Create tables to be used in operations on a test app. This step results in the creation of database tables for the series directory data model:

- `Series`
- `Seasons`
- `Episodes`

After the tables are created, a method for retrieving information about data schema objects is called, and the result of its execution is displayed.

```
await sql`
    CREATE TABLE series (
        series_id Uint64,
        title Text,
        series_info Text,
        release_date Date,
        PRIMARY KEY (series_id)
    )
`

await sql`
    CREATE TABLE seasons (
        series_id Uint64,
        season_id Uint64,
        title Text,
        first_aired Date,
        last_aired Date,
        PRIMARY KEY (series_id, season_id)
    )
`

await sql`
    CREATE TABLE episodes (
        series_id Uint64,
        season_id Uint64,
        episode_id Uint64,
        title Text,
        air_date Date,
        PRIMARY KEY (series_id, season_id, episode_id)
    )
`
```

Adding data

Add data to the created tables using the `UPSERT` statement in YQL. A data update request is sent to the server as a single request with transaction auto-commit mode enabled.

Code snippet for data insert/update:

```
await sql`
    UPSERT INTO episodes (series_id, season_id, episode_id, title)
    VALUES (2, 6, 1, "TBD")
`
```

For inserting data using parameters:

```
import { Uint64, Text, Date as YdbDate } from '@ydbjs/value/primitive'

const data = [
  {
    series_id: new Uint64(1n),
    title: new Text('IT Crowd'),
    series_info: new Text('British sitcom'),
    release_date: new YdbDate(new Date('2006-02-03')),
  },
]

await sql`INSERT INTO series SELECT * FROM AS_TABLE(${data})`
```

Retrieving data

Retrieve data using a `SELECT` statement in YQL. Handle the retrieved data selection in the app.

The tagged template syntax is used for executing YQL queries. The result is an array of result sets (YDB supports multiple result sets per query).

```
const resultSets = await sql`
    SELECT series_id, title, release_date
    FROM series
    WHERE series_id = 1
`

// resultSets[0] contains the first result set
const [firstResultSet] = resultSets
console.log(firstResultSet)
// [ { series_id: 1n, title: 'IT Crowd', release_date: 2006-02-03T00:00:00.000Z } ]
```

For queries with multiple result sets:

```
type Result = [[{ id: bigint }], [{ count: bigint }]]
const [rows, [{ count }]] = await sql<Result>`
    SELECT series_id as id FROM series;
    SELECT COUNT(*) as count FROM series;
`
```

Parameterized queries

Query data using parameters. This query execution method is preferable because it allows the server to reuse the query execution plan for subsequent calls and protects against vulnerabilities such as SQL injection.

The SDK automatically binds parameters through interpolation in template strings. Native JavaScript types, YDB value classes, arrays, and objects are all supported.

```
const seriesId = 1n
const title = 'IT Crowd'

const resultSets = await sql`
    SELECT series_id, title, release_date
    FROM series
    WHERE series_id = ${seriesId} AND title = ${title}
`
```

For named parameters and custom types:

```
import { Uint64 } from '@ydbjs/value/primitive'

const id = new Uint64(1n)
const resultSets = await sql`SELECT * FROM series WHERE series_id = $id`.parameter('id', id)
```

Queries are executed with streaming data transfer by default. For working with large volumes of data, use standard queries:

```
const resultSets = await sql`
    SELECT series_id, season_id, title, first_aired
    FROM seasons
    WHERE series_id IN (1, 2)
    ORDER BY season_id
`

for (const row of resultSets[0]) {
  console.log(`Season ${row.season_id}: ${row.title}`)
}
```

Managing transactions

Transactions are managed through TCL `Begin` and `Commit` calls.

In most cases, instead of explicitly using `Begin` and `Commit` calls, it's better to use transaction control parameters in execute calls. This allows to avoid additional requests to YDB server and thus run queries more efficiently.

To execute queries within a transaction, use the `sql.begin()` or `sql.transaction()` methods:

begin() — serializable read-write

```
const result = await sql.begin(async (tx) => {
  await tx`
      UPDATE episodes
      SET air_date = CurrentUtcDate()
      WHERE series_id = 2 AND season_id = 6 AND episode_id = 1
  `
  return await tx`SELECT * FROM episodes WHERE series_id = 2`
})
```

begin() with isolation settings

```
await sql.begin({ isolation: 'snapshotReadOnly', idempotent: true }, async (tx) => {
  return await tx`SELECT COUNT(*) FROM series`
})
```

Error handling

For more information about error handling, see Error handling in the API.

The `YDBError` class is used for error handling:

```
import { YDBError } from '@ydbjs/error'

try {
  await sql`SELECT * FROM non_existent_table`
} catch (error) {
  if (error instanceof YDBError) {
    console.error('YDB Error:', error.message)
  }
}
```

Additional features

Query options

```
import { StatsMode } from '@ydbjs/api/query'

await sql`SELECT * FROM series`
  .isolation('onlineReadOnly', { allowInconsistentReads: true })
  .idempotent(true)
  .timeout(5000)
  .withStats(StatsMode.FULL)
```

Dynamic identifiers

For dynamic table and column names, use the `identifier` method:

```
const tableName = 'series'
await sql`SELECT * FROM ${sql.identifier(tableName)}`
```

Closing the driver

Always close the driver when finished:

```
driver.close()
```

Example app in PHP

This page contains a detailed description of the code of a test app that is available as part of the YDB PHP SDK.

Initializing a database connection

To interact with YDB, create instances of the driver, client, and session:

- The YDB driver facilitates interaction between the app and YDB nodes at the transport layer. It must be initialized before creating a client or session and must persist throughout the YDB access lifecycle.
- The YDB client operates on top of the YDB driver and enables the handling of entities and transactions.
- The YDB session, which is part of the YDB client context, contains information about executed transactions and prepared queries.

App code snippet for driver initialization:

```
<?php

use YdbPlatform\Ydb\Ydb;

$config = [
    // Database path
    'database'    => '/ru-central1/b1glxxxxxxxxxxxxxxx/etn0xxxxxxxxxxxxxxx',

    // Database endpoint
    'endpoint'    => 'ydb.serverless.yandexcloud.net:2135',

    // Auto discovery (dedicated server only)
    'discovery'   => false,

    // IAM config
    'iam_config'  => [
        // 'root_cert_file' => './CA.pem',  Root CA file (uncomment for dedicated server only)
    ],

    'credentials' => new AccessTokenAuthentication('AAAAAAAAAAAAAAAAAAAAAAAAAAAAAAAAAAAAAAAA') // use from ref
erence/ydb-sdk/auth
];

$ydb = new Ydb($config);
```

Creating tables

Create tables to be used in operations on a test app. This step results in the creation of database tables for the series directory data model:

- `Series`
- `Seasons`
- `Episodes`

After the tables are created, a method for retrieving information about data schema objects is called, and the result of its execution is displayed.

To create tables, use the `session->createTable()` method:

```
protected function createTabels()
{
    $this->ydb->table()->retrySession(function (Session $session) {

        $session->createTable(
            'series',
            YdbTable::make()
                ->addColumn('series_id', 'UINT64')
                ->addColumn('title', 'UTF8')
                ->addColumn('series_info', 'UTF8')
                ->addColumn('release_date', 'UINT64')
                ->primaryKey('series_id')
        );

    }, true);

    $this->print('Table `series` has been created.');

    $this->ydb->table()->retrySession(function (Session $session) {

        $session->createTable(
            'seasons',
            YdbTable::make()
                ->addColumn('series_id', 'UINT64')
                ->addColumn('season_id', 'UINT64')
                ->addColumn('title', 'UTF8')
                ->addColumn('first_aired', 'UINT64')
                ->addColumn('last_aired', 'UINT64')
                ->primaryKey(['series_id', 'season_id'])
        );

    }, true);

    $this->print('Table `seasons` has been created.');

    $this->ydb->table()->retrySession(function (Session $session) {

        $session->createTable(
            'episodes',
            YdbTable::make()
                ->addColumn('series_id', 'UINT64')
                ->addColumn('season_id', 'UINT64')
                ->addColumn('episode_id', 'UINT64')
                ->addColumn('title', 'UTF8')
                ->addColumn('air_date', 'UINT64')
                ->primaryKey(['series_id', 'season_id', 'episode_id'])
        );

    }, true);

    $this->print('Table `episodes` has been created.');
}
```

You can use the `session->describeTable()` method to output information about the table structure and make sure that it was properly created:

```
protected function describeTable($table)
{
    $data = $ydb->table()->retrySession(function (Session $session) use ($table) {

        return $session->describeTable($table);

    }, true);

    $columns = [];

    foreach ($data['columns'] as $column) {
        if (isset($column['type']['optionalType']['item']['typeId'])) {
            $columns[] = [
                'Name' => $column['name'],
                'Type' => $column['type']['optionalType']['item']['typeId'],
            ];
        }
    }

    print('Table `' . $table . '`');
    print_r($columns);
    print('');
    print('Primary key: ' . implode(', ', (array)$data['primaryKey']));
}
```

Adding data

Add data to the created tables using the `UPSERT` statement in YQL. A data update request is sent to the server as a single request with transaction auto-commit mode enabled.

Code snippet for data insert/update:

```
protected function upsertSimple()
{
    $ydb->table()->retryTransaction(function (Session $session) {
        $session->query('
        DECLARE $series_id AS Uint64;
        DECLARE $season_id AS Uint64;
        DECLARE $episode_id AS Uint64;
        DECLARE $title AS Utf8;
            UPSERT INTO episodes (series_id, season_id, episode_id, title)
            VALUES ($series_id, $season_id, $episode_id, $title);', [
                '$series_id' => (new Uint64Type(2))->toTypedValue(),
                '$season_id' => (new Uint64Type(6))->toTypedValue(),
                '$episode_id' => (new Uint64Type(1))->toTypedValue(),
                '$title' => (new Utf8Type('TBD'))->toTypedValue(),
            ]);
    }, true);

    print('Finished.');
}
```

Retrieving data

Retrieve data using a `SELECT` statement in YQL. Handle the retrieved data selection in the app.

To execute YQL queries, use the `session->query()` method.

```
$result = $ydb->table()->retryTransaction(function (Session $session) {
        return $session->query('
        DECLARE $seriesID AS Uint64;
        $format = DateTime::Format("%Y-%m-%d");
        SELECT
            series_id,
            title,
            $format(DateTime::FromSeconds(CAST(release_date AS Uint32))) AS release_date
        FROM series
        WHERE series_id = $seriesID;', [
            '$seriesID' => (new Uint64Type(1))->toTypedValue()
        ]);
}, true, $params);

print_r($result->rows());
```

Parameterized queries

Query data using parameters. This query execution method is preferable because it allows the server to reuse the query execution plan for subsequent calls and protects against vulnerabilities such as SQL injection.

Here's a code sample that shows how to use prepared queries.

```
protected function selectPrepared($series_id, $season_id, $episode_id)
{
    $result = $ydb->table()->retryTransaction(function (Session $session) use ($series_id, $season_id, $episo
de_id) {

        $prepared_query = $session->prepare('
        DECLARE $series_id AS Uint64;
        DECLARE $season_id AS Uint64;
        DECLARE $episode_id AS Uint64;

        $format = DateTime::Format("%Y-%m-%d");
        SELECT
            title AS `Episode title`,
            $format(DateTime::FromSeconds(CAST(air_date AS Uint32))) AS `Air date`
        FROM episodes
        WHERE series_id = $series_id AND season_id = $season_id AND episode_id = $episode_id;');

        return $prepared_query->execute(compact(
            'series_id',
            'season_id',
            'episode_id'
        ));
    },true);

    $this->print($result->rows());
}
```

Example app in Python

This page contains a detailed description of the code of a test app that is available as part of the YDB Python SDK.

Downloading and starting

The following execution scenario is based on git and Python3. Be sure to install the YDB Python SDK.

Create a working directory and use it to run from the command line the command to clone the GitHub repository and install the necessary Python packages:

```
git clone https://github.com/ydb-platform/ydb-python-sdk.git
python3 -m pip install iso8601
```

Next, from the same working directory, run the following command to start the test app:

Local Docker

To connect to a locally deployed YDB database according to the Docker use case, run the following command in the default configuration:

```
YDB_ANONYMOUS_CREDENTIALS=1 \
python3 ydb-python-sdk/examples/basic_example_v1/ -e grpc://localhost:2136 -d /local
```

Any database

To run the example against any available YDB database, the endpoint and the database path need to be provide.

If authentication is enabled for the database, the authentication mode needs to be chosen and credentials (a token or a username/password pair) need to be provided.

Run the command as follows:

```
<auth_mode_var>="<auth_mode_value>" \
python3 ydb-python-sdk/examples/basic_example_v1/ -e <endpoint> -d <database>
```

where

- `<endpoint>`: The endpoint.
- `<database>`: The database path.
- `<auth_mode_var>`: The environment variable that determines the authentication mode.
- `<auth_mode_value>` is the authentication parameter value for the selected mode.

For example:

```
YDB_ACCESS_TOKEN_CREDENTIALS="t1.9euelZqOnJuJlc..." \
python3 ydb-python-sdk/examples/basic_example_v1/ -e grpcs://ydb.example.com:2135 -d /path/db )
```

Initializing a database connection

To interact with YDB, create instances of the driver, client, and session:

- The YDB driver facilitates interaction between the app and YDB nodes at the transport layer. It must be initialized before creating a client or session and must persist throughout the YDB access lifecycle.
- The YDB client operates on top of the YDB driver and enables the handling of entities and transactions.
- The YDB session, which is part of the YDB client context, contains information about executed transactions and prepared queries.

App code snippet for driver initialization:

Synchronous

```
def run(endpoint, database):
    driver_config = ydb.DriverConfig(
        endpoint, database, credentials=ydb.credentials_from_env_variables(),
        root_certificates=ydb.load_ydb_root_certificate(),
    )
    with ydb.Driver(driver_config) as driver:
        try:
            driver.wait(timeout=5)
        except TimeoutError:
            print("Connect failed to YDB")
            print("Last reported errors by discovery:")
            print(driver.discovery_debug_details())
            exit(1)
```

Asynchronous

```
async def run(endpoint, database):
    driver_config = ydb.DriverConfig(
        endpoint, database, credentials=ydb.credentials_from_env_variables(),
        root_certificates=ydb.load_ydb_root_certificate(),
    )
    async with ydb.aio.Driver(driver_config) as driver:
        try:
            await driver.wait(timeout=5)
        except TimeoutError:
            print("Connect failed to YDB")
            print("Last reported errors by discovery:")
            print(driver.discovery_debug_details())
            exit(1)
```

App code snippet for session pool initialization:

Synchronous

```
with ydb.QuerySessionPool(driver) as pool:
    pass  # operations with pool here
```

Asynchronous

```
async with ydb.aio.QuerySessionPool(driver) as pool:
    pass  # operations with pool here
```

Executing queries

YDB Python SDK supports queries described by YQL syntax.
There are two primary methods for executing queries, each with different properties and use cases:

- `pool.execute_with_retries`:
  - Buffers the entire result set in client memory.
  - Automatically retries execution in case of retriable issues.
  - Does not allow specifying a transaction execution mode.
  - Recommended for one-off queries that are expected to produce small result sets.
- `tx.execute`:
  - Returns an iterator over the query results, allowing processing of results that may not fit into client memory.
  - Retries must be handled manually via `pool.retry_operation_sync`.
  - Allows specifying a transaction execution mode.
  - Recommended for scenarios where `pool.execute_with_retries` is insufficient.

Creating tables

Create tables to be used in operations on a test app. This step results in the creation of database tables for the series directory data model:

- `Series`
- `Seasons`
- `Episodes`

After the tables are created, a method for retrieving information about data schema objects is called, and the result of its execution is displayed.

To execute `CREATE TABLE` queries, use the `pool.execute_with_retries()` method:

Synchronous

```
def create_tables(pool: ydb.QuerySessionPool):
    print("\nCreating table series...")
    pool.execute_with_retries(
        """
        CREATE TABLE `series` (
            `series_id` Int64,
            `title` Utf8,
            `series_info` Utf8,
            `release_date` Date,
            PRIMARY KEY (`series_id`)
        )
        """
    )

    print("\nCreating table seasons...")
    pool.execute_with_retries(
        """
        CREATE TABLE `seasons` (
            `series_id` Int64,
            `season_id` Int64,
            `title` Utf8,
            `first_aired` Date,
            `last_aired` Date,
            PRIMARY KEY (`series_id`, `season_id`)
        )
        """
    )

    print("\nCreating table episodes...")
    pool.execute_with_retries(
        """
        CREATE TABLE `episodes` (
            `series_id` Int64,
            `season_id` Int64,
            `episode_id` Int64,
            `title` Utf8,
            `air_date` Date,
            PRIMARY KEY (`series_id`, `season_id`, `episode_id`)
        )
        """
    )
```

Asynchronous

```
async def create_tables(pool: ydb.aio.QuerySessionPool):
    print("\nCreating table series...")
    await pool.execute_with_retries(
        """
        CREATE TABLE `series` (
            `series_id` Int64,
            `title` Utf8,
            `series_info` Utf8,
            `release_date` Date,
            PRIMARY KEY (`series_id`)
        )
        """
    )

    print("\nCreating table seasons...")
    await pool.execute_with_retries(
        """
        CREATE TABLE `seasons` (
            `series_id` Int64,
            `season_id` Int64,
            `title` Utf8,
            `first_aired` Date,
            `last_aired` Date,
            PRIMARY KEY (`series_id`, `season_id`)
        )
        """
    )

    print("\nCreating table episodes...")
    await pool.execute_with_retries(
        """
        CREATE TABLE `episodes` (
            `series_id` Int64,
            `season_id` Int64,
            `episode_id` Int64,
            `title` Utf8,
            `air_date` Date,
            PRIMARY KEY (`series_id`, `season_id`, `episode_id`)
        )
        """
    )
```

Adding data

Add data to the created tables using the `UPSERT` statement in YQL. A data update request is sent to the server as a single request with transaction auto-commit mode enabled.

Code snippet for data insert/update:

Synchronous

```
def upsert_simple(pool: ydb.QuerySessionPool):
    print("\nPerforming UPSERT into episodes...")
    pool.execute_with_retries(
        """
        UPSERT INTO episodes (series_id, season_id, episode_id, title) VALUES (2, 6, 1, "TBD");
        """
    )
```

Asynchronous

```
async def upsert_simple(pool: ydb.aio.QuerySessionPool):
    print("\nPerforming UPSERT into episodes...")
    await pool.execute_with_retries(
        """
        UPSERT INTO episodes (series_id, season_id, episode_id, title) VALUES (2, 6, 1, "TBD");
        """
    )
```

Retrieving data

Retrieve data using a `SELECT` statement in YQL. Handle the retrieved data selection in the app.

To execute YQL queries, the `pool.execute_with_retries()` method is often sufficient.

Synchronous

```
def select_simple(pool: ydb.QuerySessionPool):
    print("\nCheck series table...")
    result_sets = pool.execute_with_retries(
        """
        SELECT
            series_id,
            title,
            release_date
        FROM series
        WHERE series_id = 1;
        """,
    )
    first_set = result_sets[0]
    for row in first_set.rows:
        print(
            "series, id: ",
            row.series_id,
            ", title: ",
            row.title,
            ", release date: ",
            row.release_date,
        )
    return first_set
```

Asynchronous

```
async def select_simple(pool: ydb.aio.QuerySessionPool):
    print("\nCheck series table...")
    result_sets = await pool.execute_with_retries(
        """
        SELECT
            series_id,
            title,
            release_date
        FROM series
        WHERE series_id = 1;
        """,
    )
    first_set = result_sets[0]
    for row in first_set.rows:
        print(
            "series, id: ",
            row.series_id,
            ", title: ",
            row.title,
            ", release date: ",
            row.release_date,
        )
    return first_set
```

As the result of executing the query, a list of `result_set` is returned, iterating on which the text is output to the console:

```
> SelectSimple:
series, Id: 1, title: IT Crowd, Release date: 2006-02-03
```

Parameterized queries

For parameterized query execution, `pool.execute_with_retries()` and `tx.execute()` behave similarly. To execute parameterized queries, you need to pass a dictionary with parameters to one of these functions, where each key is the parameter name, and the value can be one of the following:

1. A value of a basic Python type
2. A tuple containing the value and its type
3. A special type, `ydb.TypedValue(value=value, value_type=value_type)`

If you specify a value without an explicit type, the conversion takes place according to the following rules:

Python type	YDB type
`int`	`ydb.PrimitiveType.Int64`
`float`	`ydb.PrimitiveType.Double`
`str`	`ydb.PrimitiveType.Utf8`
`bytes`	`ydb.PrimitiveType.String`
`bool`	`ydb.PrimitiveType.Bool`
`list`	`ydb.ListType`
`dict`	`ydb.DictType`

Warning

Automatic conversion of lists and dictionaries is possible only if the structures are homogeneous. The type of nested values will be determined recursively according to the rules explained above. In case of using heterogeneous structures, requests will raise `TypeError`.

A code snippet demonstrating the parameterized query execution:

Synchronous

```
def select_with_parameters(pool: ydb.QuerySessionPool, series_id, season_id, episode_id):
    result_sets = pool.execute_with_retries(
        """
        DECLARE $seriesId AS Int64;
        DECLARE $seasonId AS Int64;
        DECLARE $episodeId AS Int64;

        SELECT
            title,
            air_date
        FROM episodes
        WHERE series_id = $seriesId AND season_id = $seasonId AND episode_id = $episodeId;
        """,
        {
            "$seriesId": series_id,  # data type could be defined implicitly
            "$seasonId": (season_id, ydb.PrimitiveType.Int64),  # could be defined via a tuple
            "$episodeId": ydb.TypedValue(episode_id, ydb.PrimitiveType.Int64),  # could be defined via a spec
ial class
        },
    )

    print("\n> select_with_parameters:")
    first_set = result_sets[0]
    for row in first_set.rows:
        print("episode title:", row.title, ", air date:", row.air_date)

    return first_set
```

Asynchronous

```
async def select_with_parameters(pool: ydb.aio.QuerySessionPool, series_id, season_id, episode_id):
    result_sets = await pool.execute_with_retries(
        """
        DECLARE $seriesId AS Int64;
        DECLARE $seasonId AS Int64;
        DECLARE $episodeId AS Int64;

        SELECT
            title,
            air_date
        FROM episodes
        WHERE series_id = $seriesId AND season_id = $seasonId AND episode_id = $episodeId;
        """,
        {
            "$seriesId": series_id,  # could be defined implicitly
            "$seasonId": (season_id, ydb.PrimitiveType.Int64),  # could be defined via a tuple
            "$episodeId": ydb.TypedValue(episode_id, ydb.PrimitiveType.Int64),  # could be defined via a spec
ial class
        },
    )

    print("\n> select_with_parameters:")
    first_set = result_sets[0]
    for row in first_set.rows:
        print("episode title:", row.title, ", air date:", row.air_date)

    return first_set
```

The code snippet above outputs the following text to the console:

```
> select_prepared_transaction:
('episode title:', u'To Build a Better Beta', ', air date:', '2016-06-05')
```

Managing transactions

Transactions are managed through TCL `Begin` and `Commit` calls.

In most cases, instead of explicitly using `Begin` and `Commit` calls, it's better to use transaction control parameters in execute calls. This allows to avoid additional requests to YDB server and thus run queries more efficiently.

The `session.transaction().execute()` method can also be used to execute YQL queries. Unlike `pool.execute_with_retries`, this method allows explicit control of transaction execution by configuring the desired transaction mode using the `TxControl` class.

Available transaction modes:

- `ydb.QuerySerializableReadWrite()` (default);
- `ydb.QueryOnlineReadOnly(allow_inconsistent_reads=False)`;
- `ydb.QuerySnapshotReadOnly()`;
- `ydb.QueryStaleReadOnly()`.

For more information about transaction modes, see Transaction modes.

The result of executing `tx.execute()` is an iterator. This iterator allows you to read result rows without loading the entire result set into memory. However, the iterator must be read to the end after each request to correctly maintain the transaction state on the YDB server side. If this is not done, write queries could not be applied on the YDB server side. For convenience, the result of the `tx.execute()` function can be used as a context manager that automatically iterates to the end upon exit.

Synchronous

```
with tx.execute(query) as _:
    pass
```

Asynchronous

```
async with await tx.execute(query) as _:
    pass
```

The code snippet below demonstrates the explicit use of `transaction().begin()` and `tx.commit()`:

Synchronous

```
def explicit_transaction_control(pool: ydb.QuerySessionPool, series_id, season_id, episode_id):
    def callee(session: ydb.QuerySession):
        query = """
        DECLARE $seriesId AS Int64;
        DECLARE $seasonId AS Int64;
        DECLARE $episodeId AS Int64;

        UPDATE episodes
        SET air_date = CurrentUtcDate()
        WHERE series_id = $seriesId AND season_id = $seasonId AND episode_id = $episodeId;
        """

        # Get newly created transaction id
        tx = session.transaction().begin()

        # Execute data query.
        # Transaction control settings continues active transaction (tx)
        with tx.execute(
            query,
            {
                "$seriesId": (series_id, ydb.PrimitiveType.Int64),
                "$seasonId": (season_id, ydb.PrimitiveType.Int64),
                "$episodeId": (episode_id, ydb.PrimitiveType.Int64),
            },
        ) as _:
            pass

        print("\n> explicit TCL call")

        # Commit active transaction(tx)
        tx.commit()

    return pool.retry_operation_sync(callee)
```

Asynchronous

```
async def explicit_transaction_control(
    pool: ydb.aio.QuerySessionPool, series_id, season_id, episode_id
):
    async def callee(session: ydb.aio.QuerySession):
        query = """
        DECLARE $seriesId AS Int64;
        DECLARE $seasonId AS Int64;
        DECLARE $episodeId AS Int64;

        UPDATE episodes
        SET air_date = CurrentUtcDate()
        WHERE series_id = $seriesId AND season_id = $seasonId AND episode_id = $episodeId;
        """

        # Get newly created transaction id
        tx = await session.transaction().begin()

        # Execute data query.
        # Transaction control settings continues active transaction (tx)
        async with await tx.execute(
            query,
            {
                "$seriesId": (series_id, ydb.PrimitiveType.Int64),
                "$seasonId": (season_id, ydb.PrimitiveType.Int64),
                "$episodeId": (episode_id, ydb.PrimitiveType.Int64),
            },
        ) as _:
            pass

        print("\n> explicit TCL call")

        # Commit active transaction(tx)
        await tx.commit()

    return await pool.retry_operation_async(callee)
```

However, a transaction can be opened implicitly with the first request and can be committed automatically by setting the `commit_tx=True` flag in arguments. Implicit transaction management is preferable because it requires fewer server calls.

Iterating over query results

If a `SELECT` query is expected to return a potentially large number of rows, it is recommended to use the `tx.execute` method instead of `pool.execute_with_retries` to avoid excessive memory consumption on the client side. Instead of buffering the entire result set into memory, `tx.execute` returns an iterator for each top-level `SELECT` statement in the query.

Example of a `SELECT` with unlimited data and implicit transaction control:

Synchronous

```
def huge_select(pool: ydb.QuerySessionPool):
    def callee(session: ydb.QuerySession):
        query = """SELECT * from episodes;"""

        with session.transaction(ydb.QuerySnapshotReadOnly()).execute(
            query,
            commit_tx=True,
        ) as result_sets:
            print("\n> Huge SELECT call")
            for result_set in result_sets:
                for row in result_set.rows:
                    print("episode title:", row.title, ", air date:", row.air_date)

    return pool.retry_operation_sync(callee)
```

Asynchronous

```
async def huge_select(pool: ydb.aio.QuerySessionPool):
    async def callee(session: ydb.aio.QuerySession):
        query = """SELECT * from episodes;"""

        async with await session.transaction(ydb.QuerySnapshotReadOnly()).execute(
            query,
            commit_tx=True,
        ) as result_sets:
            print("\n> Huge SELECT call")
            async for result_set in result_sets:
                for row in result_set.rows:
                    print("episode title:", row.title, ", air date:", row.air_date)

    return await pool.retry_operation_async(callee)
```

Example app in Rust

This page provides a detailed description of the code for a test app that uses the YDB Rust SDK.

Downloading and starting

Git and Rust 1.85+ are required. For SDK installation, see Installing the YDB SDK.

Clone the repository:

```
git clone https://github.com/ydb-platform/ydb-rs-sdk.git
```

Start the example:

Local Docker

To connect to a locally deployed YDB database according to the Docker use case, run the following command in the default configuration:

```
export YDB_CONNECTION_STRING=grpc://localhost:2136/local
cd ydb-rs-sdk/ydb
cargo run --example basic
```

Any database

To run the example against any available YDB database, provide the endpoint and the database path.

If authentication is enabled, choose an authentication mode and set the corresponding environment variables.

```
export <auth_mode_var>="<auth_mode_value>"
export YDB_CONNECTION_STRING="<endpoint>/<database>"
cd ydb-rs-sdk/ydb
cargo run --example basic
```

where

- `<endpoint>`: The endpoint.
- `<database>`: The database path.
- `<auth_mode_var>`: The environment variable for the authentication mode.
- `<auth_mode_value>`: The credential value for the selected mode.

For example:

```
export YDB_ACCESS_TOKEN_CREDENTIALS="t1.9euelZqOnJuJlc..."
export YDB_CONNECTION_STRING="grpcs://ydb.example.com:2135/somepath/somelocation"
cd ydb-rs-sdk/ydb
cargo run --example basic
```

Initializing a database connection

To interact with YDB, create instances of the driver, client, and session:

- The YDB driver facilitates interaction between the app and YDB nodes at the transport layer. It must be initialized before creating a client or session and must persist throughout the YDB access lifecycle.
- The YDB client operates on top of the YDB driver and enables the handling of entities and transactions.
- The YDB session, which is part of the YDB client context, contains information about executed transactions and prepared queries.

Import the crate and open a client:

```
use ydb::{ClientBuilder, YdbResult};

#[tokio::main]
async fn main() -> YdbResult<()> {
    let connection_string = std::env::var("YDB_CONNECTION_STRING")
        .unwrap_or_else(|_| "grpc://localhost:2136/local".to_string());

    let client = ClientBuilder::new_from_connection_string(connection_string)?.client()?;
    client.wait().await?;

    let mut qc = client.query_client().clone_with_idempotent_operations(true);
    // ...
    Ok(())
}
```

`ClientBuilder::new_from_connection_string` accepts a YDB connection string (`grpc://host:port/database`). `client.wait()` waits until the driver discovers cluster endpoints. `query_client()` is the entry point for the Query Service API.

By default, anonymous authentication is used for local Docker. For token auth, use `ClientBuilder::with_credentials` — see authentication recipes.

Query Service client

To run a single transactional SQL statement, use awaitable builders on `QueryClient`:

- `qc.exec(yql)` — statement with no result set (DDL, DML).

- `qc.query_row(yql)` — exactly one row.
- `qc.query(yql).await?` — streaming `QueryStream` for large results.

Automatic retries are enabled via `clone_with_idempotent_operations(true)` for idempotent reads and DDL.

Creating tables

Create tables to be used in operations on a test app. This step results in the creation of database tables for the series directory data model:

- `Series`
- `Seasons`
- `Episodes`

After the tables are created, a method for retrieving information about data schema objects is called, and the result of its execution is displayed.

Table creation (no explicit transaction control — implicit session, server-side DDL):

```
qc.exec(format!(
    "CREATE TABLE IF NOT EXISTS `{}` (
        series_id Bytes,
        title Text,
        series_info Text,
        release_date Date,
        comment Text,
        PRIMARY KEY(series_id)
    )",
    "native/query/series"
))
.await?;
```

Adding data

Add data to the created tables using the `UPSERT` statement in YQL. A data update request is sent to the server as a single request with transaction auto-commit mode enabled.

Bulk load with `AS_TABLE` and typed parameters:

```
use ydb::{Value, ydb_struct};

let rows: Vec<Value> = /* ... */;
let list = Value::list_from(example_row, rows)?;
qc.exec("UPSERT INTO ... FROM AS_TABLE($seriesData);")
    .param("$seriesData", list)
    .await?;
```

Retrieving data

Retrieve data using a `SELECT` statement in YQL. Handle the retrieved data selection in the app.

Read materialized result with snapshot read-only isolation:

```
use ydb::QueryTxMode;

let mut result = qc
    .query("SELECT series_id, title, release_date FROM `native/query/series`")
    .with_tx_mode(QueryTxMode::SnapshotReadOnly)
    .idempotent(true)
    .await?;

while let Some(result_set) = result.next_result_set().await? {
    for mut row in result_set {
        // extract columns from row
    }
}
result.close().await?;
```

Parameterized queries

Query data using parameters. This query execution method is preferable because it allows the server to reuse the query execution plan for subsequent calls and protects against vulnerabilities such as SQL injection.

Per-call parameters use `.param(name, value)` or the `ydb_params!` macro:

```rust
use ydb::ydb_params;

// one parameter at a time
qc.exec("UPSERT INTO `native/query/series` (series_id, title) VALUES ($id, $title)")
    .param("$id", b"series-1".to_vec())
    .param("$title", "Example title")
    .await?;

// several parameters via macro
qc.exec("UPSERT INTO `native/query/series` (series_id, title) VALUES ($id, $title)")
    .params(ydb_params!(
        "$id" => b"series-2".to_vec(),
        "$title" => "Another title",
    ))
    .await?;
```

Managing transactions

Transactions are managed through TCL `Begin` and `Commit` calls.

In most cases, instead of explicitly using `Begin` and `Commit` calls, it's better to use transaction control parameters in execute calls. This allows to avoid additional requests to YDB server and thus run queries more efficiently.

The Rust SDK does not expose explicit `Begin` / `Commit` to application code. Use `retry_transaction` with `QueryTransactionOptions` for interactive transactions. For a single SQL statement, set isolation with `.with_tx_mode(...)`.

Single statement in snapshot read-only mode:

```rust
use ydb::QueryTxMode;

let mut row = qc
    .query_row("SELECT title FROM `native/query/series` WHERE series_id = $id")
    .param("$id", b"series-1".to_vec())
    .with_tx_mode(QueryTxMode::SnapshotReadOnly)
    .idempotent(true)
    .await?;
```

Interactive transaction with multiple operations:

```rust
use ydb::{QueryTransactionOptions, QueryTxMode};

let mut qc = qc.clone_with_transaction_options(
    QueryTransactionOptions::new().with_mode(QueryTxMode::SerializableReadWrite),
);

let title: String = qc
    .retry_transaction(async |tx| {
        let mut row = tx
            .query_row("SELECT title FROM `native/query/series` WHERE series_id = $id")
            .param("$id", b"series-1".to_vec())
            .await?;
        Ok(row.remove_field_by_name("title")?.try_into()?)
    })
    .await?;
```

By default, such calls use implicit transaction control — the server infers isolation from the SQL statement.

Generate code from YQL (sqlc-ydb)

sqlc-ydb generates typed code for YDB from a schema and YQL queries. You write SQL; the tool creates methods that bind parameters and read results through the selected SDK or driver. It is an independent project following the familiar sqlc workflow.

This guide takes a schema and two queries through code generation and execution in an application.

Installation

On Linux and macOS, run the commands below. Generation needs no SDK or database connection. The installer selects the latest stable release, verifies SHA256 and places the executable in `~/.local/bin`. If PATH setup is needed, follow the installer's instructions before running `sqlc-ydb version`.

```
curl -fsSL https://raw.githubusercontent.com/ydb-platform/sqlc-ydb/main/install.sh | bash
sqlc-ydb version
```

For Windows, download the appropriate archive from the latest stable release. See the installation guide for other installation methods and version selection.

Schema and queries

Create an empty project directory and save this schema, shared by all languages, as `schema.sql`:

```
CREATE TABLE authors (
    id Uint64 NOT NULL,
    name Utf8 NOT NULL,
    PRIMARY KEY (id)
);
```

Save these two queries as `queries.sql`. `UpsertAuthor` inserts an author or updates an existing author's name; `GetAuthor` reads by primary key. Parameter names start with `$`; their types are inferred from the schema, so no `DECLARE` is needed here.

```
-- name: UpsertAuthor :exec
UPSERT INTO authors (id, name) VALUES ($author_id, $author_name);

-- name: GetAuthor :one
SELECT id, name FROM authors WHERE id = $author_id;
```

The `-- name:` comment sets the generated method name. `:exec` executes a statement without result rows; `:one` retrieves one row. Every example below uses these same input files.

1. Generator configuration in sqlc.yaml

Save the configuration from the selected tab as `sqlc.yaml`. Input paths and the `out` directory are resolved relative to this file. To list the languages and frameworks available in your installed version, run:

```
sqlc-ydb init --help
```

Choose a language and runtime from that output, then request help for the generator's options:

```
sqlc-ydb init --language <language> --runtime <runtime> --help
```

Replace `<language>` and `<runtime>` with values from the help output. The command describes each option's purpose, type, allowed values, and default. Omitting `--runtime` selects the language's default runtime. Calls with `--help` do not create files.

The tabs below illustrate configuration examples. For the current list of supported languages, runtimes, and options, consult the help provided by your installed sqlc-ydb version.

C++

YDB SDK

```
version: "2"

        package: "authors"
        runtime: "exposed"
```

2. Code generation

Run these commands next to `sqlc.yaml`. `compile` checks the inputs, `generate` writes code, and `diff` checks that saved files match generation. Add `diff` to CI: it exits with code 1 when files differ.

```
sqlc-ydb compile
sqlc-ydb generate
sqlc-ydb diff
```

The following excerpts show actual generated row types or read methods for the shared query. Imports and enclosing class declarations are omitted. Use the complete files in `out`; do not edit generated code manually.

C++

YDB SDK

```
struct GetAuthorRow final {
    std::uint64_t id;
    std::string name;
};

    void UpsertAuthor(std::uint64_t author_id, const std::string& author_name) const;
    std::optional<GetAuthorRow> GetAuthor(std::uint64_t author_id) const;
```

userver

```
struct GetAuthorRow final {
    std::uint64_t id;
    ::userver::ydb::Utf8 name;
};

    void UpsertAuthor(std::uint64_t author_id, const ::userver::ydb::Utf8& author_name) const;
    std::optional<GetAuthorRow> GetAuthor(std::uint64_t author_id) const;
```

Go

YDB SDK

```
// -- name: GetAuthor :one
func (q *Queries) GetAuthor(ctx context.Context, arg uint64, opts ...query.ExecuteOption) (GetAuthorRow, erro
r) {
    parameters := ydb.ParamsBuilder()
    parameters = parameters.Param("$author_id").Uint64(arg)

            _prepared.setObject(1, PrimitiveValue.newUint64(authorId))
            _prepared.executeQuery().use { _rows ->
                if (!_rows.next()) return null
                val _value0: Long = _rows.getLong(1)
                val _value1: String = _rows.getString(2)
                return GetAuthorRow(_value0, _value1)
            }
        }
    }
```

Exposed

```
data class GetAuthorRow(
    val id: Long,
    val name: String
)

    // -- name: GetAuthor :one
    fun getAuthor(authorId: Long): GetAuthorRow? {
        val _connection = client.connection.connection as java.sql.Connection
        _connection.prepareStatement(
            "SELECT id, name FROM authors WHERE id = ?;").use { _prepared ->
            _prepared.setObject(1, PrimitiveValue.newUint64(authorId))
            _prepared.executeQuery().use { _rows ->
                if (!_rows.next()) return null
                val _value0: Long = _rows.getLong(1)
                val _value1: String = _rows.getString(2)
                return GetAuthorRow(_value0, _value1)
            }
        }
    }
```

Application setup

The generator does not create database tables. Apply `schema.sql` using your migration tool or the YDB CLI, then add a row for the single-query example:

```
UPSERT INTO authors (id, name) VALUES (42, "Alice");
```

Add the selected SDK/driver dependencies and configure authentication. The fragments below assume initialized connections or clients and imported generated code. See the project examples for complete projects with dependencies and connection setup.

3. Individual query execution

Call the generated method for author 42:

C++

YDB SDK

```
authors::Queries queries{client};
auto author = queries.GetAuthor(42);
```

`client` is a configured `NYdb::NQuery::TQueryClient`; C++20 and the YDB C++ SDK are required. Standalone calls use SDK retries; `RetryQuerySync` retries the entire transaction. `Queries` does not finish a supplied transaction: the example commits or rolls it back explicitly. Complete example.

userver

```
authors::Queries queries{table_client};
auto author = queries.GetAuthor(42);
```

`table_client` is a `userver::ydb::TableClient` obtained from the YDB component; run this code in a userver coroutine. `RetryTx` retries the whole callback and finishes the transaction according to `TxAction`; return `kRollback` to discard changes. `Utf8` is userver's string type for YQL Utf8. Complete example.

Go

YDB SDK

```
q := authors.New(driver.Query())
author, err := q.GetAuthor(ctx, 42)
if err != nil {
    return err
}
fmt.Println(author.Name)
```

`driver` is an initialized `*ydb.Driver`; `ctx` is a context. Import the generated package as `authors` and `github.com/ydb-platform/ydb-go-sdk/v3/query` for the transaction. These fragments belong in a function returning `error`.

database/sql

```
q := authors.New(connection)
author, err := q.GetAuthor(ctx, 42)
if err != nil {
    return err
}
fmt.Println(author.Name)
```

`connection` is an initialized `*sql.DB` using the YDB driver; `ctx` is a context. Import the generated package as `authors`. These fragments belong in a function returning `error`; retry the complete transaction block when needed.

Java

YDB SDK

```
GetAuthorRow author = retry.supplyResult(session -> {
    var tx = session.createNewTransaction(TxMode.SERIALIZABLE_RW);
    try {
        var row = new Queries(tx).getAuthor(42L).orElseThrow();
        return CompletableFuture.completedFuture(tx.commit().join().map(info -> row));
    } finally {
        if (tx.isActive()) {
            tx.rollback().join().expectSuccess();
        }
    }
}).join().getValue();
```

`retry` is an application-configured `SessionRetryContext`; import `TxMode`, `CompletableFuture`, and the generated `Queries` and `GetAuthorRow`. Even one Java native call uses an open transaction. `retry` reruns the whole function with a new session; the caller completes the transaction.

JDBC

```
GetAuthorRow author = new Queries(connection).getAuthor(42L).orElseThrow();
```

`connection` is a `java.sql.Connection` initially in autocommit mode, with no other active transaction. Import the generated `Queries` and `GetAuthorRow`. The transaction code restores autocommit after commit or rollback and propagates exceptions. The application can retry the whole transaction when appropriate.

jOOQ

```
GetAuthorRow author = new Queries(dsl).getAuthor(ULong.valueOf(42)).orElseThrow();
```

`dsl` is a `YdbDSLContext`; import `YDB`, `ULong`, and the generated `Queries` and `GetAuthorRow`. The single call uses an autocommit connection. `transactionResult` commits on success and rolls back on an exception; `YDB.using(configuration)` uses the current transaction connection. The application handles retries around the whole transaction.

Python

YDB SDK

```
import ydb
from python.ydb.queries import Querier

queries = Querier(pool, retry_settings=ydb.RetrySettings(idempotent=True))
author = queries.get_author(42)
```

`pool` is an initialized `ydb.QuerySessionPool`. `retry_tx_sync` retries the whole transaction and commits after the callback; the callback must have no external side effects. The repeated UPSERT in this example sets fixed values. Runnable example.

DB-API

```
from python.dbapi.queries import Querier

author = Querier(connection).get_author(42)
```

`connection` is an open `ydb_dbapi` connection with no active transaction. The driver defaults to AUTOCOMMIT: select SERIALIZABLE before `begin()` to share a transaction. The caller manages retries of the whole transaction. Runnable example.

SQLAlchemy

```
from python.sqlalchemy.queries import Querier

with engine.connect() as connection:
    author = Querier(connection).get_author(42)
```

`engine` is an initialized SQLAlchemy Engine using the `yql+ydb` dialect. Set SERIALIZABLE before `begin()`: a transaction block alone does not override the driver's AUTOCOMMIT. The context commits or rolls back; the caller manages retries of the whole transaction. Runnable example.

C#

ADO.NET

```
var author = await dataSource.ExecuteAsync(
    (connection, ct) => new Authors.Queries(connection).GetAuthorAsync(42UL, ct),
    cancellationToken);
```

Requires .NET 8, Ydb.Sdk, a configured `YdbDataSource dataSource`, and a `CancellationToken cancellationToken`. `ExecuteAsync` retries the whole callback according to the data source policy. For multiple calls in one transaction, use `ExecuteInTransactionAsync`: the provider manages commit, rollback and whole-transaction retries. Complete example. `GetAuthorAsync` throws `InvalidOperationException` when no row is found.

Dapper

```
var author = await dataSource.ExecuteAsync(
    (connection, ct) => new Authors.Queries(connection).GetAuthorAsync(42UL, ct),
    cancellationToken);
```

Requires .NET 8, Ydb.Sdk and Dapper, a configured `YdbDataSource dataSource`, and a `CancellationToken cancellationToken`. `ExecuteAsync` retries the whole callback according to the data source policy. For multiple calls in one transaction, use `ExecuteInTransactionAsync`: the provider manages commit, rollback and whole-transaction retries. Complete example. `GetAuthorAsync` throws `InvalidOperationException` when no row is found.

TypeScript

YDB SDK

```
import { Queries } from "./typescript/queries.js";

const queries = new Queries(sql);
const author = await queries.getAuthor(42n);
console.log(author?.name);
```

`sql` is the `query(driver)` function from `@ydbjs/query` for an initialized driver. `transaction` commits on callback success and rolls back on failure.

Rust

YDB SDK

```
use generated::queries::Queries;

let mut queries = Queries::new(&mut query_client);
let author = queries.author().author_id(42).call().await?;
println!("{}", author.name);
```

`query_client` is a mutable `ydb::QueryClient`. Expose the files in `rust/` as the `generated` module and add the `ydb` and `bon` dependencies. The SDK commits on callback success and retries the whole callback.

PHP

YDB SDK

```
use Authors\Queries;

$queries = new Queries($table, idempotent: true);
$author = $queries->getAuthor('42');
```

`$table` is an initialized `YdbPlatform\Ydb\Table`; generated classes are available through autoload. Pass `Uint64` as a decimal string. For this SELECT, safe retries are explicitly enabled with `idempotent: true`. Runnable example.

Kotlin

YDB SDK

```
val author = requireNotNull(Queries(retry).getAuthor(42L))
```

`retry` is an application-configured `SessionRetryContext`; import `TxMode`, `CompletableFuture`, and the generated `Queries`. The single call uses the retry context; the composed operation passes one `QueryTransaction` to the helpers. The outer `retry` retries the whole transaction.

JDBC

```
val author = requireNotNull(Queries(connection).getAuthor(42L))
```

`connection` is a `java.sql.Connection` initially in autocommit mode, with no other active transaction; import the generated `Queries`. The transaction code restores autocommit after commit or rollback and propagates exceptions. The application can retry the whole transaction when appropriate.

Exposed

```
val author = ydbTransaction(database) {
    requireNotNull(Queries(this).getAuthor(42L))
}
```

`database` is a configured Exposed `Database` with the YDB dialect registered; import `tech.ydb.exposed.dialect.ydbTransaction` and the generated `Queries`. `ydbTransaction` supplies one `JdbcTransaction`, commits on success, and rolls back on an exception. Retry policy applies to the whole block.

4. Multiple query execution in one transaction

In each example, two generated methods execute two YQL queries in one transaction: `UpsertAuthor` writes the name, then `GetAuthor` reads it. The application controls transaction boundaries and retries; retry the whole block when needed. Keep external side effects out of callbacks that the SDK may retry.

C++

YDB SDK

```
std::optional<authors::GetAuthorRow> author;
const auto status = client.RetryQuerySync([&](NYdb::NQuery::TSession session) -> NYdb::TStatus {
    auto started = session.BeginTransaction(
        NYdb::NQuery::TTxSettings::SerializableRW()).GetValueSync();
    if (!started.IsSuccess()) {
        return started;
    }
    auto transaction = started.GetTransaction();
    try {
        authors::Queries queries{transaction};
        queries.UpsertAuthor(42, "Alice");
        author = queries.GetAuthor(42);
    } catch (const NYdb::NStatusHelpers::TYdbErrorException& error) {
        transaction.Rollback().GetValueSync();
        return error.GetStatus();
    } catch (...) {
        transaction.Rollback().GetValueSync();
        throw;
    }
    return transaction.Commit().GetValueSync();
});
NYdb::NStatusHelpers::ThrowOnError(status);
```

userver

```
std::optional<authors::GetAuthorRow> author;
table_client.RetryTx("upsert-and-read-author", {}, [&](::userver::ydb::TxActor& transaction) {
    authors::Queries queries{transaction};
    queries.UpsertAuthor(42, ::userver::ydb::Utf8{"Alice"});
    author = queries.GetAuthor(42);
    return ::userver::ydb::TxAction::kCommit;
});
```

Go

YDB SDK

```
return driver.Query().DoTx(ctx, func(ctx context.Context, tx query.TxActor) error {
    q := authors.New(tx)
    if err := q.UpsertAuthor(ctx, authors.UpsertAuthorParams{
        AuthorID: 42, AuthorName: "Alice",
    }); err != nil {
        return err
    }
    _, err := q.GetAuthor(ctx, 42)
    return err
})
```

database/sql

```
tx, err := connection.BeginTx(ctx, nil)
if err != nil {
    return err
}
defer tx.Rollback()

q := authors.New(tx)
if err := q.UpsertAuthor(ctx, authors.UpsertAuthorParams{
    AuthorID: 42, AuthorName: "Alice",
}); err != nil {
    return err
}
if _, err := q.GetAuthor(ctx, 42); err != nil {
    return err
}
return tx.Commit()
```

Java

YDB SDK

```
GetAuthorRow author = retry.supplyResult(session -> {
    var tx = session.createNewTransaction(TxMode.SERIALIZABLE_RW);
    try {
        var queries = new Queries(tx);
        queries.upsertAuthor(42L, "Alice");
        var row = queries.getAuthor(42L).orElseThrow();
        return CompletableFuture.completedFuture(tx.commit().join().map(info -> row));
    } finally {
        if (tx.isActive()) {
            tx.rollback().join().expectSuccess();
        }
    }
}).join().getValue();
```

JDBC

```
connection.setAutoCommit(false);
try {
    var queries = new Queries(connection);
    queries.upsertAuthor(42L, "Alice");
    GetAuthorRow author = queries.getAuthor(42L).orElseThrow();
    connection.commit();
} catch (Exception error) {
    connection.rollback();
    throw error;
} finally {
    connection.setAutoCommit(true);
}
```

jOOQ

```
GetAuthorRow author = dsl.transactionResult(configuration -> {
    var queries = new Queries(YDB.using(configuration));
    var id = ULong.valueOf(42);
    queries.upsertAuthor(id, "Alice");
    return queries.getAuthor(id).orElseThrow();
});
```

Python

YDB SDK

```
import ydb
from python.ydb.queries import Querier

def update_author(tx):
    queries = Querier(tx)
    queries.upsert_author(42, "Alice")
    return queries.get_author(42)

author = pool.retry_tx_sync(
    update_author,
    tx_mode=ydb.QuerySerializableReadWrite(),
    retry_settings=ydb.RetrySettings(idempotent=True),
)
```

DB-API

```
import ydb_dbapi
from python.dbapi.queries import Querier

connection.set_isolation_level(ydb_dbapi.IsolationLevel.SERIALIZABLE)
connection.begin()
try:
    queries = Querier(connection)
    queries.upsert_author(42, "Alice")
    author = queries.get_author(42)
    connection.commit()
except Exception:
    connection.rollback()
    raise
```

SQLAlchemy

```
from python.sqlalchemy.queries import Querier

with engine.connect().execution_options(isolation_level="SERIALIZABLE") as connection:
    with connection.begin():
        queries = Querier(connection)
        queries.upsert_author(42, "Alice")
        author = queries.get_author(42)
```

C#

ADO.NET

```
var author = await dataSource.ExecuteInTransactionAsync(async (connection, ct) =>
{
    var queries = new Authors.Queries(connection);
    await queries.UpsertAuthorAsync(new Authors.UpsertAuthorParams(42UL, "Alice"), ct);
    return await queries.GetAuthorAsync(42UL, ct);
}, cancellationToken: cancellationToken);
```

Dapper

```
var author = await dataSource.ExecuteInTransactionAsync(async (connection, ct) =>
{
    var queries = new Authors.Queries(connection);
    await queries.UpsertAuthorAsync(new Authors.UpsertAuthorParams(42UL, "Alice"), ct);
    return await queries.GetAuthorAsync(42UL, ct);
}, cancellationToken: cancellationToken);
```

TypeScript

YDB SDK

```
import { Queries } from "./typescript/queries.js";
import type { ConfigureQuery } from "./typescript/queries.js";

const author = await sql.transaction(async (tx, signal) => {
  const queries = new Queries(tx);
  const configure: ConfigureQuery = (stmt) => { stmt.signal(signal); };
  await queries.upsertAuthor({ authorId: 42n, authorName: "Alice" }, configure);
  return queries.getAuthor(42n, configure);
});
console.log(author?.name);
```

Rust

YDB SDK

```
use generated::queries::Queries;

let author = query_client.retry_tx(ydb::closure!(async |tx| {
    let mut queries = Queries::new(tx);
    queries.upsert_author()
        .author_id(42)
        .author_name("Alice")
        .call().await?;
    Ok(queries.author().author_id(42).call().await?)
})).await?;
println!("{}", author.name);
```

PHP

YDB SDK

```
use Authors\Queries;
use Authors\UpsertAuthorParams;

$session = $table->session();
$txId = $session->beginTransaction();
$queries = (new Queries($table))->withTx($session, $txId);

$queries->upsertAuthor(new UpsertAuthorParams('42', 'Alice'));
$author = $queries->getAuthor('42');

$session->commitTransaction();
```

Both queries execute in the same transaction. `$table` is an initialized `YdbPlatform\Ydb\Table`, and generated classes are available through autoload. Error handling is omitted: on failure, the application must call `$session->rollbackTransaction()`. The bound helper does not retry individual queries; retries must repeat the entire transaction. After commit or rollback, the session returns to the pool; acquire a session again and create a new bound helper for the next transaction. PHP contract.

Kotlin

YDB SDK

```
val author = retry.supplyResult { session ->
    val tx = session.createNewTransaction(TxMode.SERIALIZABLE_RW)
    try {
        val queries = Queries(tx)
        queries.upsertAuthor(42L, "Alice")
        val row = requireNotNull(queries.getAuthor(42L))
        CompletableFuture.completedFuture(tx.commit().join().map { row })
    } finally {
        if (tx.isActive) {
            tx.rollback().join().expectSuccess()
        }
    }
}.join().getValue()
```

JDBC

```
connection.autoCommit = false
try {
    val queries = Queries(connection)
    queries.upsertAuthor(42L, "Alice")
    val author = requireNotNull(queries.getAuthor(42L))
    connection.commit()
} catch (error: Exception) {
    connection.rollback()
    throw error
} finally {
    connection.autoCommit = true
}
```

Exposed

```
val author = ydbTransaction(database) {
    val queries = Queries(this)
    queries.upsertAuthor(42L, "Alice")
    requireNotNull(queries.getAuthor(42L))
}
```

The current set of supported commands, configuration options, and YQL constructs is maintained in the sqlc-ydb compatibility contract. If a query is unsupported or generated code is awkward to use, open an issue with a minimal schema, query, configuration and the output of `sqlc-ydb version --verbose`.

YQL Tutorial - Overview

From this tutorial, you will learn how to perform basic operations with data in YDB and get familiar with the YQL syntax. A detailed description of this syntax is also available in the YQL reference documentation.

The tutorial consists of 15 steps:

1. Creating a table
2. Adding data to a table
3. Selecting data from all columns
4. Selecting data from specific columns
5. Sorting and filtering
6. Data aggregation
7. Additional selection criteria
8. Joining tables with JOIN
9. Inserting and updating data with REPLACE
10. Inserting and updating data with UPSERT
11. Inserting data with INSERT
12. Updating data with UPDATE
13. Deleting data
14. Adding and deleting columns
15. Deleting a table

Creating a table

Create the tables and set the data schema for them using the statement CREATE TABLE.

> **Note**
>
> Keywords are case-insensitive and written in capital letters for clarity only.

```
CREATE TABLE series         -- series is the table name.
(                           -- Must be unique within the folder.
    series_id Uint64,
    title Utf8,
    series_info Utf8,
    release_date Uint64,
    PRIMARY KEY (series_id) -- The primary key is a column or
                            -- combination of columns that uniquely identifies
                            -- each table row (contains only
                            -- non-repeating values). A table can have
                            -- only one primary key. For every table
                            -- in YDB, the primary key is required.
);

CREATE TABLE seasons
(
    series_id Uint64,
    season_id Uint64,
    title Utf8,
    first_aired Uint64,
    last_aired Uint64,
    PRIMARY KEY (series_id, season_id)
);

CREATE TABLE episodes
(
    series_id Uint64,
    season_id Uint64,
    episode_id Uint64,
    title Utf8,
    air_date Uint64,
    PRIMARY KEY (series_id, season_id, episode_id)
);

COMMIT;
```

Adding data to a table

Populate the created tables with data using the REPLACE INTO statement.

```
REPLACE INTO series (series_id, title, release_date, series_info)

VALUES

    -- By default, numeric literals have type Int32
    -- if the value is within the range.
    -- Otherwise, they automatically expand to Int64.
    (
        1,
        "IT Crowd",
        CAST(Date("2006-02-03") AS Uint64),   -- CAST converts one datatype into another.
                                              -- You can convert a string
                                              -- literal into a primitive literal.
                                              -- The Date() function converts a string
                                              -- literal in ISO 8601 format into a date.

        "The IT Crowd is a British sitcom produced by Channel 4, written by Graham Linehan, produced by Ash A
talla and starring Chris O'Dowd, Richard Ayoade, Katherine Parkinson, and Matt Berry."),
    (
        2,
        "Silicon Valley",
        CAST(Date("2014-04-06") AS Uint64),
        "Silicon Valley is an American comedy television series created by Mike Judge, John Altschuler and Da
ve Krinsky. The series focuses on five young men who founded a startup company in Silicon Valley."
    )
    ;

REPLACE INTO seasons (series_id, season_id, title, first_aired, last_aired)
VALUES
    (1, 1, "Season 1", CAST(Date("2006-02-03") AS Uint64), CAST(Date("2006-03-03") AS Uint64)),

(
    2,
    5,
    12,
    "Test Episode !!!",
    CAST(Date("2018-08-27") AS Uint64)
)
;

-- COMMIT is called so that the next SELECT operation
-- can see the changes made by the previous transaction.
COMMIT;

-- View result:
SELECT * FROM episodes WHERE series_id = 2 AND season_id = 5;

COMMIT;
```

Inserting and updating data with UPSERT

Add data to the table using UPSERT INTO:

> **Note**
>
> We assume that you already created tables in step Creating a table and populated them with data in step Adding data to a table.

```
UPSERT INTO episodes
(
    series_id,
    season_id,
    episode_id,
    title,
    air_date
)
VALUES
(
    2,
    5,
    13,
    "Test Episode",
    CAST(Date("2018-08-27") AS Uint64)
)
;

COMMIT;

-- View result:
SELECT * FROM episodes WHERE series_id = 2 AND season_id = 5;

COMMIT;
```

Inserting data with INSERT

Add data to the table using INSERT INTO:

> **Note**
>
> We assume that you already created tables in step Creating a table and populated them with data in step Adding data to a table.

```
INSERT INTO episodes
(
    series_id,
    season_id,
    episode_id,
    title,
    air_date
)
VALUES
(
    2,
    5,
    21,
    "Test 21",
    CAST(Date("2018-08-27") AS Uint64)
),                                          -- Rows are separated by commas.
(
    2,
    5,
    22,
    "Test 22",
    CAST(Date("2018-08-27") AS Uint64)
)
;

COMMIT;

-- View result:
SELECT * FROM episodes WHERE series_id = 2 AND season_id = 5;

COMMIT;
```

Updating data with UPDATE

Update data in the table using the UPDATE operator:

> **Note**
>
> We assume that you already created tables in step Creating a table and populated them with data in step Adding data to a table.

```
UPDATE episodes
SET title="test Episode 2"
WHERE
    series_id = 2
    AND season_id = 5
    AND episode_id = 12
;

COMMIT;

-- View result:
SELECT * FROM episodes WHERE series_id = 2 AND season_id = 5;

-- YDB doesn't see changes that take place at the start of the transaction,
-- which is why it first performs a read. You can't UPDATE or DELETE a table
-- already changed within the current transaction. UPDATE ON and
-- DELETE ON let you read, update, and delete multiple rows from one table
-- within a single transaction.

$to_update = (
    SELECT series_id,
           season_id,
           episode_id,
           Utf8("Yesterday's Jam UPDATED") AS title
    FROM episodes
    WHERE series_id = 1 AND season_id = 1 AND episode_id = 1
);

SELECT * FROM episodes WHERE series_id = 1 AND season_id = 1;

UPDATE episodes ON
SELECT * FROM $to_update;

COMMIT;

-- View result:
SELECT * FROM episodes WHERE series_id = 1 AND season_id = 1;

COMMIT;
```

Deleting data

Delete data from the table using DELETE.

> **Note**
>
> We assume that you already created tables in step Creating a table and populated them with data in step Adding data to a table.

```
DELETE
FROM episodes
WHERE
    series_id = 2
    AND season_id = 5
    AND episode_id = 12
;

COMMIT;

-- View result:
SELECT * FROM episodes WHERE series_id = 2 AND season_id = 5;

-- YDB doesn't see changes that take place at the start of the transaction,
-- which is why it first performs a read. It is impossible to execute UPDATE or DELETE on
-- if the table was changed within the current transaction. UPDATE ON and
-- DELETE ON let you read, update, and delete multiple rows from one table
-- within a single transaction.

$to_delete = (
    SELECT series_id, season_id, episode_id
    FROM episodes
    WHERE series_id = 1 AND season_id = 1 AND episode_id = 2
);

SELECT * FROM episodes WHERE series_id = 1 AND season_id = 1;

DELETE FROM episodes ON
SELECT * FROM $to_delete;

COMMIT;

-- View result:
SELECT * FROM episodes WHERE series_id = 1 AND season_id = 1;

COMMIT;
```

Adding and deleting columns

Add a new column to the table and then delete it.

> **Note**
>
> We assume that you already created tables in step Creating a table and populated them with data in step Adding data to a table.

Adding a column

Add a non-key column to the existing table:

```
ALTER TABLE episodes ADD COLUMN viewers Uint64;
```

Deleting a column

Delete the column you added from the table:

```
ALTER TABLE episodes DROP COLUMN viewers;
```

Deleting a table

Delete the created tables using the DROP TABLE statement.

```
DROP TABLE episodes;
DROP TABLE seasons;
DROP TABLE series;
```

Choosing a primary key

The recommendations for choosing a proper primary key for a table depend on its type:

- Row-oriented tables
- Column-oriented tables

Selecting a primary key for maximum performance

The way columns are selected for a table's primary key defines YDB's ability to scale load and improve performance.

General recommendations for choosing a primary key:

- Avoid situations where the main load falls on one partition of a table. The more evenly load is distributed across partitions, the better the performance.
- Reduce the number of partitions that can be affected in a single request. Moreover, if the request affects no more than one partition, it is performed using a special simplified protocol. This significantly increases the speed and saves the resources.

All YDB tables are sorted by primary key in ascending order. In a table with a monotonically increasing primary key, this will result in new data being added at the end of a table. As YDB splits table data into partitions based on key ranges, inserts are always processed by the same server that is responsible for the "last" partition. Concentrating the load on a single server results in slow data uploading and inefficient use of a distributed system.

You get the same behaviour if the monotonically increasing value is the **only** primary-key column or the **first component of a composite primary key**: partition ranges are driven by the key prefix, so monotonicity at the beginning of the key produces the same hot-spot pattern. Auto-increment types (`SERIAL`), when used as the sole or leading component of `PRIMARY KEY`, behave in the same way.

As an example, let's take logging of user events to a table with the `( timestamp, userid, userevent, PRIMARY KEY (timestamp, userid) )` schema.

The values in the `timestamp` column increase monotonically resulting in all new records being added at the end of a table, and the final partition, which is responsible for this range of keys, handles all the table inserts. This makes scaling insert loads impossible and performance will be limited by the single process servicing this partition and won't increase as new servers are added to a cluster.

YDB supports further automatic partition splitting upon a threshold size or load being reached. However, in this situation, once it splits off, the new partition will again begin handling all the inserts, and the situation will recur.

Techniques that let you evenly distribute load across table partitions

Changing the sequence of key components

Writing data to a table with the `( timestamp, userid, userevent, PRIMARY KEY (timestamp, userid) )` schema results in an uneven load on table partitions due to a monotonically increasing primary key. Changing the sequence of key components so that the monotonically increasing part isn't the first component can help distribute the load more evenly. If you redefine a table's primary key as `PRIMARY KEY (userid, timestamp)`, the DB writes will distribute more evenly across the partitions provided there is a sufficient number of users generating events.

Using a hash of key column values as a primary key

To obtain a more even distribution of operations across a table's partitions and reduce the size of internal data structures, make the primary key "prefix" (initial part) values more varied. To do this, make the primary key include the value of a hash of the entire primary key or a part of the primary key.

For instance, the schema of this table with the schema `( timestamp, userid, userevent, PRIMARY KEY (userid, timestamp) )` might be made to include an additional field computed as a hash: `userhash = HASH(userid)`. This would change the table schema as follows:

```
( userhash, userid, timestamp, userevent, PRIMARY KEY (userhash, userid, timestamp) )
```

If you select the hash function properly, rows will be distributed fairly evenly throughout the entire key space, which will result in a more even load on the system. At the same time, the fact that the key includes `userid, timestamp` after `userhash` keeps the data local and sorted by time for a specific user.

The `userhash` field in the example above must be computed by the application and specified explicitly both for inserting new records into the table and for data access by primary key.

Another common special case of the same idea is monotonically increasing identifiers (`SERIAL` , a sequence, or a sequential numeric id)—not only the timestamp from the log example above.

Monotonically increasing identifier (SERIAL, sequence, auto increment)

Don't use a monotonically increasing value as the sole primary-key column or as the **first** component of a composite primary key. Typical examples are an auto-increment id (`SERIAL`), a value from a sequence, or a sequential numeric id.

Row-oriented tables in YDB are partitioned by ranges of the primary key, so rows with a monotonic key keep landing in the last partition and create a hot spot: most write load concentrates on a small set of partitions while others are underused.

The same issue applies to a composite key when the **first** component increases monotonically—for example, `PRIMARY KEY (order_id, customer_id)`.

YDB supports auto-increment types (`SERIAL`), but using them as the only or leading primary-key column isn't recommended for insert-heavy workloads.

Prefer a random identifier (such as UUID) or a composite business key without a monotonic prefix whenever possible. If you must keep a monotonically increasing id in the key, use a composite primary key where the **first** column is a hash of the id and the **second** is the id itself. That tends to yield **more even** distribution of rows across partitions while preserving uniqueness (a hash does not guarantee a perfectly balanced split).

Poor example

```
CREATE TABLE orders (
    order_id Uint64,
    customer_id Uint64,
    amount Double,
    PRIMARY KEY (order_id)
);

INSERT INTO orders (order_id, customer_id, amount) VALUES
    (1001, 10, 999.99),
    (1002, 11, 1499.00),
    (1003, 12, 499.50);

SELECT *
FROM orders
WHERE order_id = 1001;
```

Good example

```
CREATE TABLE orders (
    order_hash Uint64,
    order_id Uint64,
    customer_id Uint64,
    amount Double,
    PRIMARY KEY (order_hash, order_id)
);

INSERT INTO orders (order_hash, order_id, customer_id, amount) VALUES
    (Digest::NumericHash(1001), 1001, 10, 999.99),
    (Digest::NumericHash(1002), 1002, 11, 1499.00),
    (Digest::NumericHash(1003), 1003, 12, 499.50);

SELECT *
FROM orders
WHERE order_hash = Digest::NumericHash(1001)
    AND order_id = 1001;
```

Compute `order_hash` on write and on keyed reads—the same rule as for `userhash` in the example above.

Reducing the number of partitions affected by a single query

Let's assume that the main scenario for working with table data is to read all events by a specific `userid`. Then, when you use the `( timestamp, userid, userevent, PRIMARY KEY (timestamp, userid) )` table schema, each read affects all the partitions of the table. Moreover, each partition is fully scanned, since the rows related to a specific `userid` are located in an order that isn't known in advance. Changing the sequence of `( timestamp, userid, userevent, PRIMARY KEY (userid, timestamp) )` key components causes all rows related to a specific `userid` to follow each other. This row distribution will be useful for reading data by `userid` and will reduce load.

NULL value in a key column

In YDB, all columns, including key ones, may contain a NULL value. Using NULL as values in key columns isn't recommended. According to the SQL standard (ISO/IEC 9075), you can't compare NULL with other values. Therefore, the use of concise SQL statements with simple comparison operators may lead, for example, to skipping rows containing NULL during filtering.

Row size limit

To achieve high performance, we don't recommend writing rows larger than 8 MB and key columns larger than 2 KB to the DB.

Choosing keys for maximum column-oriented table performance

Unlike row-oriented YDB tables, column-oriented tables are partitioned by designated **partitioning keys**. Within each partition, data is distributed based on the table's primary key.

Partitioning key

The partitioning key must be a non-empty subset of the primary key columns. The hash of the partition key determines the partition to which the row belongs. The partition key should be chosen to ensure that data is evenly distributed across partitions. This is typically achieved by including high-cardinality columns, such as high-resolution timestamps (`Timestamp` data type), in the partition key. Using a partitioning key with low cardinality can lead to an uneven distribution of data across partitions, causing some partitions to become overloaded. Overloaded partitions may result in suboptimal query performance and/or limit the maximum rate of data insertion.

Column-oriented tables do not support automatic repartitioning at the moment. That's why it's important to specify a realistic number of partitions at table creation. You can evaluate the number of partitions you need based on the expected data amounts you are going to add to the table. The average insert throughput for a partition is 1 MB/s. The throughput is mostly affected by the selected primary keys (the need to sort data inside the partition when inserting data). We do not recommend setting up more than 128 partitions for small data streams.

Primary key

The primary key determines how the data will be stored inside the partition. That's why, when selecting a primary key, you need to keep in mind both the effectiveness of reading data from the partition and the effectiveness of inserting data into the partition. The optimum insert use case is to write data to the beginning or end of the table, making rare local updates of previously inserted data. For example, an effective use case would be to store application logs by timestamps, adding records to the end of the partition using the current time in the primary key.

Example

When your data stream is 1 GB per second, an analytical table with 1,000 partitions is an optimal choice. Nevertheless, it is not advisable to create tables with an excessive number of partitions: this could raise resource consumption in the cluster and negatively impact the query rate.

Secondary indexes

Indexes are auxiliary structures within databases that help find data by certain criteria without having to search an entire database and retrieve sorted samples without actually sorting, which would require processing the entire dataset.

Data in a YDB table is always sorted by the primary key. That means that retrieving any entry from the table with specified field values comprising the primary key always takes the minimum fixed time, regardless of the total number of table entries. Indexing by the primary key makes it possible to retrieve any consecutive range of entries in ascending or descending order of the primary key. Execution time for this operation depends only on the number of retrieved entries rather than on the total number of table records.

To use a similar feature with any field or combination of fields, additional indexes called **secondary indexes** can be created for them.

In transactional systems, indexes are used to limit or avoid performance degradation and increase of query cost as your data grows.

This article describes the main operations with secondary indexes and gives references to detailed information on each operation. For more information about various types of secondary indexes and their specifics, see Secondary indexes in the Concepts section.

Creating secondary indexes

A secondary index is a data schema object that can be defined when creating a table with the `CREATE TABLE` YQL command or added to it later with the `ALTER TABLE` YQL command.

The `table index add` command is supported in the YDB CLI.

Since an index contains its own data derived from table data, when creating an index on an existing table with data, an operation is performed to initially build an index. This may take a long time. This operation is executed in the background and you can keep working with the table while it's in progress. However, you can't use the new index until its build is completed.

An index can only be used in the order of the fields included in it. If an index contains two fields, such as `a` and `b`, you can effectively use it for queries such as:

- `WHERE a = $var1 AND b = $var2`.
- `WHERE a = $var1`.
- `WHERE a > $var1` and other comparison operators.
- `WHERE a = $var1 AND b > $var2` and any other comparison operators in which the first field must be checked for equality.

This index can't be used in the following queries:

- `WHERE b = $var1`.
- `WHERE a > $var1 AND b > $var2`, which is equivalent to `WHERE a > $var1` in terms of applying the index.
- `WHERE b > $var1`.

To effectively limit the result of a query using the `LIMIT` command, you must use one-way sorting in the `ORDER BY` command:

- `WHERE a = $var1 AND b > $var2 ORDER BY a, b DESC LIMIT 1`, all index rows that match the filter conditions will be read;
- `WHERE a = $var1 AND b > $var2 ORDER BY a DESC, b DESC LIMIT 1`, only one row will be read.

Considering the above, there's no use in pre-indexing all possible combinations of table columns to speed up the execution of any query. An index is always a compromise between the lookup and write speed and the storage space occupied by the data. Indexes are created for specific queries and search criteria made by an app in the database.

Using secondary indexes when selecting data

For a table to be accessed by a secondary index, its name must be explicitly specified in the `VIEW` section after the table name as described in the article about the YQL `SELECT` statement. For example, a query to retrieve orders from the `orders` table by the specified customer ID (`id_customer`) looks like this:

```
DECLARE $customer_id AS Uint64;

SELECT *
FROM   orders VIEW idx_customer AS o
WHERE  o.id_customer = $customer_id
```

Where `idx_customer` is the name of the secondary index on the `orders` table with the `id_customer` field specified first.

If no `VIEW` section is specified, making a query like this results in a full scan of the `orders` table.

In transactional applications, such information queries are executed with paginated data output. This eliminates an increase in the cost and time of query execution if the number of entries that meet the filtering conditions grows. The described approach to writing paginated queries using the primary key can also be applied to columns that are part of a secondary index.

An experimental capability to automatically select a secondary index for use in a query is also available. The selection algorithm is currently rule-based and uses only the query text to automatically select a secondary index.

Automatic use of indexes when selecting data

Explicitly specifying the `VIEW` section takes priority over the optimizer's decision to use secondary indexes. That is, the query

```
SELECT * FROM `Table` VIEW Index
```

is guaranteed to perform selection using the `Index` index.

To explicitly specify reading using the primary key, use the following construct:

```
SELECT * FROM `Table` VIEW PRIMARY KEY
```

Criteria for selecting a secondary index

The index used for reading is selected during query optimization when determining the row ranges that need to be read (predicate pushdown). Indexes, like the main table, are a set of rows ordered by a set of key columns.

Selection between reading using an index and reading using the primary key is based on the following metrics:

1. Need for additional reads from the main table. If the index contains all columns required for the query, no additional reads are needed.
2. Length of the point prefix of the predicate for the corresponding table's key. That is, the predicate constrains a set of columns that are the first components of the key with point conditions: `=`, `IN`, `IS NULL`. Priority is given to indexes for which all indexed columns are fixed, or to the main table if the entire primary key is point-fixed.
3. Number of columns used in the read range bounds. In the following query to the `Table` table with primary key (Key1, Key2, Key3)

```
SELECT * FROM `Table` WHERE (Key1, Key2, Key3) < ($param1, $param2, $param3) AND (Key1, Key2) > ($param4, $pa
ram5)
```

reading will be performed in the range `(($param4, $param5), ($param1, $param2, $param3))`, and thus the number of used columns will be 3. Similarly, preference is given to indexes for which all indexed columns are used.

Read methods are ranked against each other according to criterion 2, with ties broken by criterion 3, and criterion 1 is additionally taken into account.

Examples of automatic index selection

```
CREATE TABLE `Table` (
     Key Int32,
     SubKey1 Int32,
     SubKey2 String,
     Value1 String,
     Value2 String,
     PRIMARY KEY (Key, SubKey1, SubKey2),
     INDEX Index12 GLOBAL ON (SubKey1, SubKey2),
     INDEX Index21 GLOBAL ON (SubKey2, Value1),
     INDEX Index212 GLOBAL ON (SubKey2) COVER (Value2)
);
```

`SELECT * FROM Table WHERE SubKey1 = $p1 and SubKey2 > $p2` — `Index12` will be used. The range expression is `(($p1; $p2), ($p1)]`. The point prefix length for `Index12` is 1; for other indexes, it is 0.

`SELECT * FROM Table WHERE Key = $p1 and SubKey1 = $p2 And SubKey2 = $p2` — no index will be used. When selecting a scan of the main table, all 3 columns are used: `[Key, Fk1, Fk2]`, and the point prefix length is 3.

`SELECT * FROM Table WHERE Key = $p1 and SubKey2 = $p2` — secondary indexes will not be used. When selecting any secondary index, 1 column is used, and the point prefix is also at most 1 for any index choice.

`SELECT * FROM Table WHERE Key >= $p1 and SubKey1 = $p2 And SubKey2 = $p3` — `Index12` should be selected, because when it is selected, the resulting range `[[Fk1; Fk2; Key], [Fk1; Fk2])` yields a point prefix length of 2, and 3 columns are used.

`SELECT * FROM Table WHERE Key = 2 and SubKey2 = 3` — secondary indexes should not be used. When reading by `PK` or using any of the secondary indexes, the point prefix consists of at most one column. Also, at most one column is used.

`SELECT * FROM Table WHERE SubKey1 > 2` — `Index12` should be selected. Only when using `Index12` will the read range be non-trivial.

`SELECT * FROM Table WHERE SubKey2 = 2` — either `Index21` or `Index212` may be selected. When using the indexes mentioned above, the point prefix length will be 1. The number of used columns is also maximized when selecting `Index21` and `Index212`.

`SELECT Value2 FROM Table WHERE SubKey2 = 2` — `Index212` should be selected. When using `Index21` and `Index212`, the point prefix length will be 1, but when using `Index212`, no read from the main table is required.

`SELECT * FROM Table WHERE SubKey2 > 2` — `Index21` or `Index212` will be used, because the read range is non-trivial only when using them.

`SELECT * FROM Table WHERE SubKey1 = 2` — `Index12` will be used, because when using it, the point prefix length will be 1, whereas in other cases it is 0.

Checking the cost of queries

Any query made in a transactional application should be checked in terms of the number of I/O operations it performed in the database and how much CPU was used to run it. You should also make sure these indicators don't continuously grow as the database volume grows. YDB returns statistics required for the analysis after running each query.

If you use the YDB CLI, select the `--stats` option to enable printing statistics after executing the `yql` command. All YDB SDKs also contain structures with statistics returned after running a query. If you make a query in the UI, you'll see a tab with statistics next to the results tab.

Updating data using a secondary index

The `UPDATE`, `UPSERT`, and `REPLACE` YQL record modification statements don't permit specifying a secondary index to perform a search for data, so an attempt to make an `UPDATE ... WHERE indexed_field = $value` will result in a full scan of the table. To avoid this, you can first run `SELECT` by index to get the primary key value and then run `UPDATE` by the primary key. You can also use `UPDATE ON`.

To update data in the `table1` table, run the query:

```
$to_update = (
    SELECT pk_field, $f1 AS field1, $f2 AS field2, ...
    FROM   table1 VIEW idx_field3
    WHERE  field3 = $f3)

UPDATE table1 ON SELECT * FROM $to_update
```

Note

Currently, data updating is possible only using a synchronous secondary index. This limitation exists because data modification is permitted only in Serializable transactions, and accessing asynchronous indices would violate the guarantees of this transaction mode.

Deleting data using a secondary index

To delete data by secondary index, use `SELECT` with a predicate by secondary index and then call `DELETE ON`.

To delete all data about series with zero views from the `series` table, run the query:

```
DELETE FROM series ON
SELECT series_id
FROM series VIEW views_index
WHERE views = 0;
```

Note

Currently, deleting data is possible only using a synchronous secondary index. This is because data removal is permitted only in Serializable transactions, and accessing asynchronous indices would violate the guarantees of this transaction mode.

Atomic replacement of a secondary index

You can atomically replace a secondary index. This can be useful if you want your index to become covering. This operation is totally transparent for your running applications: when you replace the index, the compiled queries are invalidated.

To replace an existing index atomically, use the YDB CLI command ydb table index rename with the `--replace` parameter.

Performance of data writes to tables with secondary indexes

You need additional data structures to enable secondary indexes. Support for these structures makes table data update operations more costly.

During synchronous index updates, a transaction is only committed after all the necessary data is written in both a table and synchronous indexes. As a result, it takes longer to execute it and makes it necessary to use distributed transactions even if adding or updating entries in a single partition.

Indexes that are updated asynchronously let you use single-shard transactions. However, they only guarantee eventual consistency and still put a load on the database.

Vector Indexes

Vector indexes are a specialized type of secondary index that enable efficient vector search in multidimensional spaces. While traditional secondary indexes optimize searching by equality or range, vector indexes allow similarity searching based on similarity or distance functions.

Data in a YDB table is stored and sorted by the primary key, ensuring efficient searching by exact match and range scanning. Vector indexes provide similar efficiency for nearest neighbor searches in vector spaces.

Types of Vector Indexes

A vector index can be global or global filtered. Indexes of any of these types can also be covering and include a copy of additional column data from the main table.

Global Vector Index

A global vector index on the `embedding` column enables fast approximate nearest neighbor search across the entire table:

```
ALTER TABLE my_table
  ADD INDEX my_index
  GLOBAL USING vector_kmeans_tree
  ON (embedding)
  COVER (embedding, data)
  WITH (distance=cosine, vector_type="float", vector_dimension=512, overlap_clusters=3);
```

Example search query using this index:

```
PRAGMA ydb.KMeansTreeSearchTopSize = "10";

DECLARE $query_vector AS string;

$query_vector = Knn::ToBinaryStringFloat([1.0, 1.2, 0, ...]);

SELECT user, data
FROM my_table VIEW my_index
ORDER BY Knn::CosineSimilarity(embedding, $query_vector) DESC
LIMIT 10;
```

Note that:

- Both the `embedding` column and the `$query_vector` parameter must be of string type and contain an array of numbers in the simple binary format.
- It is more efficient to pass the parameter from the SDK as a string by serializing the numbers on the application side (examples). Alternatively, the value can be passed from the SDK as a vector of numbers and converted from a list using `Knn::ToBinaryString*` functions, but this is slower.
- The `COVER (embedding, data)` clause is optional and is used to create a covering index. This helps further speed up the search.
- Vector index search is always approximate — its results differ from a full-scan search.
- Increasing the `PRAGMA KMeansTreeSearchTopSize` parameter improves search quality (recall) at the cost of speed. The parameter sets the number of index clusters nearest to the query that are scanned. The default value is 1 (minimum quality, maximum speed).
- The `overlap_clusters=3` parameter significantly improves future search quality during indexing by specifying the number of clusters each vector is added to, but increases the index size.
- The `vector_type` and `vector_dimension` parameters can be omitted if the table is not empty — they will be autodetected from existing rows.

Filtered Vector Index

A filtered vector index enables searching for nearest neighbors within each category defined by unique values of additional columns.

To create such an index, specify multiple index columns. The last column must be the vector column; the others (category columns) can be of any type:

```
ALTER TABLE my_table
  ADD INDEX my_index
  GLOBAL USING vector_kmeans_tree
  ON (user, embedding)
  COVER (embedding, data)
  WITH (distance=cosine, vector_type="float", vector_dimension=512);
```

Search queries using this filtered index must include conditions on the `user` column:

```
PRAGMA ydb.KMeansTreeSearchTopSize = "10";

DECLARE $query_vector AS string;

$query_vector = Knn::ToBinaryStringFloat([1.0, 1.2, 0, ...]);

SELECT user, data
FROM my_table VIEW my_index
WHERE user = 'john'
ORDER BY Knn::CosineSimilarity(embedding, $query_vector) DESC
LIMIT 10;
```

Indexing and search parameters work the same as for a global index.

Covering Vector Index

A covering vector index stores a copy of additional column data to avoid reading from the main table and further speed up the search.

Note that by default the index does not contain a copy of the vector column (in the example — `embedding`), so if it is not explicitly added to the list of covered columns, reading from the main table cannot be avoided, since vectors are always used for exact result sorting in the final search step.

```
ALTER TABLE my_table
  ADD INDEX my_index
  GLOBAL USING vector_kmeans_tree
  ON (embedding)
  COVER (embedding, data)
  WITH (distance=cosine);
```

Distance Functions

The following similarity or distance functions are supported:

- `distance=cosine` or `similarity=cosine` — cosine distance, corresponds to `ORDER BY Knn::CosineDistance(...) ASC` or `ORDER BY Knn::CosineSimilarity(...) DESC`.
- `distance=manhattan` — Manhattan distance (L1 metric), corresponds to `ORDER BY Knn::ManhattanDistance(...) ASC`.
- `distance=euclidean` — Euclidean distance (L2 metric), corresponds to `ORDER BY Knn::EuclideanDistance(...) ASC`.
- `similarity=inner_product` — inner product, corresponds to `ORDER BY Knn::InnerProductSimilarity(...) DESC`.

Full Vector Index Syntax

Creating a vector index:

- During table creation: CREATE TABLE.
- Adding to an existing table: ALTER TABLE.

Full syntax for queries using a vector index:

- VIEW VECTOR INDEX.

Search Algorithm

The current implementation offers one type of index: `vector_kmeans_tree`.

Vector Index Type `vector_kmeans_tree`

The `vector_kmeans_tree` index implements hierarchical data clustering. The structure of the index includes:

1. Hierarchical clustering:
   - the index builds multiple levels of k-means clusters;
   - at each level, vectors are distributed across a predefined number of clusters raised to the power of the level;
   - the first level clusters the entire dataset;
   - subsequent levels recursively cluster the contents of each parent cluster.
2. Search process:
   - search proceeds recursively from the first level to the subsequent ones;
   - during queries, the index analyzes only the most promising clusters;
   - such search space pruning avoids complete enumeration of all vectors.
3. Parameters:
   - `levels`: number of levels in the tree, defining search depth (recommended 1-3);
   - `clusters`: number of clusters in k-means, defining search width (recommended 64-512).
   - `overlap_clusters`: number of leaf-level clusters each vector is added to (recommended 3).

Internally, a vector index consists of index tables named `indexImpl*Table`. In selection queries using the vector index, these tables appear in query statistics. For more on the structure of the vector index, see the dedicated article Vector index type: vector_kmeans_tree.

Overlapping Clusters

A vector index in YDB can add each vector to multiple clusters to improve search recall and speed:

```
ALTER TABLE my_table
  ADD INDEX my_index
  GLOBAL USING vector_kmeans_tree
  ON (embedding)
  WITH (distance=cosine, overlap_clusters=3);
```

In this example, each vector will be added to 3 nearest clusters instead of 1.

The `overlap_clusters` parameter is recommended for nearly all use cases, especially for vector indexes with `levels > 1`, as it significantly improves search recall even with small `PRAGMA KMeansTreeSearchTopSize` values (for example, 3).

This way, you can reduce the PRAGMA value and significantly speed up the search while maintaining the same recall.

Partitioning of Index Tables

The most heavily loaded table in a vector index is `indexImplLevelTable`, the cluster structure table. Every search query reads this table, so load on its partitions may limit query performance.

To improve performance, you can enable auto-partitioning by load:

```
ALTER TABLE `my_table/my_index/indexImplLevelTable`
SET AUTO_PARTITIONING_BY_LOAD ENABLED;
```

Or by size:

```
ALTER TABLE `my_table/my_index/indexImplLevelTable`
SET AUTO_PARTITIONING_PARTITION_SIZE_MB 100;
```

The same settings can be applied to other index tables (`indexImplPostingTable` and `indexImplPrefixTable`), but the Level table is the most loaded while being small in size, so auto-partitioning settings are most relevant for it.

Using Index Table Replicas

Another way to speed up search is to use table replicas. To do this:

1. Create a covering index so that only index tables are involved in search queries.
2. Enable replicas on all index tables:

   ```
   ALTER TABLE `my_table/my_index/indexImplLevelTable` SET READ_REPLICAS_SETTINGS 'PER_AZ:3';
   ALTER TABLE `my_table/my_index/indexImplPostingTable` SET READ_REPLICAS_SETTINGS 'PER_AZ:3';
   ```

   And, for a filtered index, also:

   ```
   ALTER TABLE `my_table/my_index/indexImplPrefixTable` SET READ_REPLICAS_SETTINGS 'PER_AZ:3';
   ```

3. Use the Stale Read-Only query mode.

Updating Vector Indexes

Updating vector indexes has the following limitations:

Clusters are not recalculated during update

When a table with a vector index is updated, its internal structure — a tree of clusters (groups of similar vectors) — is not recalculated. New or modified records are simply assigned to existing clusters.

Over time, this can lead to index degradation, resulting in:

1. Reduced completeness — the index may return fewer relevant results because clusters no longer reflect the actual data distribution.
2. Reduced performance — unbalanced clusters (for example, one cluster containing too many records) can slow down search queries and, in the worst case, lead to full table scans.

The extent of degradation depends on the nature of the updates:

- If the index was built on a representative sample (e.g., a random 50% of the data) and the remaining records are added later, the index structure remains mostly relevant, and degradation is minimal.
- If entire groups of similar vectors were absent from the initial dataset, the clustering may fail to partition the space effectively, leading to a significant drop in result relevance.

A particularly problematic corner case arises when a vector index is created on an empty table. In this scenario, the index consists of a single cluster, and all new records are placed within it. As a result, searches using such an index are equivalent to full table scans.

To prevent degradation:

- Avoid creating a vector index on an empty table.
- If a large volume of new data has been added, build a new index and atomically replace the old index with the updated one.

Update inconsistency during index build

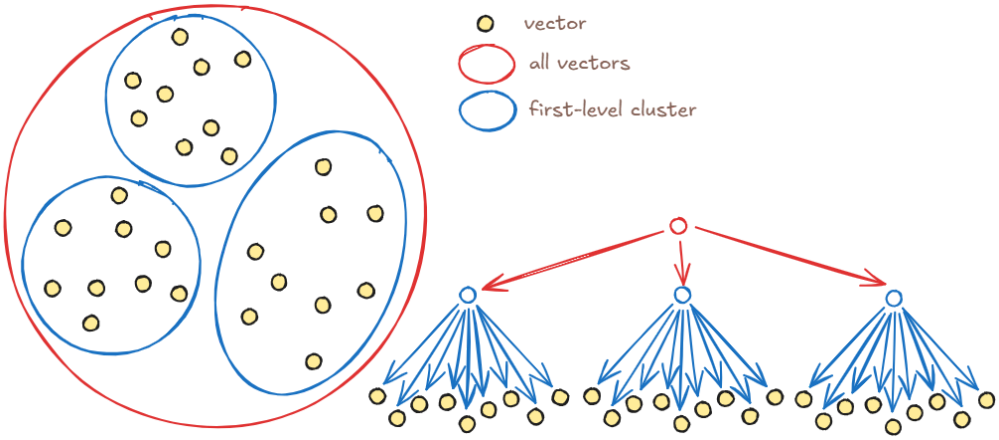
Vector indexes do not support consistent updates during build. That is, a vector index is not updated when data in the main table is modified until the index build is finished.

This means that if you want a vector index to remain 100% consistent, you have to pause table updates while it is being built.

Updates are not blocked automatically because vector index search is approximate by nature, and in many cases temporary inconsistency during the build is acceptable.

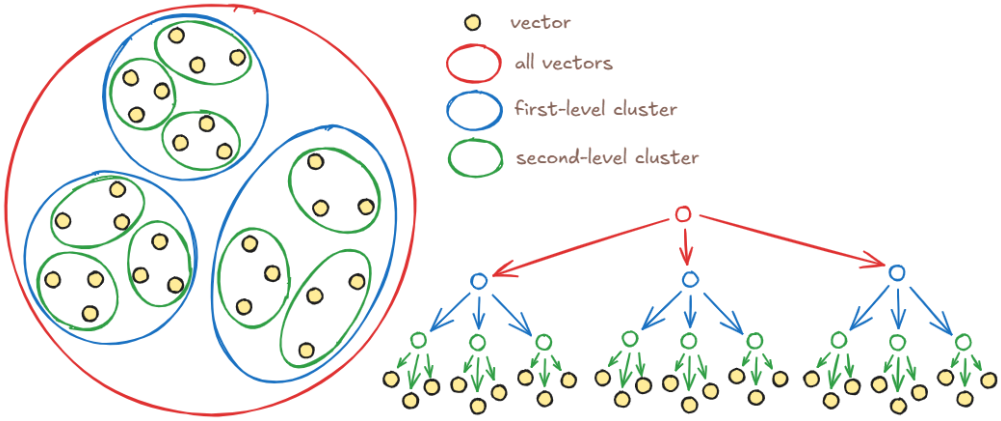
Recipes for Working with Vector Indexes

To get started with vector indexes, you can use the following recipes:



- YDB CLI & YQL

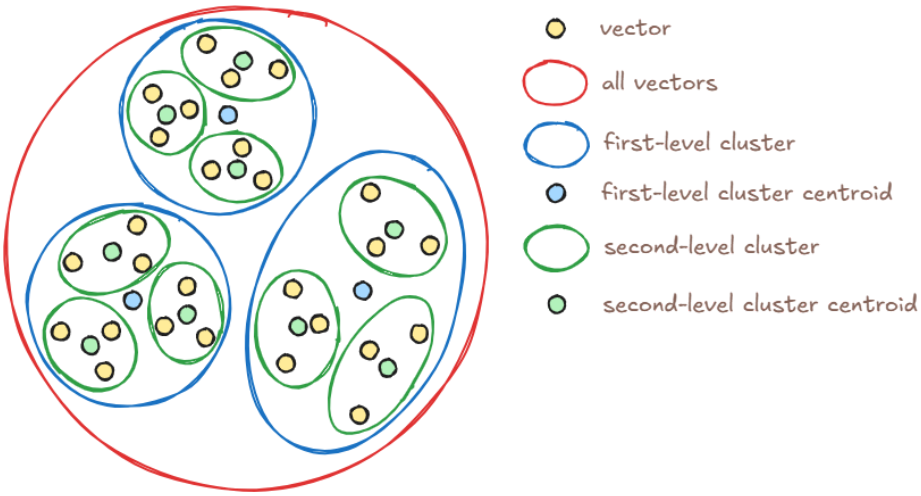
Vector index type: vector_kmeans_tree



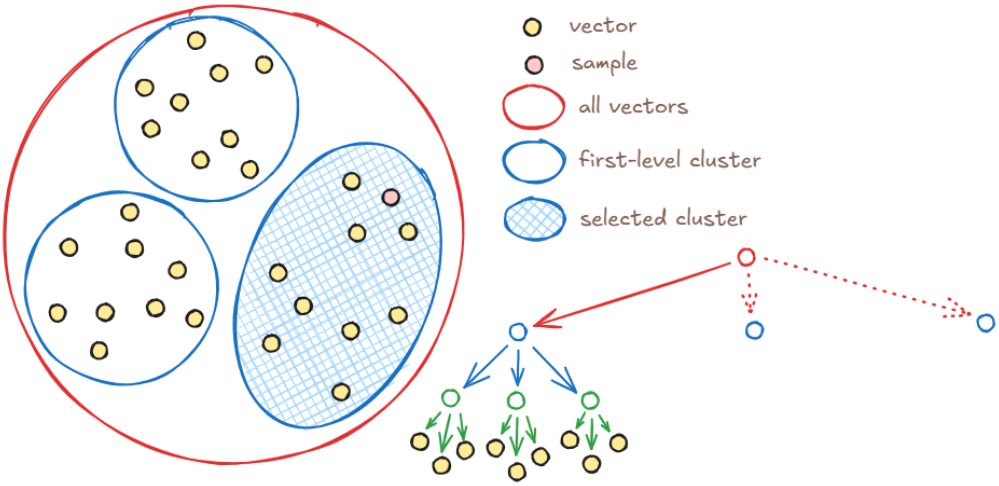
Vector indexes are specialized data structures that enable efficient vector search in multidimensional spaces. They are described in the overview; this article details the `vector_kmeans_tree` vector index type.

Creating the vector index

The `vector_kmeans_tree` algorithm recursively partitions all vectors to be searched into clusters using K-means. First, vectors are split into the number of clusters specified when creating the index via the vector index parameter `clusters`. For example, first-level clusters might look like this:

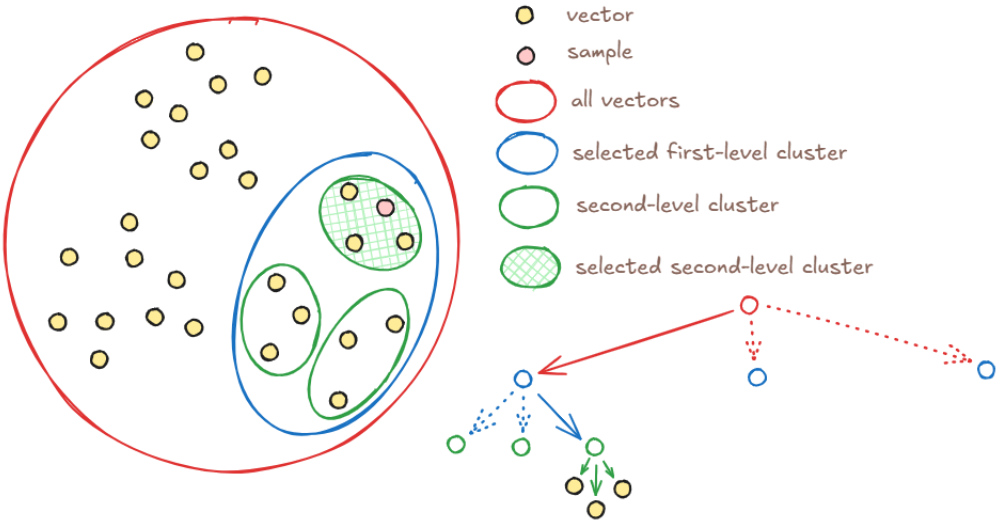


Each cluster is then split into the same number of clusters. Because each first-level cluster contains second-level clusters, a cluster tree is formed. The number of levels in the tree is set by the vector index parameter `levels`. For example, second-level clusters look like this:



The vector index tree will have three first-level clusters, each containing three second-level clusters, each of which in turn contains three vectors.

Search in the vector index



For search in a `vector_kmeans_tree` vector index, one of several clusters is chosen at each level; that cluster contains vectors similar to the query vector. To choose the right cluster, a centroid — the arithmetic mean of all vectors in the cluster — is computed and stored for each cluster.

After choosing a cluster at one level, YDB moves to the next level and considers the clusters that belong to the cluster chosen at the previous level. YDB compares distances between cluster centroids and the query vector and selects the cluster with the smallest distance. Approximate search assumes that if a cluster's centroid is closest to the query, the vectors in that cluster are also closest to the query.

Each first-level cluster is split into second-level clusters, and so on. The algorithm “descends” the tree step by step, each time selecting a smaller cluster until it reaches a leaf cluster that holds vectors instead of centroids. YDB scans these vectors and returns the requested number of nearest neighbors. By limiting the number of clusters at each level, YDB keeps search complexity at `O(1)`.

If a leaf cluster has fewer vectors than requested, YDB returns all vectors found. To improve recall in such cases, use the `KMeansTreeSearchTopSize` parameter described below.

Index parameters

YDB lets you configure the number of levels in the vector index with the `levels` parameter and the number of clusters per level with the `clusters` parameter. Choose these values based on the expected number of vectors and cluster characteristics: network latency between nodes, network throughput, and CPU performance.

Clusters in the vector index tree are stored in distributed storage. On each step down the tree, YDB reads from distributed storage and receives binary data with the list of vectors over the network. The time for this operation depends on datacenter hardware, network load, and the amount of data transferred between clusters.

Choosing one cluster at a level requires scanning all centroid vectors and computing the distance to the query. You can estimate scan speed on your hardware using this query.

For small datasets, set `levels` to 1. For billions of vectors, you may need to increase it to 4 and tune `clusters` for your hardware.

The optimal number of clusters largely depends on server performance — how many vectors they can scan per second. So after choosing `levels` from expected data volume and network latency, tune `clusters` using performance tests.

For most hardware configurations, 20 to 50 clusters is recommended; this range is chosen for typical 256-dimensional vectors and balances performance and search recall.

Also aim for a configuration where the leaf clusters of the vector index contain at most 512 vectors, so that scanning them stays within milliseconds.

For example, if you expect 10 million vectors, set `levels` to 3 and `clusters` to 50. The vector index will look like this:

- Level 1: 50 clusters of 200,000 vectors each;
- Level 2: each level-1 cluster split into 50 clusters of 4,000 vectors each;
- Level 3: each level-2 cluster split into 50 clusters of 80 vectors each.

Search recall tuning

If a cluster’s centroid is closest to the query, the vectors in that cluster are usually closer to the query than vectors in other clusters. For complex data topologies this may not hold, so YDB allows scanning vectors in more than one cluster per level.

The number of clusters participating in search is set by the `KMeansTreeSearchTopSize` parameter. By default it is 1: YDB picks one nearest cluster at the first level, then requests its child clusters at the second level over the network, picks one nearest again, and so on. This parameter is not set at index creation time but for the search.

If you set a larger value, e.g. 3, the system will select three nearest clusters at each level instead of one. Moving to the next level then requires fetching the child vectors of all three selected clusters over the network, from which the next three are chosen. This improves recall but increases network traffic and the number of vectors scanned.

Covering index

By default, the leaf cluster stores not the vectors themselves but only a list of keys of those vectors in the table. Such a list is called a Posting Table — a form of inverted index. Storing references to vectors instead of vectors minimizes the size of the vector index.

However, after finding the leaf cluster, YDB must run a `SELECT` against the table to fetch the vectors (the exact number depends on the size of the leaf cluster).

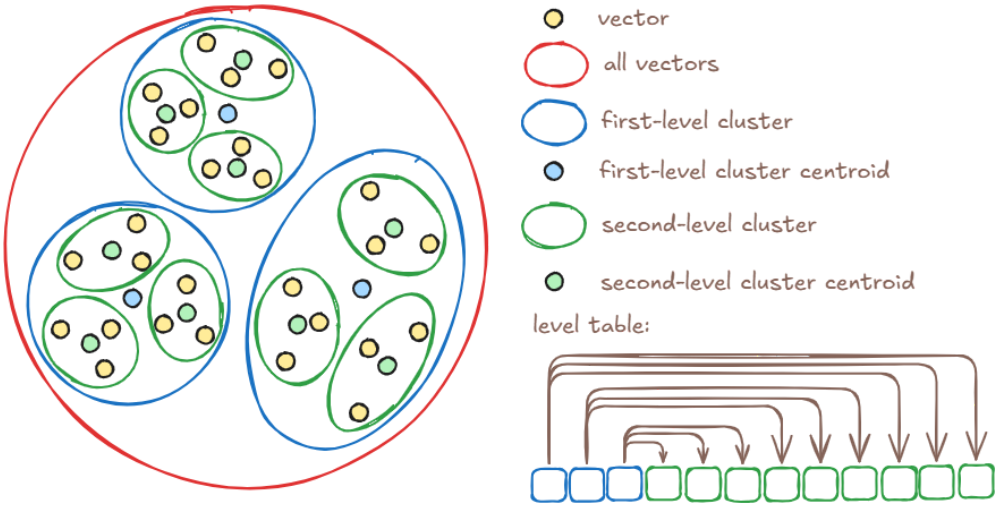
Fetching vectors from the leaf cluster can be slow if `clusters` is too large or the table index does not include the vector column. In such cases you can speed up search by increasing index size: if you make the index covering, vectors are stored in the index. Data is still read over the network from distributed storage, but that is faster than a full query to the indexed table.

A covering index can include not only vectors but any other columns from the indexed table. Then `SELECT`s on those columns will be faster at the cost of storing an extra copy of their data in the index.

A covering index can be made faster by enabling read from replicas.

Vector index with filtering

Often you need to filter by additional attributes or metadata. A vector index with filtering speeds up queries with WHERE conditions by returning similar objects only among those that match the filter. With such an index, nearest-neighbor search is restricted to rows that satisfy the filter, which keeps performance high on large datasets.

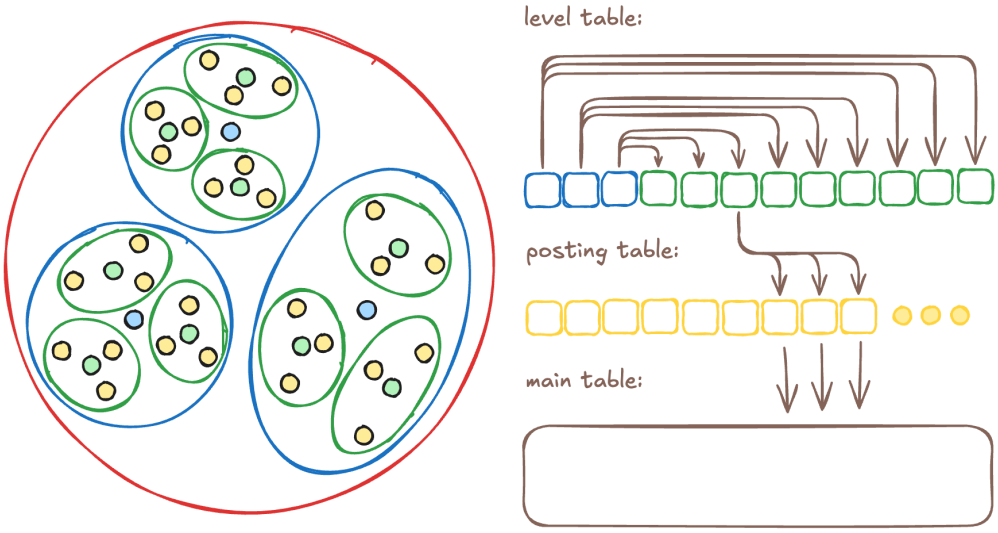


Fast, accurate filtered search is supported at the index structure level. The filtered column must be explicitly listed in the SQL index creation statement.

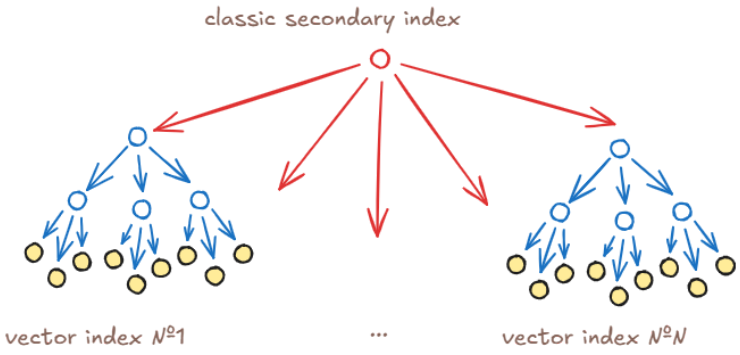
Filtering is built into the vector index because:

- If you filter before search, you get a set of rows in which to find nearest vectors. A normal vector index can only search over all vectors in the table, not an arbitrary subset. To find nearest vectors, the DB would have to scan all remaining rows and compute distance to the query for each.
- If you filter after search, you may get fewer results than needed and recall drops. You would have to repeat the search with a higher limit, which is also slow. In YDB, filtering is integrated into the vector index structure and algorithm, so rows that do not match the filter are excluded from consideration immediately.

Index internals



The index is implemented with two extra tables: the level table (`indexImplLevelTable`) and the posting table (`indexImplPostingTable`). The level table stores centroids for the cluster tree. YDB queries this table when moving from level to level during vector search. For example, if the vector index is built over 27 vectors with `levels=2` and `clusters=3`, the level table looks like this:



For each centroid in the level table, the parent cluster at the level above is also stored. YDB uses this to request only the centroids that belong to clusters selected at the previous level when moving down.

To avoid re-reading centroids from distributed storage on every query, the level table can be cached in memory on each node — see `resource_manager.kqp_level_cache_max_size_bytes` in `table_service_config`.

The posting table links the leaf-level centroids in the level table to the vectors in the source table. If a covering index is used, vectors and extra columns specified at index creation are also stored in this table:

With a filtered index, a regular secondary index on the filtered columns is added in front of the vector index. A separate vector index is built for each distinct value in the secondary index. The secondary index is stored in an extra relational table, the prefix table (`indexImplPrefixTable`), and all vector index trees remain in the level table:

Structure of table `indexImplLevelTable`

The primary key of this table includes the columns `__ydb_parent` and `__ydb_id`.

Column	Data type	Description
`__ydb_parent`	`Uint64`	Parent cluster identifier
`__ydb_id`	`Uint64`	Current cluster identifier
`__ydb_centroid`	`String`	Centroid vector of the current cluster

Structure of table `indexImplPostingTable`

The primary key of this table includes the column `__ydb_parent` and the columns that form the primary key of the indexed table (`id` in the example below).

Column	Data type	Description
`__ydb_parent`	`Uint64`	Identifier of the cluster containing the current vector
`id`	`Uint64`	Primary key of the indexed table that holds the vectors. Column names and types are copied from the indexed table.

Example structure of `indexImplPostingTable` with a covering index

With a covering index, the specified columns from the indexed table are copied into `indexImplPostingTable`. The primary key is the same as for `indexImplPostingTable` without covering. If the covering index includes the `embedding` column, the table looks like this:

Column	Data type	Description
`__ydb_parent`	`Uint64`	Identifier of the cluster containing the current vector
`id`	`Uint64`	Primary key of the indexed table that holds the vectors. Column names and types are copied from the indexed table.
`embedding`	`String`	Copy of the vector from the indexed table

Example structure of `indexImplPrefixTable` for a filtered index

With a filtered index, column names and types are copied from the indexed table into `indexImplPrefixTable`. If the index is filtered by the `category_id` column, the table looks like this:

Column	Data type	Description
`category_id`	`Uint64`	Column names and types are copied from the indexed table
`__ydb_id`	`Uint64`	Root cluster identifier of the vector index

Fulltext Indexes

Fulltext indexes are a specialized type of secondary index that enable efficient text search within table columns. While traditional secondary indexes optimize searching by equality or range, fulltext indexes allow searching by words, phrases, and (with n-grams) by substrings.

For the general idea of fulltext search, see Fulltext search.

Characteristics of Fulltext Indexes

Fulltext indexes in YDB are built by tokenizing text and creating an inverted index. This enables:

- fast filtering with FulltextMatch
- relevance ranking (BM25) with FulltextScore when using fulltext_relevance
- case normalization, stemming, and n-gram matching via index filters

The current implementation supports two indexes:

- fulltext_plain — basic fulltext index
- fulltext_relevance — fulltext index with BM25 statistics for relevance scoring

Additionally, a fulltext index can be **covering** (via `COVER`), meaning it includes a copy of extra columns from the base table.

Types of Fulltext Indexes

YDB supports two types of fulltext indexes, differing in the statistics they store:

- fulltext_plain — stores only the inverted index. Supports filtering via FulltextMatch, but does not support relevance ranking.
- fulltext_relevance — additionally stores term frequency statistics (TF-IDF / BM25) required by FulltextScore.

Indexes of either type can also be filtered to scope search to a specific logical partition.

Basic fulltext index (`fulltext_plain`)

Use `fulltext_plain` when you only need to check whether terms are present in the text, without relevance ranking. This index is more compact than `fulltext_relevance` and is suitable for most filtering tasks.

Example: create a global fulltext index on the `body` column:

```
ALTER TABLE articles
  ADD INDEX ft_index
  GLOBAL USING fulltext_plain
  ON (body)
  WITH (tokenizer=standard, use_filter_lowercase=true);
```

Here `tokenizer=standard` splits text into words on whitespace and punctuation, and `use_filter_lowercase=true` normalizes all tokens to lowercase, making the search case-insensitive.

Example query:

```
SELECT id, title
FROM articles VIEW ft_index
WHERE FulltextMatch(body, "search terms")
LIMIT 20;
```

Fulltext index for ranking (`fulltext_relevance`)

`fulltext_relevance` stores the inverted index along with term frequency statistics (BM25), which allows FulltextScore to compute a relevance score for each document. Use this type when you need not just to find documents containing certain words, but also to rank them by how well they match the query.

Example index:

```
ALTER TABLE articles
  ADD INDEX ft_index
  GLOBAL USING fulltext_relevance
  ON (body)
  WITH (tokenizer=standard, use_filter_lowercase=true);
```

Example ranking query:

```
SELECT id, title, FulltextScore(body, "search terms") AS relevance
FROM articles VIEW ft_index
WHERE FulltextScore(body, "search terms") > 0
ORDER BY relevance DESC
LIMIT 10;
```

Substring search (n-grams)

If you need substring search, create the index with n-grams. Two types of n-grams are available:

- **Regular n-grams** (`use_filter_ngram`) — split words into all possible substrings of specified length, allowing matches anywhere within a word. For example, the word "search" will be split into "sea", "ear", "arc", "rch", etc.
- **Edge n-grams** (`use_filter_edge_ngram`) — create substrings only from the beginning of words, which is ideal for autocomplete functionality. For example, the word "search" will be split into "se", "sea", "sear", "searc", "search".

When using n-grams, the following becomes available:

- FulltextMatch(..., "Wildcard" AS Mode) — patterns with `%` and `_` (similar to `LIKE`)

- `LIKE` / `ILIKE` predicates over the indexed text column — YDB automatically uses the n-gram index when accessed via `VIEW IndexName`

Example index with n-grams:

```
ALTER TABLE articles
  ADD INDEX ngram_index
  GLOBAL USING fulltext_plain
  ON (body)
  WITH (
    tokenizer=standard,
    use_filter_lowercase=true,
    use_filter_ngram=true,
    filter_ngram_min_length=3,
    filter_ngram_max_length=5
  );
```

Example query with `FulltextMatch`:

```
SELECT id, title
FROM articles VIEW ngram_index
WHERE FulltextMatch(body, "%learn%", "Wildcard" AS Mode)
LIMIT 20;
```

Example query with `LIKE`:

```
SELECT id, title
FROM articles VIEW ngram_index
WHERE body LIKE "%learn%ing%"
LIMIT 20;
```

A `LIKE` / `ILIKE` query uses the same logic as `FulltextMatch(body, ..., "Wildcard" AS Mode)` and accesses the same n-gram index.

Filtered fulltext index

A filtered fulltext index enables fulltext search within each logical partition defined by filter columns. To create such an index, specify one or more filter columns before the text column in the `ON` clause. The last column must be the text column; the others can be of any comparable type:

```
ALTER TABLE articles
  ADD INDEX ft_index
  GLOBAL USING fulltext_plain
  ON (user_id, body)
  WITH (tokenizer=standard, use_filter_lowercase=true);
```

Search queries using a filtered index must include an equality predicate on every filter column:

```
SELECT id, title
FROM articles VIEW ft_index
WHERE user_id = 42 AND FulltextMatch(body, "search terms")
LIMIT 20;
```

Multiple filter columns are supported. The equality predicates may appear in any order in `WHERE`; YDB reorders them internally to match the index column order.

Primary key types

Inside the inverted index, every indexed document is identified by a numeric document id (`doc_id`). How YDB derives the `doc_id` depends on the base table's primary key:

- **Single integer primary key** (`Uint64`, `Int64`, `Uint32`, or `Int32`) — the primary key value is used directly as the `doc_id`. This is the most compact form, and no additional structures are created.
- **Any other primary key** (for example, `Utf8`, `String`, other non-integer types, or a composite key of several columns) — YDB maintains a system column `__ydb_row_id` of type `Uint64` and uses it as the `doc_id`.

When you create a fulltext index on a table whose primary key is not a single integer column, YDB automatically:

- adds the `__ydb_row_id` column to the table — existing rows are backfilled while the index is being built;
- generates a `__ydb_row_id` value for every row where the column is omitted from `INSERT` / `UPSERT`;
- creates a unique secondary index named `__ydb_unique_row_id` over `__ydb_row_id`. At query time this index maps a matched `__ydb_row_id` back to the table's primary key before the row is read from the main table.

If the table already has more than one fulltext index, they all **reuse** the same `__ydb_row_id` column and `__ydb_unique_row_id` index — these structures are created only once per table.

Warning

The `__ydb_row_id` column and the `__ydb_unique_row_id` index are managed by YDB:

- Let YDB populate `__ydb_row_id` — omit it from `INSERT` / `UPSERT` and it is filled in automatically. User modification of the `__ydb_row_id` column is forbidden — any attempts to set or change the value of this column will be rejected.
- The `__ydb_unique_row_id` index cannot be dropped while any fulltext index depends on it. Drop the dependent fulltext index(es) first.

Full syntax for fulltext indexes

Creating a fulltext index:

- during table creation: CREATE TABLE
- adding to an existing table: ALTER TABLE

Full syntax for querying a fulltext index:

- VIEW (Fulltext index)

Functions and expressions for fulltext search:

- Fulltext built-in functions
- LIKE / ILIKE with a fulltext index

Note

The optimizer doesn't select a fulltext index automatically, so you must specify it explicitly using `VIEW IndexName`.

If the `VIEW` expression is not used, `FulltextMatch` / `FulltextScore` queries will fail.

This limitation may be removed in future versions of YDB.

Updating Fulltext Indexes

Fulltext indexes are maintained automatically on data modifications. Tables with fulltext indexes support:

- `INSERT`
- `UPSERT`
- `REPLACE`
- `UPDATE`
- `DELETE`

Dropping Fulltext Indexes

```
ALTER TABLE articles DROP INDEX ft_index;
```

Limitations

- Tables with a non-integer or composite primary key get an auto-managed `__ydb_row_id` column and `__ydb_unique_row_id` unique index (see Primary key types).
- `BulkUpsert` isn't supported for tables with fulltext indexes.
- Fulltext index access must be specified explicitly using `VIEW IndexName`.
- Only one text column can be indexed (per fulltext index). Use `COVER` for additional columns.
- `FulltextMatch` / `FulltextScore` can't be used with `OR` or `NOT`. Combining them with other predicates via `AND` is supported.
- A single read through `VIEW` supports only one fulltext predicate: multiple `FulltextScore` calls are not supported, and mixing `FulltextMatch` and `FulltextScore` in the same `WHERE` is not supported.
- For relevance access, you must include `FulltextScore(...) > 0` in `WHERE` (otherwise the query fails).
- Filtered fulltext indexes: every filter column needs an equality predicate in `WHERE`.
- Filtered fulltext indexes: filter columns must not be primary key columns.

Hybrid search

Hybrid search combines fulltext search and vector search into a single ranked result: each document is scored by both its text relevance and its embedding similarity, and the two rankings are fused into one. This brings together the precision of lexical matching and the recall of semantic similarity, and is a common building block for the retrieval stage of Retrieval-Augmented Generation (RAG).

For the general idea of hybrid search, see Hybrid search concept.

Hybrid search is not a separate index type. It reuses two existing indexes on the same table:

- a fulltext_relevance index over the text column — provides the BM25 relevance signal;
- a vector_kmeans_tree index over the embedding column — provides the nearest-neighbor (semantic) signal.

Preparing the indexes

Create a table with a text column and an embedding column, then add both indexes.

```
CREATE TABLE documents (
    id Uint64,
    text Utf8,
    embedding String,
    PRIMARY KEY (id)
);
```

Add a `fulltext_relevance` index over the text column (relevance scoring requires this type, not `fulltext_plain`):

```
ALTER TABLE documents
  ADD INDEX ft_idx
  GLOBAL USING fulltext_relevance
  ON (text)
  WITH (tokenizer=standard, use_filter_lowercase=true);
```

Add a `vector_kmeans_tree` index over the embedding column:

```
ALTER TABLE documents
  ADD INDEX vec_idx
  GLOBAL USING vector_kmeans_tree
  ON (embedding)
  WITH (distance=cosine);
```

For details on each index type, see Fulltext Indexes and Vector Indexes.

Running a hybrid query

A hybrid query is a regular `SELECT` over the base table (without `VIEW`) whose `ORDER BY` key is a single `HybridRank` call. `HybridRank` takes one scoring expression per branch: a FullTextScore for the text branch and a Knn distance or similarity for the vector branch.

```
PRAGMA ydb.KMeansTreeSearchTopSize = "10";

$queryText = "machine learning";
$queryVector = Knn::ToBinaryStringFloat([0.1, 0.2, 0.3, 0.4]);

SELECT id, text
FROM documents
ORDER BY HybridRank(
    FullTextScore(text, $queryText),
    Knn::CosineDistance(embedding, $queryVector))
LIMIT 10;
```

Both inputs come from the same user query: `$queryText` is the search text (matched lexically), and `$queryVector` is its embedding computed by the application (matched semantically). YDB cannot compute embeddings itself, so the vector is passed in — here it is built from a literal via Knn::ToBinaryStringFloat, but in an application it is the output of an embedding model.

YDB resolves each branch to its index automatically by the scored column (`text` → the fulltext relevance index, `embedding` → the vector index), retrieves a candidate pool from each, and fuses the two rankings. The result is the top `LIMIT` documents by the fused score.

Note that, unlike fulltext and vector search, a hybrid query does **not** use `VIEW IndexName`: the indexes are selected from the `HybridRank` arguments, and the query reads through the base table.

`PRAGMA ydb.KMeansTreeSearchTopSize` controls the recall of the vector branch — see KMeansTreeSearchTopSize. As with plain vector search, it should be set explicitly.

Tuning the fusion

The fusion method and its parameters are passed as named arguments to `HybridRank`. The most common ones:

- `Mode` — `"rrf"` (default, Reciprocal Rank Fusion) or `"linear"` (weighted sum of normalized scores);
- `Weights` — a per-branch weight tuple, one value per scoring argument, to bias the ranking toward one signal;
- `K` — the RRF constant (default `60.0`);
- `Indexes` / `Limits` — explicit per-branch index names and candidate-pool sizes.

For the built-in modes, the per-branch contribution is fixed by the formula. For full control over the fusion, pass a custom lambda instead of `Mode`:

- `RankLambda` — a lambda that receives each document's per-branch ranks (1-based position within each branch) and returns the fused score;
- `ScoreLambda` — a lambda that receives each document's per-branch raw scores (the fulltext relevance or vector distance/similarity) and returns the fused score.

A custom lambda replaces the built-in fusion, so it cannot be combined with `Mode`, `Weights`, `K`, or `Normalize` — fold any weights and constants into the lambda body. For a detailed description and examples, see Hybrid search query syntax (HybridRank).

For example, to weight the vector branch twice as much as the text branch under RRF:

```
$queryText = "machine learning";
$queryVector = Knn::ToBinaryStringFloat([0.1, 0.2, 0.3, 0.4]);

SELECT id, text
FROM documents
ORDER BY HybridRank(
    FullTextScore(text, $queryText),
    Knn::CosineDistance(embedding, $queryVector),
    (1, 2) AS Weights)
LIMIT 10;
```

For the full list of parameters and their semantics, see Hybrid search (HybridRank).

Limitations

- The table must have both a ready `fulltext_relevance` index and a non-prefixed `vector_kmeans_tree` index over the respective columns; otherwise the query fails with a clear message.
- Prefixed vector indexes are not supported yet.
- If more than one fulltext (or vector) index matches a branch's column, the branch is ambiguous and must be disambiguated with an explicit `AS Indexes` override.
- `LIMIT` must be a literal, because it sizes the per-branch candidate pools. To use a parameterized `LIMIT`, pass explicit `AS Limits`.
- `HybridRank(...)` must be the entire `ORDER BY` key — it cannot be negated, wrapped, or combined with other sort keys.
- A custom fusion lambda (`RankLambda` or `ScoreLambda`) replaces the built-in fusion and cannot be combined with `Mode`, `Weights`, `K`, or `Normalize`. At most one of `RankLambda` or `ScoreLambda` may be specified.

JSON indexes

JSON indexes are a type of secondary index implemented on top of an inverted index that speeds up filtering table rows by conditions imposed on the contents of columns of type `Json` and `JsonDocument`. The index is used if the `WHERE` predicate uses the functions JSON_EXISTS and JSON_VALUE with JsonPath expressions. Unlike traditional secondary indexes optimized for equality or range searches on individual table columns, a JSON index works with arbitrary paths within a JSON document.

For a general description of JSON search and the structure of an inverted index on JSON document paths, see the Searching JSON document contents section.

Characteristics of JSON indexes

JSON indexes in YDB allow:

- Quickly filter rows by JSON_EXISTS and JSON_VALUE with JsonPath expressions
- combine indexed conditions with `AND` and `OR` operators
- use query parameter values passed by the application when processing checked predicates.

A JSON index is a global synchronous index — its data is always consistent with the base table.

When executing a query, a JSON index can be applied:

- explicitly — via the `<table_name> VIEW <index_name>` operator
- automatically by the optimizer, if the predicate matches the formal rules.

Syntax of JSON indexes

Creating a JSON index:

- when creating a table: INDEX (CREATE TABLE)
- Adding to an existing table: ALTER TABLE.

Deleting JSON indexes is done via ALTER TABLE:

```
ALTER TABLE documents DROP INDEX json_idx
```

Query syntax with explicit JSON index specification:

- VIEW (JSON index).

Functions and expressions for working with JSON in predicates:

- JSON functions — `JSON_EXISTS` and `JSON_VALUE`
- JsonPath — a query language for accessing values inside JSON.

Ready-made use cases are collected in the JSON document search recipes section.

Updating JSON indexes

JSON indexes are automatically maintained when data is modified and are updated synchronously together with the main table. Tables with JSON indexes support:

- `INSERT`
- `UPSERT`
- `REPLACE`
- `UPDATE`
- `DELETE`

Batch operations (`BATCH UPDATE` and `BATCH DELETE`) are not supported for tables with JSON indexes. When attempting to execute such a query on a table for which a JSON index has been created, the query will be rejected, a corresponding error will be returned to the application, and the data will remain unchanged.

Additionally, tables with JSON indexes do not support:

- Bulk data loading via a `BulkUpsert` call — the requested operation will be rejected with a corresponding error message.
- automatic deletion of rows by TTL — errors are returned when attempting to create a table with both a TTL policy and a JSON index, as well as when trying to retrieve such a combination of properties using the `ALTER TABLE` commands.

Supported predicates

For execution via JSON indexes, only expressions based on the `JSON_EXISTS` and `JSON_VALUE` functions in the `WHERE` block, combined by the `AND` / `OR` operators according to the rules below, are supported.

JSON_EXISTS

Checking the existence of a path or value inside a JsonPath filter.

Allowed:

```
-- Document root (value not NULL)
WHERE JSON_EXISTS(doc, '$')

-- Key chain; array indexes are 'transparent'
WHERE JSON_EXISTS(doc, '$.user.name')
WHERE JSON_EXISTS(doc, '$.items[*].sku')
WHERE JSON_EXISTS(doc, '$.items[0 to last].active')

-- Filter ? (...) — predicates inside the filter are allowed
WHERE JSON_EXISTS(doc, '$.items ? (@.price == 100)')
WHERE JSON_EXISTS(doc, '$.items ? (@.qty >= 1 && @.qty <= 10)')
WHERE JSON_EXISTS(doc, '$.items ? (@.tag == $t)' PASSING "sale" AS t)

-- JsonPath methods (path is indexed up to the method; exact check is performed by post-filter)
WHERE JSON_EXISTS(doc, '$.value.type()')
WHERE JSON_EXISTS(doc, '$.arr.size()')

-- Combinations on one column
WHERE JSON_EXISTS(doc, '$.a') AND JSON_EXISTS(doc, '$.b')
WHERE JSON_EXISTS(doc, '$.a') OR JSON_EXISTS(doc, '$.b')
```

Prohibited (error when using the `VIEW` statement or index auto-selection failure):

```
-- Comparison predicates at the top level of the path (outside ? (...))
WHERE JSON_EXISTS(doc, '$.key == 10')
WHERE JSON_EXISTS(doc, 'exists($.key)')
WHERE JSON_EXISTS(doc, '$.key starts with "a"')

-- Negation in JsonPath
WHERE JSON_EXISTS(doc, '!($.key == 10)')

-- ON ERROR TRUE
WHERE JSON_EXISTS(doc, '$.key' TRUE ON ERROR)

-- Path without context operator ($) — the passed document is not used
WHERE JSON_EXISTS(doc, '1')
```

Note

The `JSON_EXISTS` function returns `true` for any non-empty JsonPath result. The `$.key == 10` predicate specified at the top level would give "path existence" even when the comparison is false, which does not match the expected semantics. Comparisons should be moved into `JSON_VALUE` calls or into a filter of the form `? (...)`.

JSON_VALUE

Extracting a scalar value with a required `RETURNING <type>`.

To compare a value using `JSON_VALUE`, you must always specify `RETURNING` with the required type. By default, `JSON_VALUE` returns type `Utf8`, which leads to incorrect comparison during query execution — values of different types are compared as strings:

```
$tmp = Json(@@["1", 1]@@);
SELECT JSON_VALUE($tmp, '$[0]') == "1"; -- true: correct, string compared with string
SELECT JSON_VALUE($tmp, '$[1]') == "1"; -- true: incorrect, number compared with string
```

Supported types for the `RETURNING` section: `Int8` … `Int64`, `Uint8` … `Uint64`, `Float`, `Double`, `Bytes` (`String`), `Text` (`Utf8`), `Bool`.

Examples of predicates applied via a JSON index:

```
-- Equality (path + value are included in the index)
WHERE JSON_VALUE(doc, '$.user.age' RETURNING Int32) = 25
WHERE JSON_VALUE(doc, '$.flag' RETURNING Bool) = true
WHERE JSON_VALUE(doc, '$.name' RETURNING Utf8) = "Alice"u

-- Implicit comparison with true for Bool
WHERE JSON_VALUE(doc, '$.active' RETURNING Bool)

-- Parameters
WHERE JSON_VALUE(doc, '$.user.id' RETURNING Int64) = $id
WHERE JSON_VALUE(doc, '$.tag' RETURNING Utf8) = $tag

-- Comparisons (only the path is used in the index, comparison is performed by post-filter)
WHERE JSON_VALUE(doc, '$.score' RETURNING Int64) > 0
WHERE JSON_VALUE(doc, '$.score' RETURNING Int64) != 100
WHERE JSON_VALUE(doc, '$.score' RETURNING Int64) BETWEEN 1 AND 10
WHERE JSON_VALUE(doc, '$.score' RETURNING Int64) NOT BETWEEN 0 AND 5

-- IN: list of literals
WHERE JSON_VALUE(doc, '$.status' RETURNING Utf8) IN ("open"u, "pending"u)

-- IN: specified parameter of type List<Utf8>
WHERE JSON_VALUE(doc, '$.status' RETURNING Utf8) IN $status_list

-- PASSING for JsonPath variables
WHERE JSON_VALUE(doc, '$.x ? (@.y == $v)' RETURNING Int64 PASSING 42 AS v) = 10

-- JsonPath predicates inside the path.
-- Unlike JSON_EXISTS, predicates at the top level are allowed.
WHERE JSON_VALUE(doc, '$.user ? (@.role == "admin")' RETURNING Utf8) = "ok"u
WHERE JSON_VALUE(doc, '$.code starts with "A"' RETURNING String) != ""
WHERE JSON_VALUE(doc, 'exists($.meta)' RETURNING Bool)

-- AND / OR combinations on one column
WHERE JSON_VALUE(doc, '$.a' RETURNING Int32) = 1
   OR JSON_VALUE(doc, '$.b' RETURNING Int32) = 2
WHERE JSON_EXISTS(doc, '$.a') AND JSON_VALUE(doc, '$.a' RETURNING Int32) = 10
```

Examples of predicates that cannot be applied via a JSON index:

```
-- JSON_VALUE call without RETURNING
WHERE JSON_VALUE(doc, '$.key') = "x"

-- DEFAULT with ON EMPTY / ON ERROR (except NULL)
WHERE JSON_VALUE(doc, '$.k' RETURNING Utf8 DEFAULT "x" ON ERROR) = "y"

-- Unsupported data type in RETURNING
WHERE JSON_VALUE(doc, '$.ts' RETURNING Timestamp) = ...

-- RETURNING Bool with comparison operators
WHERE JSON_VALUE(doc, '$.flag' RETURNING Bool) >= true

-- IS NULL / IS NOT NULL — semantically contradict the 'path existence' index
WHERE JSON_VALUE(doc, '$.k' RETURNING Utf8) IS NULL

-- Comparison of two JSON_VALUE from different columns
WHERE JSON_VALUE(doc1, '$.k' RETURNING Utf8) = JSON_VALUE(doc2, '$.k' RETURNING Utf8)

-- Nested JSON_* in arguments
WHERE JSON_VALUE(JSON_QUERY(doc, '$.a'), '$.b' RETURNING Utf8) = "x"
```

Note

To check 'value equals `false`' or 'value equals `null`', use a JsonPath filter inside `JSON_EXISTS`, for example `JSON_EXISTS(doc, '$.k ? (@ == false)')` or `JSON_EXISTS(doc, '$.k ? (@ == null)')`, not `JSON_VALUE(...) IS NULL`.

Limitations

- JSON indexes are supported only for row tables.
- The table's primary key must consist of a single column of an integer type (`Uint64`, `Uint32`, `Int64`, or `Int32`). This is a temporary limitation that will be removed in future development.
- A single JSON index indexes exactly one column of type `Json` or `JsonDocument`.
- The `COVER` expression is not supported for JSON indexes.
- A number of data modification operations and mechanisms are not supported for tables with JSON indexes.
- The parameter type of a read query from the index cannot be wrapped in `Optional<T>` — optional parameters are not supported.
- Equality comparison with an integer literal whose absolute value exceeds 2^{53} is not accelerated by the value index (such numbers do not fit into the numeric type used in `Json` and `JsonDocument`) and is reduced to a path existence check.
- Casting floating-point literals (`Float`, `Double`) to integer types during comparison is not performed — such comparison is not accelerated by the index.

Recipes

Ready-made scenarios for working with a JSON index:

- JSON index – quick start — quick start.
- Catalog with nested attributes — product catalog with nested attributes.
- Parameterized queries and JsonPath variables — parameterized queries and JsonPath variables.
- Checking field type and path existence — field type check and path existence.

Related materials

- JSON functions — `JSON_EXISTS`, `JSON_VALUE`, `JSON_QUERY`, JsonPath syntax.
- Secondary indexes — general information about global indexes and `VIEW`.
- Full-text indexes — a related mechanism built on top of an inverted index of words and phrases.
- INDEX (CREATE TABLE) and VIEW (JSON index) — syntax reference.

Local indexes

Local indexes are auxiliary structures stored together with table data and applied while reading from storage. Unlike global indexes, they do not materialize a separate index table and are not selected in queries with `VIEW`.

This section contains practical materials on local index types:

- Bloom skip indexes — Bloom indexes for accelerating selective queries by skipping data fragments.
- min_max index — min_max index that skips data fragments based on saved value ranges.

Bloom skip indexes

Bloom skip indexes are local auxiliary structures based on a Bloom filter that speed up selective queries by skipping data fragments that cannot contain the requested value. Unlike global secondary indexes, they act as read-time filters on the main table and reduce the amount of data that must be actually read.

Types

YDB supports two types:

- `bloom_filter`: a filter over exact values of the indexed column; use for equality and `IN` (see when to use which).
- `bloom_ngram_filter`: a filter over n-grams of a string column (`String`, `Utf8`); use for substring and `LIKE` pattern search on column-oriented tables.

Local bloom skip indexes

The `bloom_filter` type is supported on both row-oriented (OLTP) and column-oriented (OLAP) tables, but the underlying implementation differs:

- On row-oriented tables, the filter is built as a prefix bloom filter over a left prefix of the primary key. The indexed columns must be a contiguous leading subset of the primary key columns. This accelerates point lookups and range scans that constrain the leading key columns. Use ALTER TABLE ... ADD INDEX to create a prefix bloom filter and ALTER TABLE ... DROP INDEX to remove it.
- On column-oriented tables, the filter is built over the indexed column values in each data fragment (portion). It is applied during analytical scans to skip fragments that cannot contain the requested value.

`bloom_ngram_filter` is supported only on column-oriented tables.

Parameters and defaults

Full list of `WITH (...)` parameters and defaults:

- `bloom_filter`
  - `false_positive_probability`: Target false-positive rate of the filter: the fraction of fragments that are not skipped even though the requested value is not there (range `(0, 1)`). A lower value reduces extra reads but increases index size.
    - If omitted, the default is `0.0001` for row-oriented tables and `0.1` for column-oriented tables. The stricter default on row-oriented tables matches OLTP point lookups; on column-oriented tables it reflects analytical scans, where a larger trade-off between index size and fragment skipping is acceptable.
  - Indexed columns: YQL types that support equality comparison, except `Yson`, `Json`, and `JsonDocument` (see comparison operators). One column in a column-oriented table; multiple columns in a row-oriented table. On row-oriented tables, the indexed columns must form a left prefix of the primary key.
- `bloom_ngram_filter` (`String` and `Utf8` columns; column-oriented tables only)
  - `ngram_size`: N-gram length, an integer from `3` to `8` (default `3`).
  - `false_positive_probability`: Target false-positive rate (range `(0, 1)`; default `0.1`).
  - `case_sensitive`: Whether n-grams respect character case: `true` or `false` (default `true`).

Creation syntax: CREATE TABLE, ALTER TABLE ADD INDEX.

To change parameters after creation, use ALTER INDEX.

Examples

Create a table with a `bloom_filter` index:

```
CREATE TABLE events (
    id Uint64,
    resource_id Utf8,
    message Utf8,
    PRIMARY KEY (id),
    INDEX idx_bloom LOCAL USING bloom_filter
        ON (resource_id)
        WITH (false_positive_probability = 0.01)
);
```

Add a `bloom_ngram_filter` index to an existing table:

```
ALTER TABLE events
  ADD INDEX idx_ngram LOCAL USING bloom_ngram_filter
  ON (message)
  WITH (
    ngram_size = 3,
    false_positive_probability = 0.01,
    case_sensitive = true
  );
```

Create a row-oriented (OLTP) table with prefix bloom filters on primary-key prefixes. On row-oriented tables the indexed columns must be a left prefix of the primary key:

```
CREATE TABLE orders (
    customer_id Utf8,
    order_id Utf8,
    amount Decimal(10,2),
    PRIMARY KEY (customer_id, order_id),
    -- Prefix bloom filter on the first key column
    INDEX idx_customer LOCAL USING bloom_filter
        ON (customer_id)
        WITH (false_positive_probability = 0.001),
    -- Prefix bloom filter on the full primary key
    INDEX idx_full_key LOCAL USING bloom_filter
        ON (customer_id, order_id)
);
```

Alter index parameters:

```
ALTER TABLE events ALTER INDEX idx_ngram SET (
    ngram_size = 4,
    false_positive_probability = 0.005,
    case_sensitive = false
);
```

Parameter tuning

If queries still read too much data after deploying the index, try lowering `false_positive_probability`. If the index uses too much space, try raising it.

Use `ALTER INDEX` to change values, as in the example above.

Tips:

- Start with `false_positive_probability = 0.01`, then adjust based on real read metrics and index size.
- For `bloom_ngram_filter`, `ngram_size` typically starts at `3`; increasing it can make filtering stricter for longer substrings.
- Change one parameter at a time and compare results under the same workload.

Behavior and limitations

- The index is always local (`LOCAL`); there is no global variant.
- Queries do not use the `VIEW <index>` syntax (unlike, for example, fulltext indexes).
- The filter is applied on read only to data fragments where an index block was already stored during a write or portion merge, other fragments are not skipped by this index until merge.
- On row-oriented tables, `bloom_filter` is implemented as a **prefix bloom filter**: the indexed columns must form a left prefix of the primary key. The filter is built over that key prefix and accelerates point lookups and range scans that constrain the prefix. Multiple bloom indexes over the same prefix length are not allowed.

Limitations

- `COVER (...)` and extra index columns are not supported.
- Column-oriented tables allow only one indexed column. Row-oriented tables allow multiple indexed columns.
- `bloom_ngram_filter` is not supported on row-oriented tables.
- On row-oriented tables, the indexed columns of a `bloom_filter` must be a left prefix of the primary key. Non-prefix column sets are rejected.
- On row-oriented tables, two `bloom_filter` indexes cannot share the same prefix length (the same set of leading primary-key columns).

min_max index

min_max index is a local index that speeds up scanning queries with a highly selective filter by skipping fragments. Unlike global secondary indexes, it acts as a read filter for the base table and reduces the amount of data that actually needs to be read.

For each indexed data fragment, the min_max index stores the minimum and maximum value of one column. During query execution, YDB evaluates the predicate on these two values. If the evaluation results show that the predicate will filter out all tuples of the fragment, the fragment is skipped.

Examples

Creation syntax: CREATE TABLE, ALTER TABLE ADD INDEX.

Creating a columnar table with a min_max index:

```
CREATE TABLE events (
    id Uint64,
    created_at Timestamp,
    level Int32,
    resource_id Utf8,
    PRIMARY KEY (id),
    INDEX idx_created_at LOCAL USING min_max
        ON (created_at),
    INDEX idx_level LOCAL USING min_max
        ON (level)
)
WITH (
    STORE = COLUMN
);
```

Adding a min_max index to an existing columnar table:

```
ALTER TABLE events
  ADD INDEX idx_resource_id LOCAL USING min_max
  ON (resource_id);
```

Queries with range predicates can use the index to skip non-matching fragments:

```
SELECT id, resource_id
FROM events
WHERE created_at BETWEEN Timestamp("2024-01-01T00:00:00.000000Z")
                     AND Timestamp("2024-01-02T00:00:00.000000Z");
```

When to use

The min_max index is useful when the values of the indexed column change little between rows that are adjacent in the primary key order: for example, timestamps, monotonically increasing identifiers, or other values correlated with the primary key.

The min_max index can also be useful when the filter predicate selects a very small fraction of the data (on the order of one row per million). For example, when querying a service log table and keeping only records with the `ERROR` level: if the service writes one error per 1,000,000 records, the min_max index will likely significantly reduce the read volume.

Features and limitations

- The index is always local (`LOCAL`); there is no global variant.
- Queries do not use the `VIEW <index>` syntax (unlike, for example, full-text indexes).
- The filter is applied during reads only to data fragments for which the minimum and maximum values of the indexed column have already been computed and stored with the table data at write time or merge. For other fragments, no skip by this index is performed.

Limitations

- Supported only for columnar tables.
- `ON (...)` must specify exactly one column.
- `COVER (...)` and additional data columns are not supported.
- Specific parameters of `WITH (...)` are not supported.
- `ALTER INDEX` is not supported for the min_max index.
- Columns of types `Json` and `JsonDocument` are not supported.

Additional materials

- Secondary indexes
- Local indexes
- YQL reference: CREATE TABLE
- YQL reference: SELECT
- YQL reference: ALTER TABLE

Query execution optimization

When executing queries against a database, the SQL text is converted into a query plan suitable for distributed execution on a cluster. The same query can often be executed in many different ways, and the optimizer in YDB chooses the most efficient one.

Using query optimization tools in YDB, you can:

- understand how the database plans to execute a query;
- analyze how the query was actually executed;
- identify and use opportunities to speed up execution.

> **Note**
>
> The examples in this section use the TPC-H dataset. The table schema and relationships are described in the TPC-H specification. Some examples are queries from the benchmark adapted for YDB; others were prepared specifically to illustrate the material. The SQL source for all examples lets you reproduce everything described.

How the database plans to execute a query

After compilation and optimization, a query execution plan is built — a sequence of operators that need to be executed to obtain the result. This plan can be obtained using the `--explain` parameter of the CLI command `ydb sql` without actually processing data. This plan will reflect the query execution structure and contain estimates from the cost-based optimizer, based on the existing **source data statistics**, such as the number of rows in the table and its size in bytes.

This plan is output in JSON format, but for studying it, it is more convenient to represent it as a visualization. The available options depend on how the query was executed (SDK, CLI, UI) — see Query execution plan.

How the query was actually executed

For a more detailed and specific analysis of query execution, YDB collects **execution statistics**:

- Duration of individual steps (operators).
- Volumes of transferred data.
- Waits that occurred during interaction between individual nodes of the distributed system.

Each step of the plan is executed as a set of tasks, in parallel on many nodes. Detailed information for each individual task would take up too much space; instead, it is processed by the server and, for each set of identical tasks, published in an aggregated form, enriching the plan in JSON format.

But even in aggregated form, **execution statistics** are still too large for independent analysis. To solve this problem, a special way of visualizing this statistics together with the plan in SVG format has been developed. To learn how to obtain such a plan, see Query execution plan.

What you can do to speed up query execution

This section focuses on analyzing and interpreting query execution plans: it discusses ways to understand how the server plans and executes queries, as well as how to identify bottlenecks by examining the plan and related metrics. Practical aspects of speeding up work are covered by finding potential optimization points based on the analysis of this data.

Section structure

- Query execution plan
- Optimizer hints
- Parameterized queries and recompilation

Query execution plan

It's very useful to to analyze execution plans for queries in order to detect and eliminate the causes of possible inefficiencies. YDB provides two types of query plans: logical plan and execution plan. Logical plan is better suited for analyzing complex queries with a large number of JOIN operators. Execution plan is more detailed: it additionally shows the stages of the distributed plan and connectors between them, which makes it more convenient for analyzing simple OLTP queries.

Logical Query Plan

You can get the logical plan via YDB CLI.

This plan allows you to compare the query optimizer's predictions with the execution statistics. If the predictions differ significantly from the actual data at the execution stage, this may indicate that the optimizer has not built the most efficient plan for the current query. In this case, you can use optimizer hints to create a more efficient plan.

Query Execution Plan

To illustrate how to work with the execution plan, consider the following OLTP query that searches for a series by name:

```
SELECT season_id, episode_id
  FROM episodes
  WHERE title = 'The Work Outing'
```

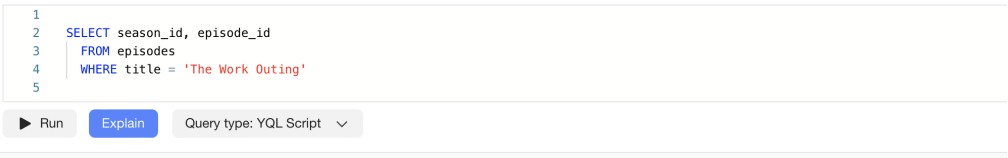
Schema of the `episodes` table:

Id	Key	Name	Type	NotNull
1	🔑	series_id	Uint64	
2	🔑	season_id	Uint64	
3	🔑	episode_id	Uint64	
5		air_date	Uint64	
4		title	Utf8	

Let's build a query execution plan for this query. You can do this via either UI or YDB CLI:

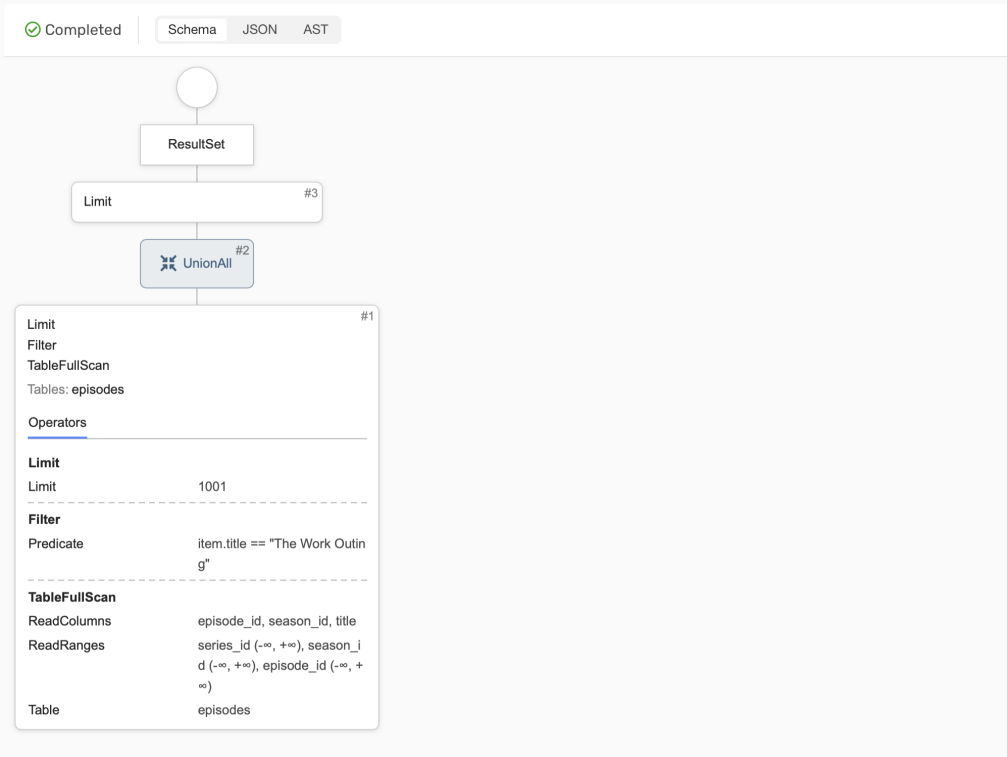
YDB CLI

You can build a query plan via YDB CLI using the following command:



```
ydb -p <profile_name> table query explain \
  -q "SELECT season_id, episode_id
  FROM episodes
  WHERE title = 'The Work Outing'"
```

Result:



```
Query Plan:
ResultSet
└──Limit (Limit: 1001)
   └──<UnionAll>
      └──Limit (Limit: 1001)
      └──Filter (Predicate: item.title == "The Work Outing")
      └──TableFullScan (ReadRanges: ["series_id (-∞, +∞)","season_id (-∞, +∞)","episode_id (-∞, +∞)"], ReadCo
lumns: ["episode_id","season_id","title"], Table: episodes)
         Tables: ["episodes"]
```

YDB UI

You can also build a query plan via YDB UI. You need to navigate to the database page, go to the `Query` section, type the query text, and click on `Explain`:

Result:

Both plan representations contain the result being returned to the client at the root, table operations at the leaves, and data transformations at the intermediate nodes. It is important to pay attention to the node containing the table reading operation. In this case, it is a `TableFullScan` for the `episodes` table. Full table scans consume time and resources proportional to the size of the table, so it is advisable to avoid them whenever possible in tables that tend to grow over time or are simply large.

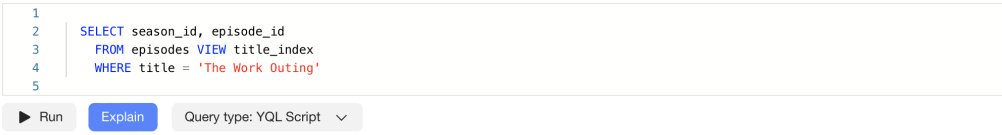
One typical approach to avoid full scans is using a secondary index. In this case, it makes sense to add a secondary index for the column `title` using the following query:

```
ALTER TABLE episodes
  ADD INDEX title_index GLOBAL ON (title)
```

Please note that this example uses synchronous secondary index. Building an index in YDB is an asynchronous operation. Even if the index creation query is successful, it is advisable to wait for some time because the index may not be ready for use immediately. You can manage asynchronous operations through the CLI.

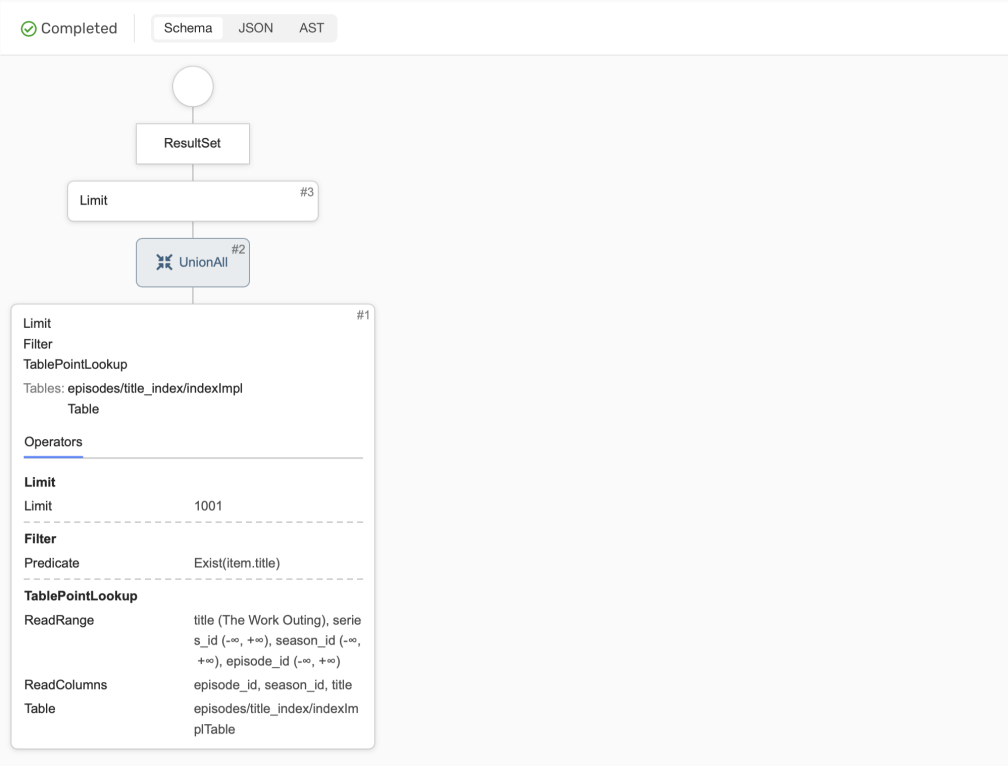
Let's build the query plan using the secondary index `title_index`. Secondary indexes to be used need to be explicitly specified in the `VIEW` clause.

YDB CLI



Command:

```
ydb -p <profile_name> table query explain \
  -q "SELECT season_id, episode_id
  FROM episodes VIEW title_index
  WHERE title = 'The Work Outing'"
```



Result:

```
Query Plan:
ResultSet
└──Limit (Limit: 1001)
   └──<UnionAll>
      └──Limit (Limit: 1001)
      └──Filter (Predicate: Exist(item.title))
      └──TablePointLookup (ReadRange: ["title (The Work Outing)","series_id (-∞, +∞)","season_id (-∞, +∞)","episode_id (-∞, +∞)"], ReadLimit: 1001, ReadColumns: ["episode_id","season_id","title"], Table: episodes/title_index/indexImplTable)
         Tables: ["episodes/title_index/indexImplTable"]
```

YDB UI

Result:

The secondary index allowed the query to be executed without fully scanning the main table. Instead of a `TableFullScan,` we received a `TablePointLookup`—reading the index table by key. We no longer need to read the main table because all necessary columns are contained in the index table.

Optimizer hints

Optimizer hints allow you to influence the behavior of the cost-based optimizer when planning the execution of SQL queries. YDB supports four types of hints for managing joins and statistics.

Usage

Hints are specified via the `PRAGMA ydb.OptimizerHints` pragma at the beginning of the SQL query.
If the optimizer was unable to apply at least one of the specified hints to the query, the user will be notified via a warning.

Syntax

Hints are specified as a string containing an array of expressions of one of four types:

```
JoinType(TableList JoinType)
Rows(TableList Op Value)
Bytes(TableList Op Value)
JoinOrder(JoinTree)

where:
TableList - list of table names or aliases from the query
Op - operation:
- `#` - set absolute value
- `*` - multiply by value
- `/` - divide by value
- `+` - add value
- `-` - subtract value
- `Number` - absolute numeric value
Value - numeric value
JoinTree - representation of binary tree using parentheses, for example: (R S) (T U)
```

For example, the following query uses 3 cardinality (number of records) hints `Rows`, a total join order hint `JoinOrder`, and a join algorithm selection hint `JoinType`:

```
PRAGMA ydb.OptimizerHints =
'
    Rows(R # 10e8)
    Rows(T # 1)
    Rows(R T # 1)
    JoinOrder( (R S) (T U) )
    JoinType(T U Broadcast)
';

SELECT * FROM
    R   INNER JOIN  S   on  R.id = S.id
        INNER JOIN  T   on  R.id = T.id
        INNER JOIN  U   on  T.id = U.id;
```

Requirements for CBO (Cost Based Optimizer)

> **Note**
>
> All hints (`Rows`, `Bytes`, `JoinOrder`) work only with **enabled** cost based optimizer, except `JoinType` - it can be specified even if CBO is disabled.

Hint types

JoinType - Join algorithm

Allows you to force the join algorithm for specific tables.

There are currently three types of join algorithms supported in YDB:

- BroadcastJoin - is a join type where one of the data sets is small enough to be copied (broadcasted) to all required nodes in the cluster. This allows each node to perform the join locally, without transmitting the data over the network.

> **Note**
>
> If the join order is not fixed by a separate hint, the optimizer will build both variants of the plan: where the left and right input of the join is broadcasted. If the join order is fixed by a hint, the right side of the join will be broadcasted.

- ShuffleJoin is a type of join in which the data is divided (shuffled) by the join key so that records with the same key are processed on the same processing node. After such a redistribution of data, each node performs a local join of the tables. The results are combined into one common data set.
- LookupJoin - for each row of one input, a query is made to the table or index of the other input, currently supported only for row tables.

> **Note**
>
> If the join order is not fixed by a separate hint, the optimizer will build both variants of the plan: where queries are made to the left and right inputs of the join. If the join order is fixed by a hint, queries will be made to the right side of the join.

Syntax

```
JoinType(t1 t2 ... tn Broadcast | Shuffle | Lookup)
```

Parameters

- `t1 t2 ... tn` - tables involved in the join
- Algorithm:
- `Broadcast` - select the BroadcastJoin algorithm
- `Shuffle` - select the ShuffleJoin algorithm
- `Lookup` - select the LookupJoin algorithm

How it works

If the query plan contains a join operator that joins only those tables listed in the hint, the optimizer will choose the specified join algorithm if it is applicable (for example, you cannot apply the LookupJoin algorithm to column-oriented tables). If the algorithm cannot be applied, the user will be notified via a warning.

Examples

```
-- Use Broadcast to join tables nation, region
JoinType(nation region Broadcast)

-- Use HashJoin for a join whose subtree will contain only tables customers, orders, products
JoinType(customers orders products Shuffle)

JoinType(nation region Lookup)
```

Apply join algorithm hints to the following query:

```
PRAGMA ydb.OptimizerHints =
'
JoinType(R S Shuffle)
JoinType(R S T Broadcast)
JoinType(R S T U Shuffle)
JoinType(R S T U V Broadcast)
';

SELECT * FROM
R INNER JOIN S on R.id = S.id
INNER JOIN T on R.id = T.id
INNER JOIN U on T.id = U.id
INNER JOIN V on U.id = V.id;
```

You can view the query plan using the CLI command:

```
 ydb -p <profile_name> sql --explain -f query.sql
```

```
┌──────────────────────────────────────────────────────────────────────────────────────────────┐
│ Operation                                                                                    │
├──────────────────────────────────────────────────────────────────────────────────────────────┤
│ ┌─> ResultSet                                                                                │
│ └─┬─> InnerJoin (MapJoin) (U.id = V.id)                                                      │
│   ├─┬─> InnerJoin (Grace) (T.id = U.id)                                                      │
│   │ ├─┬─> HashShuffle (KeyColumns: ["T.id"], HashFunc: "HashV2")                             │
│   │ │ └─┬─> InnerJoin (MapJoin) (R.id = T.id)                                                │
│   │ │   ├─┬─> InnerJoin (Grace) (R.id = S.id)                                              │
│   │ │   │ ├─┬─> HashShuffle (KeyColumns: ["id"], HashFunc: "HashV2")                       │
│   │ │   │ │ └──> TableFullScan (Table: R, ReadColumns: ["id (-∞, +∞)","payload1","ts"])   │
│   │ │   │ └─┬─> HashShuffle (KeyColumns: ["id"], HashFunc: "HashV2")                       │
│   │ │   │   └──> TableFullScan (Table: S, ReadColumns: ["id (-∞, +∞)","payload2"])        │
│   │ │   └──> TableFullScan (Table: T, ReadColumns: ["id (-∞, +∞)","payload3"])            │
│   │ └─┬─> HashShuffle (KeyColumns: ["id"], HashFunc: "HashV2")                           │
│   │   └──> TableFullScan (Table: U, ReadColumns: ["id (-∞, +∞)","payload4"])              │
│   └──> TableFullScan (Table: V, ReadColumns: ["id (-∞, +∞)","payload5"])                  │
└──────────────────────────────────────────────────────────────────────────────────────────────┘
```

Since the optimizer may change the join order during query optimization, the join hint should reflect the exact list of tables that are being joined.
For example, in this query, the join order is assumed to be R with S, then T, and finally U. Specifying a different join algorithm may change the join order in the plan, and some join hints will not be applied. In this case, you can add an additional join order hint.

2. Rows - Cardinality Hints

Allows you to change the expected number of rows (optimizer estimate) for a join result or individual tables.

How it works

The optimizer will change its estimate of the cardinality (number of rows) for a join operation that joins only listed tables.

Syntax

```
Rows(t1 t2 ... tn (*|/|+|-|#) Number)
```

Parameters

- `t1 t2 ... tn` - tables
- Operation:
- `*` - multiply by value
- `/` - divide by value
- `+` - add value
- `-` - subtract value
- `#` - replace value
- `Number` - numeric value

Examples

```
-- Multiply expected row count by 2 for join in subtree which contains only tables users orders yandex
Rows(users orders yandex * 2.0)

-- Replace cardinality of table products by 1.3e6
Rows(products # 1.3e6)

-- Reduce expected row count by 228 times
Rows(filtered_table / 228)

-- Add 5000 rows to the expected result
Rows(table1 table2 + 5000)
```

Let's run the query without cardinality hints, and then see how the hints change the query plan.

```
SELECT * FROM
R INNER JOIN S on R.id = S.id
INNER JOIN T on R.id = T.id;
```

Without hints, the optimizer builds the following plan:

```
┌─────────┬─────────┬─────────┬──────────────────────────────────────────────────────────────────────────────────────┐
│ E-Cost  │ E-Rows  │ E-Size  │ Operation                                                                            │
├─────────┼─────────┼─────────┼──────────────────────────────────────────────────────────────────────────────────────┤
│         │         │         │ ┌> ResultSet                                                                         │
│ 114     │ 10      │ 300     │ └─┬> InnerJoin (MapJoin) (S.id = R.id)                                               │
│ 57      │ 10      │ 200     │   ├─┬> InnerJoin (MapJoin) (S.id = T.id)                                             │
│ 0       │ 10      │ 100     │   │ ├──> TableFullScan (Table: S, ReadColumns: ["id (-∞, +∞)","payload2"])         │
│ 0       │ 10      │ 100     │   │ └──> TableFullScan (Table: T, ReadColumns: ["id (-∞, +∞)","payload3"])         │
│ 0       │ 10      │ 100     │   └──> TableFullScan (Table: R, ReadColumns: ["id (-∞, +∞)","payload1","ts"])      │
└─────────┴─────────┴─────────┴──────────────────────────────────────────────────────────────────────────────────────┘
```

If we specify the following hints:

```
PRAGMA ydb.OptimizerHints =
'
    Rows(R # 10e8)
    Rows(T # 1)
    Rows(S # 10e8)
    Rows(R T # 1)
    Rows(R S # 10e8)
';
SELECT * FROM
    R   INNER JOIN  S   on  R.id = S.id
        INNER JOIN  T   on  R.id = T.id;
```

The resulting plan will look like:

```
┌─────────────┬─────────┬─────────┬──────────────────────────────────────────────────────────────────────────────────────
──┐
│ E-Cost      │ E-Rows  │ E-Size  │ Operation
│
├─────────────┼─────────┼─────────┼──────────────────────────────────────────────────────────────────────────────────────
──┤
│             │         │         │ ┌> ResultSet
│
│ 3.000e+09   │ 1       │ 100     │ └─┬> InnerJoin (MapJoin) (S.id = R.id)
│

│
│ 1.500e+09   │ 1       │ 100     │   └─┬> InnerJoin (MapJoin) (R.id = T.id)
│
│ 0           │ 1e+09   │ 100     │     ├──> TableFullScan (Table: R, ReadColumns: ["id (-∞, +∞)","payload1","t
s"]) │
│ 0           │ 10      │ 100     │     └──> TableFullScan (Table: T, ReadColumns: ["id (-∞, +∞)","payload3"])
│
└─────────────┴─────────┴─────────┴──────────────────────────────────────────────────────────────────────────────────────
──┘
```

Also a warning will be issued:

```
Warning: Unapplied hint: Rows(R S # 10e8)
```

Here you can see that after applying the cardinality hints of the base tables, the order of the joins changed, and one of the hints could not be applied, since there is no such join in the plan.

3. Bytes - Data Size Hints

Allows you to change the expected data size in bytes for a join or individual tables.

Syntax

```
Bytes(t1 t2 ... tn (*|/|+|-|#) Number)
```

Parameters are similar to Rows, but apply to the size of the data in bytes

Examples

```
-- Multiply the expected data size by 1.5
Bytes(large_table * 1.5)

-- Replace the size of the data for the connection with 1GB
Bytes(table1 table2 # 1073741824)

-- Reduce the expected size by 2
Bytes(compressed_table / 2)

-- Add 100MB to the expected size
Bytes(temp_table + 104857600)
```

4. JoinOrder - Join order

Allows you to fix a specific subtree of joins in the overall join tree.

Syntax

```
JoinOrder((t1 t2) (t3 (t4 ...)))
```

Parameters

- Nested parentheses structure defines the join order
- `(t1 t2)` means that t1 and t2 must be joined first
- You can set any nesting depth

How it works

The optimizer will only consider plans that have the specified partial or full join order.

Examples

```
-- Force users to join orders first, then products
JoinOrder((users orders) products)

-- More complex join order
JoinOrder(((customers orders) products) shipping)

-- Join grouping
JoinOrder((table1 table2) (table3 table4))

-- Multi-level structure
JoinOrder((users (orders products)) (addresses phones))
```

Let's apply the join order hint to the following query:

```
SELECT * FROM
R INNER JOIN S on R.id = S.id
INNER JOIN T on R.id = T.id;
```

The query plan without specifying hints is displayed as follows:

```
┌─────────┬────────┬────────┬──────────────────────────────────────────────────────────────────────────────────┐
│ E-Cost  │ E-Rows │ E-Size │ Operation                                                                        │
├─────────┼────────┼────────┼──────────────────────────────────────────────────────────────────────────────────┤
│         │        │        │ ┌> ResultSet                                                                     │
│ 114     │ 10     │ 300    │ └─┬> InnerJoin (MapJoin) (S.id = R.id)                                           │
│ 57      │ 10     │ 200    │   ├─┬> InnerJoin (MapJoin) (S.id = T.id)                                         │
│ 0       │ 10     │ 100    │   │ ├──> TableFullScan (Table: S, ReadColumns: ["id (-∞, +∞)","payload2"])     │
│ 0       │ 10     │ 100    │   │ └──> TableFullScan (Table: T, ReadColumns: ["id (-∞, +∞)","payload3"])     │
│ 0       │ 10     │ 100    │   └──> TableFullScan (Table: R, ReadColumns: ["id (-∞, +∞)","payload1","ts"]) │
└─────────┴────────┴────────┴──────────────────────────────────────────────────────────────────────────────────┘
```

Here you can see that the order of connections has changed to the one specified in the hint.

Combining hints

You can use several types of hints simultaneously within one pragma:

```
PRAGMA ydb.OptimizerHints =
'
    JoinType(users orders Broadcast)
    Rows(users orders * 0.5)
    JoinOrder((users orders) products)
    Bytes(products # 1073741824)
';
```

Parameterized queries and recompilation

Query compilation takes time and resources, so YDB provides a compile cache. The compilation result is stored in the cache on a cluster node and reused only when the query **text matches exactly**. If your application builds YQL with string concatenation or formatting, each new set of values produces a **different text**, and the server recompiles it even when the SQL structure is the same.

Consequences:

- higher latency at the compilation stage;
- increased CPU load on nodes;
- with many unique query texts, reuse of the limited per-node cache gets worse.

A **parameterized query** helps avoid extra compilation: the YQL text stays fixed, and input values are passed separately via named parameters (for example, `$userId`). Below, both approaches are compared on the same example.

Embedding values in the query text

The application inserts values directly into the query text:

```
SELECT id, name FROM users WHERE id = 123 AND status = "active";
SELECT id, name FROM users WHERE id = 456 AND status = "inactive";
```

The queries differ only in values, but the texts are different — for the server these are two different queries, and each one is compiled separately.

Passing values as parameters

The application passes values separately from the text; the query text does not change:

```
DECLARE $userId AS Uint64;
DECLARE $status AS Utf8;

SELECT id, name FROM users WHERE id = $userId AND status = $status;
```

The server handles calls to such a query differently:

1. **First call** — the server compiles the query and stores the result in the cache on the node.
2. **Later calls** — if the text is already in the cache, the ready result is reused: only `$userId` and `$status` change; recompilation is not required.

Only values can be passed as parameters: you cannot parameterize a table name or sort order; changing them changes the query text.

See Query compile cache for cache contents, and Top queries for compilation time when queries run (the `CompileDuration` field).

Cache size and settings, the `KeepInCache` flag, `DECLARE` syntax, and passing parameters from code are described in Parameterized queries in the YDB SDK reference.

Uploading data to YDB

This section provides recommendations on efficiently uploading data to YDB.

There are anti-patterns and non-optimal settings for uploading data. They don't guarantee acceptable data uploading performance. To accelerate data uploads, consider the following recommendations:

- Shard a table when creating it. This lets you effectively use the system bandwidth as soon as you start uploading data.
  - By default, a new table consists of a single shard. YDB supports automatic table sharding by data volume. This means that a table shard is divided into two shards when it reaches a certain size.
  - The acceptable size for splitting a table shard is 2 GB. As the number of shards grows, the data upload bandwidth increases, but it remains low for some time at first. Therefore, when uploading a large amount of data for the first time, we recommend initially creating a table with the desired number of shards. You can calculate the number of shards based on 1 GB of data per shard in a resulting set.
- Insert multiple rows in each transaction to reduce the overhead of the transactions themselves.
  - Each transaction in YDB has some overhead. It is recommended to make transactions that insert multiple rows to reduce the total overhead. Good performance indicators terminate a transaction when it reaches 1 MB of data or 100,000 rows.
  - When uploading data, avoid transactions that insert a single row.
- Within each transaction, insert rows from the primary key-sorted set to minimize the number of shards affected by each transaction.
  - In YDB, transactions that span multiple shards have a higher overhead compared to transactions that involve exactly one shard. Moreover, this overhead increases with the growing number of table shards involved in the transaction.
  - We recommend selecting rows to be inserted in a particular transaction so that they're located in a small number of shards, ideally, in one.
- If you need to push data to multiple tables, we recommend pushing data to a single table within a single query.
- If you need to push data to a table with a synchronous secondary index, we recommend that you first push data to a table and, when done, build a secondary index.
- You should avoid writing data sequentially in ascending or descending order of the primary key. Writing data to a table with a monotonically increasing key causes all new data to be written to the end of the table since all tables in YDB are sorted by ascending primary key. As YDB splits table data into shards based on key ranges, inserts are always processed by the same server responsible for the "last" shard. Concentrating the load on a single server will result in slow data uploading and inefficient use of a distributed system.
- Some use cases require writing the initial data (often large amounts) to a table before enabling OLTP workloads. In this case, transactionality at the level of individual queries is not required, and you can use `BulkUpsert` calls in the CLI, SDK and API. Since no transactionality is used, this approach has a much lower overhead than YQL queries. In case of a successful response to the query, the `BulkUpsert` method guarantees that all data added within this query is committed.

> **Warning**
>
> The `BulkUpsert` method isn't supported for tables with synchronous secondary indexes.

We recommend the following algorithm for efficiently uploading data to YDB:

1. Create a table with the desired number of shards based on 1 GB of data per shard.
2. Sort the source data set by the expected primary key.
3. Partition the resulting data set by the number of shards in the table. Each part will contain a set of consecutive rows.
4. Upload the resulting parts to the table shards concurrently.
5. Make a `COMMIT` after every 100,000 rows or 1 MB of data.

Paginated output

This section provides recommendations for organizing paginated data output.

To organize paginated output, we recommend selecting data sorted by primary key sequentially, limiting the number of rows with the LIMIT keyword.

Note

`$lastCity, $lastNumber`: Primary key values obtained from the previous query.

A query demonstrating the recommended way to organize paginated output:

```
--  Table `schools`:
-- ┌─────────┬──────────┬─────┐
-- | Name    | Type     | Key |
-- ├─────────┼──────────┼─────┤
-- | city    | Utf8?    | K0  |
-- | number  | Uint32?  | K1  |
-- | address | Utf8?    |     |
-- └─────────┴──────────┴─────┘

DECLARE $limit AS Uint64;
DECLARE $lastCity AS Utf8;
DECLARE $lastNumber AS Uint32;

SELECT * FROM schools
WHERE (city, number) > ($lastCity, $lastNumber)
ORDER BY city, number
LIMIT $limit;
```

In the query example shown above, the `WHERE` clause uses a tuple comparison to select the next set of rows. Tuples are compared element by element from left to right, so the order of the fields in the tuple must match the order of the fields in the primary key to avoid table full scan.

NULL value in key column

In YDB, all columns, including key ones, may have a NULL value. Despite this, using `NULL` as key column values is highly discouraged, since the SQL standard doesn't allow `NULL` to be compared. As a result, concise SQL statements with simple comparison operators won't work correctly. Instead, you'll have to use cumbersome statements with `IS NULL` / `IS NOT NULL` expressions.

Examples of paginated output implementation

- C++
- Java
- Python
- Go

Using timeouts

This section describes available timeouts and provides examples of their usage in various programming languages.

Prerequisites for using timeouts

The timeout mechanism in YDB is designed to:

- Make sure the query execution time doesn't exceed a certain interval after which its result is not interesting for further use.
- Detect network connectivity issues.

Both of these use cases are important for ensuring the fault tolerance of the entire system. Let's take a closer look at timeouts.

Operation timeout

The `operation_timeout` value shows the time during which the query result is interesting to the user. If the operation fails during this time, the server returns an error with the `Timeout` code and tries to terminate the query, but its cancellation is not guaranteed. So the query that the user was returned the `Timeout` error for can be both successfully executed on the server and canceled.

Timeout for canceling an operation

The `cancel_after` value shows the time after which the server will start canceling the query, if it can be canceled. If canceled, the server returns the `Cancelled` error code.

Transport timeout

The client must set a transport timeout for each query. This value lets you determine the amount of time that the client is ready to wait for a response from the server. If the server doesn't respond during this time, the client will get a transport error with the `DeadlineExceeded` code. Be sure to set such a client timeout value that won't trigger transport timeouts under the normal operation of the application and network.

Using timeouts

We recommend that you always set an operation timeout and transport timeout. The value of the transport timeout should be 50-100 milliseconds more than that of the operation timeout, that way there is some time left for the client to get a server error with the `Timeout` code.

Timeout usage example:

Python

```python
import ydb

def execute_in_tx(session, query):
  settings = ydb.BaseRequestSettings()
  settings = settings.with_timeout(0.5)  # transport timeout
  settings = settings.with_operation_timeout(0.4)  # operation timeout
  settings = settings.with_cancel_after(0.4)  # cancel after timeout
  session.transaction().execute(
      query,
      commit_tx=True,
      settings=settings,
  )
```

C++

```cpp
#include <ydb/public/sdk/cpp/client/ydb.h>
#include <ydb/public/sdk/cpp/client/ydb_table.h>
#include <ydb/public/sdk/cpp/client/ydb_value.h>

using namespace NYdb;
using namespace NYdb::NTable;

TAsyncStatus ExecuteInTx(TSession& session, TString query, TParams params) {
  return session.ExecuteDataQuery(
      query
      , TTxControl::BeginTx(TTxSettings::SerializableRW()).CommitTx()
      , TExecDataQuerySettings()
      .OperationTimeout(TDuration::MilliSeconds(300))  // operation timeout
      .ClientTimeout(TDuration::MilliSeconds(400))   // transport timeout
      .CancelAfter(TDuration::MilliSeconds(300)));  // cancel after timeout
}
```

Go

```
import (
  "context"
  "time"

  ydb "github.com/ydb-platform/ydb-go-sdk/v3"
  "github.com/ydb-platform/ydb-go-sdk/v3/table"
)

func executeInTx(ctx context.Context, s table.Session, query string) {
ctx, cancel := context.WithTimeout(ctx, time.Millisecond*500) // transport timeout
defer cancel()
ctx = ydb.WithOperationTimeout(ctx, time.Millisecond*400)     // operation timeout
ctx = ydb.WithOperationCancelAfter(ctx, time.Millisecond*400) // cancel after timeout
tx := table.TxControl(table.BeginTx(table.WithSerializableReadWrite()), table.CommitTx())
_, res, err := s.Execute(ctx, tx, query, table.NewQueryParameters())
}
```

System database views

To obtain system information about the database state, you can refer to system views. They are available from the root of the database tree and use the system path prefix `.sys`.

> **Note**
>
> Frequent access to system views leads to additional load on the database, especially in the case of a large database size. Exceeding a frequency of 1 query per second is not recommended.

Partitions

The following system view stores detailed information about partitions of database tables:

- `partition_stats` — contains information about instantaneous metrics and cumulative counters of operations. The former include, for example, CPU load data or the number of running transactions. The latter include the total number of rows read.

It is intended, for example, for identifying unevenly loaded partitions or displaying the size of data in them.

Instantaneous metrics (`NodeId`, `AccessTime`, `CPUCores`, etc.) contain instantaneous values.
Cumulative (non-instantaneous) metrics (`RowReads`, `RowUpdates`, `LocksAcquired`, etc.) store accumulated values since the last start of the tablet (`StartTime`) serving the partition.

View structure:

Column	Description	Data type	Instantaneous/Cumulative
`OwnerId`	Table SchemeShard ID. Key: `0`.	`Uint64`	Instant
`PathId`	Path identifier in SchemeShard. Key: `1`.	`Uint64`	Instant
`PartIdx`	Partition sequence number. Key: `2`.	`Uint64`	Instantaneous
`FollowerId`	Identifier of the replica of the partition tablet. A value of 0 means the leader. Key: `3`.	`Uint32`	Instantaneous
`DataSize`	Approximate data size of the partition in bytes.	`Uint64`	Instantaneous
`RowCount`	Approximate number of rows.	`Uint64`	Instant
`IndexSize`	Partition index size in bytes.	`Uint64`	Instantaneous
`CPUCores`	Instantaneous load value on the partition (fraction of CPU core time spent by the partition actor).	`Double`	Instant
`TabletId`	Partition tablet identifier.	`Uint64`	Instantaneous
`Path`	Full path to the table.	`Utf8`	Momentary
`NodeId`	Node ID on which the partition is currently served.	`Uint32`	Instantaneous
`StartTime`	Last start time of the partition tablet.	`Timestamp`	Instantaneous
`AccessTime`	Last read moment from the partition.	`Timestamp`	Instantaneous
`UpdateTime`	Last write moment to the partition.	`Timestamp`	Instant
`RowReads`	Number of reads by key.	`Uint64`	Cumulative
`RowUpdates`	Number of written rows.	`Uint64`	Cumulative
`RowDeletes`	Number of deleted rows.	`Uint64`	Cumulative
`RangeReads`	Number of reads by key range.	`Uint64`	Cumulative
`RangeReadRows`	Number of rows read in ranges.	`Uint64`	Cumulative
`InFlightTxCount`	Number of running transactions.	`Uint64`	Instant
`ImmediateTxCompleted`	Number of completed single-shard transactions.	`Uint32`	Cumulative
`CoordinatedTxCompleted`	Number of completed distributed transactions.	`Uint64`	Cumulative
`TxRejectedByOverload`	Number of transactions cancelled due to high load.	`Uint64`	Cumulative
`TxRejectedByOutOfStorage`	Number of transactions cancelled due to insufficient storage space.	`Uint64`	Cumulative
`TxCompleteLag`	Transaction execution delay (how far transactions lag behind the scheduled time).	`Interval`	Instantaneous
`LastTtlRunTime`	Last start time of partition cleanup by TTL	`Timestamp`	Instant
`LastTtlRowsProcessed`	Number of partition rows checked during the last TTL cleanup	`Uint64`	Instant

`LastTtlRowsErased`	Number of partition rows deleted during the last TTL cleanup	`Uint64`	Instant
`LocksAcquired`	Number of acquired locks.	`Uint64`	Cumulative
`LocksWholeShard`	Number of set whole-shard locks.	`Uint64`	Cumulative
`LocksBroken`	Number of broken locks.	`Uint64`	Cumulative

Query examples

Top 5 most loaded partitions among all database tables:

```
SELECT
    Path,
    PartIdx,
    CPUCores
FROM `.sys/partition_stats`
ORDER BY CPUCores DESC
LIMIT 5
```

List of database tables with sizes and current load:

```
SELECT
    Path,
    COUNT(*) as Partitions,
    SUM(RowCount) as Rows,
    SUM(DataSize) as Size,
    SUM(CPUCores) as CPU
FROM `.sys/partition_stats`
GROUP BY Path
```

List of database tables with the highest number of broken locks:

```
SELECT
    Path,
    COUNT(*) as Partitions,
    SUM(LocksBroken) as TotalLocksBroken
FROM `.sys/partition_stats`
GROUP BY Path
ORDER BY TotalLocksBroken DESC
```

Top queries

The following system views store data for analyzing user queries.

Maximum total query execution time:

- `top_queries_by_duration_one_minute` — data is divided into minute intervals, contains data for the last 6 hours.
- `top_queries_by_duration_one_hour`: data is split into hourly intervals, contains data for the last 2 weeks.

The largest number of bytes read from the table:

- `top_queries_by_read_bytes_one_minute` — data is split into minute intervals, contains data for the last 6 hours.
- `top_queries_by_read_bytes_one_hour` — data is split into hour intervals, contains data for the last 2 weeks.

Maximum CPU time spent:

- `top_queries_by_cpu_time_one_minute` — data is split into minute intervals, contains data for the last 6 hours.
- `top_queries_by_cpu_time_one_hour` — data is split into hour intervals, contains data for the last 2 weeks.

Queries with the same text are combined, and the query with the maximum value of the corresponding metric is included in the output. Each time interval (minute or hour) contains the TOP-5 queries executed in that time interval.

Fields providing information about CPU time spent (... `CPUTime`) are expressed in microseconds.

Query text is limited to 10 kilobytes.

All views have the same structure:

Column	Description
`IntervalEnd`	End time of the minute or hour interval for which statistics were collected. Type: `Timestamp`. Key: `0`.
`Rank`	Query rank in the top. Type: `Uint32`. Key: `1`.
`QueryText`	Query text. Type: `Utf8`.
`Duration`	Total query execution time. Type: `Interval`.
`EndTime`	End time of query execution. Type: `Timestamp`.

`Type`	Query type ("data", "scan", "script"). Type: `String`.
`ReadRows`	Number of rows read. Type: `Uint64`.
`ReadBytes`	Number of bytes read. Type: `Uint64`.
`UpdateRows`	Number of rows written. Type: `Uint64`.
`UpdateBytes`	Number of bytes written. Type: `Uint64`.
`DeleteRows`	Number of rows deleted. Type: `Uint64`.
`DeleteBytes`	Number of bytes deleted. Type: `Uint64`.
`Partitions`	Number of table partitions involved in query execution. Type: `Uint64`.
`UserSID`	User security ID. Type: `String`.
`ParametersSize`	Size of query parameters in bytes. Type: `Uint64`.
`CompileDuration`	Query compilation duration. Type: `Interval`.
`FromQueryCache`	Whether the prepared query cache was used. Type: `Bool`.
`CPUTime`	Total CPU time used for query execution (microseconds). Type: `Uint64`.
`ShardCount`	Number of shards involved in query execution. Type: `Uint64`.
`SumShardCPUTime`	Total CPU time spent in shards. Type: `Uint64`.
`MinShardCPUTime`	Minimum CPU time spent in shards. Type: `Uint64`.
`MaxShardCPUTime`	Maximum CPU time spent in shards. Type: `Uint64`.
`ComputeNodesCount`	Number of compute nodes involved in query execution. Type: `Uint64`.
`SumComputeCPUTime`	Total CPU time spent in compute nodes. Type: `Uint64`.
`MinComputeCPUTime`	Minimum CPU time spent in compute nodes. Type: `Uint64`.
`MaxComputeCPUTime`	Maximum CPU time spent in compute nodes. Type: `Uint64`.
`CompileCPUTime`	CPU time spent on query compilation. Type: `Uint64`.
`ProcessCPUTime`	CPU time spent on general query processing. Type: `Uint64`.

Query examples

Top queries by execution time. The query is run against the `.sys/top_queries_by_duration_one_minute` view:

```
PRAGMA AnsiInForEmptyOrNullableItemsCollections;
$last = (
    SELECT
        MAX(IntervalEnd)
    FROM `.sys/top_queries_by_duration_one_minute`
);
SELECT
    IntervalEnd,
    Rank,
    QueryText,
    Duration
FROM `.sys/top_queries_by_duration_one_minute`
WHERE IntervalEnd IN $last
```

Queries that read the most bytes. The query is run against the `.sys/top_queries_by_read_bytes_one_minute` view:

```
SELECT
    IntervalEnd,
    QueryText,
    ReadBytes,
    ReadRows,
    Partitions
FROM `.sys/top_queries_by_read_bytes_one_minute`
WHERE Rank = 1
```

Detailed query information

The following system view contains detailed query information:

- `query_metrics_one_minute` — data is split into minute intervals, contains up to 256 queries for the last 6 hours.

Each row of the view contains information about multiple queries with the same text that occurred during the interval. The view fields contain the minimum, maximum, and total values for each tracked query characteristic. Within the interval, queries are sorted in descending order of total CPU time spent.

Limitations:

- query text is limited to 10 kilobytes.
- statistics may be incomplete if the database is under heavy load.

View structure:

Column	Description
`IntervalEnd`	End time of the minute interval for which statistics were collected Type: `Timestamp`. Key: `0`.
`Rank`	Query rank within the interval (by SumCPUTime field). Type: `Uint32`. Key: `1`.
`QueryText`	Query text. Type: `Utf8`.
`Count`	Number of query runs. Type: `Uint64`.
`SumDuration`	Total query duration. Type: `Interval`.
`MinDuration`	Minimum query duration. Type: `Interval`.
`MaxDuration`	Maximum query duration. Type: `Interval`.
`SumCPUTime`	Total CPU time spent. Type: `Uint64`.
`MinCPUTime`	Minimum CPU time spent. Type: `Uint64`.
`MaxCPUTime`	Maximum CPU time spent. Type: `Uint64`.
`SumReadRows`	Total number of rows read. Type: `Uint64`.
`MinReadRows`	Minimum number of rows read. Type: `Uint64`.
`MaxReadRows`	Maximum number of rows read. Type: `Uint64`.
`SumReadBytes`	Total number of bytes read. Type: `Uint64`.
`MinReadBytes`	Minimum number of bytes read. Type: `Uint64`.
`MaxReadBytes`	Maximum number of bytes read. Type: `Uint64`.
`SumUpdateRows`	Total number of rows written. Type: `Uint64`.
`MinUpdateRows`	Minimum number of rows written. Type: `Uint64`.
`MaxUpdateRows`	Maximum number of rows written. Type: `Uint64`.
`SumUpdateBytes`	Total number of bytes written. Type: `Uint64`.

`MinUpdateBytes`	Minimum number of bytes written. Type: `Uint64`.
`MaxUpdateBytes`	Maximum number of bytes written. Type: `Uint64`.
`SumDeleteRows`	Total number of rows deleted. Type: `Uint64`.
`MinDeleteRows`	Minimum number of rows deleted. Type: `Uint64`.
`MaxDeleteRows`	Maximum number of rows deleted. Type: `Uint64`.
`LocksBrokenAsBreaker`	Number of locks broken by this query. Type: `Uint64`.
`LocksBrokenAsVictim`	Number of locks of this query that were broken. Type: `Uint64`.

Note

This statistic does not include:

- Locks broken due to schema changes, TTL, asynchronous replication
- Locks broken due to partition splitting or merging
- Locks broken during tablet restart
- Locks broken when committing interactive transactions (when COMMIT is executed as a separate query)

Query examples

Top 10 queries over the last 6 hours by total number of rows written in a minute interval:

```
SELECT
    SumUpdateRows,
    Count,
    QueryText,
    IntervalEnd
FROM `.sys/query_metrics_one_minute`
ORDER BY SumUpdateRows DESC LIMIT 10
```

Recent queries that read the most bytes per minute:

```
SELECT
    IntervalEnd,
    SumReadBytes,
    MinReadBytes,
    SumReadBytes / Count as AvgReadBytes,
    MaxReadBytes,
    QueryText
FROM `.sys/query_metrics_one_minute`
WHERE SumReadBytes > 0
ORDER BY IntervalEnd DESC, SumReadBytes DESC
LIMIT 100
```

Detailed information about session queries

The following system view contains detailed information about current sessions and the queries being executed in them.

- `.sys/query_sessions` — contains information about sessions and the queries being executed in them.

Column	Description
`SessionId`	Unique session identifier. Type: `Utf8`. Key: `0`.
`NodeId`	Identifier of the node where the session is running. Type: `Uint32`.
`State`	Current session state. Type: `Utf8`.
`Query`	Text of the last or currently executing query. Type: `Utf8`.
`QueryCount`	Number of queries executed within this session. Type: `Uint32`.
`ClientAddress`	Network address of the client that initiated the session. Type: `Utf8`.
`ClientPID`	Process ID (PID) of the client application. Type: `Utf8`.

`ClientUserAgent`	Client software information (User-Agent). Type: `Utf8`.
`ClientSdkBuildInfo`	Client SDK build information. Type: `Utf8`.
`ApplicationName`	Application name specified by the client when connecting. Type: `Utf8`.
`SessionStartAt`	Session start (creation) time. Type: `Timestamp`.
`QueryStartAt`	Start time of the current query execution. Type: `Timestamp`.
`StateChangeAt`	Time of the last session state change. Type: `Timestamp`.
`UserSID`	Security ID of the user owning the session. Type: `Utf8`.
`WmPoolId`	Identifier of the Workload Manager pool in which the session query is executed. Type: `Utf8`.
`WmState`	Query state in Workload Manager. Type: `Utf8`.
`WmEnterTime`	Time when the query transitioned to PENDING or DELAYED status. Type: `Timestamp`.
`WmExitTime`	Time when the query was submitted for execution. Type: `Timestamp`.

Possible values of the `WmState` field:

- `NONE` - Not being processed.
- `PENDING` - Being processed (in classification/routing).
- `DELAYED` - In queue.
- `EXITED` - Submitted for execution.

Possible values of the `State` field:

- `IDLE` - Session is waiting for a query.
- `EXECUTING` - Query is being executed.

Query examples

View all active sessions:

```
SELECT * FROM `.sys/query_sessions`
```

Top 20 longest running queries:

```
SELECT
    Query,
    SessionId,
    NodeId,
    QueryStartAt
FROM `.sys/query_sessions`
WHERE State = 'EXECUTING'
ORDER BY QueryStartAt ASC
LIMIT 20
```

Search for application sessions filtered by Workload Manager pool:

```
SELECT
    SessionId,
    Query,
    State,
    WmState,
    ClientAddress
FROM `.sys/query_sessions`
WHERE ApplicationName = 'my_analytics_app'
  AND WmPoolId = 'heavy_queries'
```

Query compilation cache

The following system view contains information about queries stored in the compilation cache on all cluster nodes:

- `compile_cache_queries` — contains information about queries in the compilation cache of all cluster nodes.

> **Warning**
>
> The `compile_cache_queries` system view is not available in serverless mode.

Each cluster node has its own cache of compiled queries. This cache is used by all sessions running on that node: if during query execution its text is already in the cache, no additional compilation is required.

The system view `compile_cache_queries` provides data on the cache state on all or selected cluster nodes. When querying this view, requests are sent to each node unless a restriction on `NodeId` is specified in the `WHERE` condition. The response returns current information about the cache contents for each node, and the resulting table combines the received data.

View structure:

Column	Description
`NodeId`	Node ID where the query is stored in the cache. Type: `Uint32`. Key: `0`.
`QueryId`	Unique query ID in the node cache. Type: `Utf8`. Key: `1`.
`Query`	Query text. If the query exceeds 10 KB, it is truncated. Type: `Utf8`.
`AccessCount`	Number of cache hits for the query text. Type: `Uint64`.
`CompiledAt`	Query compilation time. Type: `Timestamp`.
`UserSID`	Security ID of the user on whose behalf the query was compiled. May be empty for system queries. Type: `Utf8`.
`LastAccessedAt`	Time of the last access to the query compilation result in the cache. Type: `Timestamp`.
`CompilationDurationMs`	Query compilation duration in milliseconds. Type: `Uint64`.
`Warnings`	Warnings that occurred during query compilation. Type: `Utf8`.
`Metadata`	Query parameter types in JSON format. Contains the `parameters` key with parameter names and their types. Type: `Utf8`.
`IsTruncated`	Flag indicating whether the query text was truncated due to exceeding the 10 KB limit. Type: `Bool`.
`QueryType`	Query type, one of: `QUERY_TYPE_SQL_DML` — Table Service `QUERY_TYPE_SQL_GENERIC_QUERY` — Query Service `QUERY_TYPE_SQL_GENERIC_CONCURRENT_QUERY` — Query Service in concurrent mode May be empty for old entries. Type: `Utf8`.
`Syntax`	Query syntax, one of: `SYNTAX_YQL_V1` — YQL `SYNTAX_UNSPECIFIED` — for old entries without syntax information `SYNTAX_PG` — deprecated value for entries compiled before the removal of experimental PostgreSQL compatibility; new queries with this syntax are not accepted Type: `Utf8`.

Example queries

View all queries in the compilation cache:

```
SELECT * FROM `.sys/compile_cache_queries`
```

Top 20 most popular queries by number of accesses from 3 nodes:

```
SELECT
    Query,
    SUM(AccessCount) AS Hits
FROM `.sys/compile_cache_queries`
WHERE NodeId IN (50000, 50001, 50003)
GROUP BY Query
ORDER BY Hits DESC
LIMIT 20
```

Activity statistics by user:

```
SELECT
    UserSID,
    COUNT(DISTINCT QueryId) AS Plans,
    SUM(AccessCount) AS Hits,
    AVG(CompilationDurationMs) AS AvgCompileMs
FROM `.sys/compile_cache_queries`
GROUP BY UserSID
ORDER BY Hits DESC
```

Search for queries with long compilation:

```
SELECT
    Query,
    NodeId,
    CompilationDurationMs,
    AccessCount
FROM `.sys/compile_cache_queries`
WHERE CompilationDurationMs > 1000
ORDER BY CompilationDurationMs DESC
```

History of overloaded partitions

The following system views contain a history of high load moments on individual partitions of database tables:

- `top_partitions_one_minute` — data is split into minute intervals, contains history for the last 6 hours.
- `top_partitions_one_hour` — data is split into hour intervals, contains history for the last 2 weeks.

Partitions with peak load over 70% (`CPUCores` > 0.7) are included in the views. Within one interval, partitions are ranked by peak load value.

Both views contain the same set of fields:

The view keys are:

- `IntervalEnd` — interval end time;
- `Rank` — partition rank by peak load `CPUCores` in this interval.

For example, if a table has 10 partitions, then `top_partitions_one_hour` for the hour interval `"20.12.2024 10:00-11:00"` will return 10 rows sorted in descending order of `CPUCores`. They will have `Rank` from 1 to 10 and the same `IntervalEnd` `"20.12.2024 11:00"`.

Column	Description
`IntervalEnd`	End time of the minute or hour interval for which statistics are collected. Type: `Timestamp`. Key: `0`.
`Rank`	Partition rank within the interval (by `CPUCores`). Type: `Uint32`. Key: `1`.
`TabletId`	Tablet ID serving the partition. Type: `Uint64`.
`FollowerId`	Replica ID of the partition tablet. Replica value 0 means leader. Type: `Uint32`
`Path`	Full table path. Type: `Utf8`.
`PeakTime`	Peak time within the interval. Type: `Timestamp`.
`CPUCores`	Peak load value on the partition (fraction of CPU core time spent by the partition actor). Type: `Double`.
`NodeId`	Node ID where the partition was located at the peak. Type: `Uint32`.
`DataSize`	Approximate partition size in bytes at the peak. Type: `Uint64`.
`RowCount`	Approximate row count at the peak. Type: `Uint64`.
`IndexSize`	Partition index size in the tablet at the peak. Type: `Uint64`.
`InFlightTxCount`	Number of transactions in progress at the peak. Type: `Uint32`.

Example queries

The following query outputs partitions with CPU consumption over 70% in the specified time interval, with tablet IDs and their sizes at the time of exceeding. The query is run against the `.sys/top_partitions_one_minute` view, which contains data for the last 6 hours broken down by minute intervals:

```
SELECT
    IntervalEnd,
    CPUCores,
    Path,
    TabletId,
    DataSize
FROM `.sys/top_partitions_one_minute`
WHERE CPUCores > 0.7
AND IntervalEnd BETWEEN Timestamp("2000-01-01T00:00:00Z") AND Timestamp("2099-12-31T00:00:00Z")
ORDER BY IntervalEnd desc, CPUCores desc
```

The following query outputs partitions with CPU consumption over 90% in the specified time interval, with tablet IDs and their sizes at the time of exceeding. The query is run against the `.sys/top_partitions_one_hour` view, which contains data for the last 2 weeks broken down by hourly intervals:

```
SELECT
    IntervalEnd,
    CPUCores,
    Path,
    TabletId,
    DataSize
FROM `.sys/top_partitions_one_hour`
WHERE CPUCores > 0.9
AND IntervalEnd BETWEEN Timestamp("2000-01-01T00:00:00Z") AND Timestamp("2099-12-31T00:00:00Z")
ORDER BY IntervalEnd desc, CPUCores desc
```

Partition history with broken locks

The following system views contain the history of moments with a non-zero number of broken locks `LocksBroken` in individual partitions of database tables:

- `top_partitions_by_tli_one_minute` — data is broken down into minute intervals, contains history for the last 6 hours.
- `top_partitions_by_tli_one_hour` — data is broken down into hourly intervals, contains history for the last 2 weeks.

The views output the top 10 partitions with a non-zero number of broken locks `LocksBroken`. Within a single interval, partitions are ranked by the number of broken locks `LocksBroken`.

The view keys are:

- `IntervalEnd` - the end time of the interval.
- `Rank` - the rank of the partition by the number of broken locks `LocksBroken` in this interval.

For example, `top_partitions_by_tli_one_hour` for an hourly interval `"20.12.2024 10:00-11:00"` will output 10 rows sorted in descending order of `LocksBroken`. They will have `Rank` from 1 to 10 and the same `IntervalEnd` `"20.12.2024 11:00"`.

Both views contain the same set of fields:

Column	Description
`IntervalEnd`	The end time of the minute or hour interval for which statistics were collected. Type: `Timestamp`. Key: `0`.
`Rank`	The rank of the partition within the interval (by `LocksBroken`). Type: `Uint32`. Key: `1`.
`TabletId`	ID of the tablet serving the partition. Type: `Uint64`.
`FollowerId`	ID of the partition tablet replica. Value 0 means the leader. Type: `Uint32`
`Path`	Full path to the table. Type: `Utf8`.
`LocksAcquired`	Number of locks set "on a key range" in this interval. Type: `Uint64`.
`LocksWholeShard`	Number of locks set "on the entire partition" in this interval. Type: `Uint64`.
`LocksBroken`	Number of broken locks in this interval. Type: `Uint64`.
`NodeId`	ID of the node where the partition was located at the peak time. Type: `Uint32`.
`DataSize`	Approximate size of the partition in bytes at the peak time. Type: `Uint64`.
`RowCount`	Approximate number of rows at the peak time. Type: `Uint64`.
`IndexSize`	Size of the partition index in the tablet at the peak time. Type: `Uint64`.

Query examples

The following query outputs partitions in the specified time interval, with tablet IDs and the number of broken locks. The query is run against the `.sys/top_partitions_by_tli_one_minute` view:

```
SELECT
    IntervalEnd,
    LocksBroken,
    Path,
    TabletId
FROM `.sys/top_partitions_by_tli_one_hour`
WHERE IntervalEnd BETWEEN Timestamp("2000-01-01T00:00:00Z") AND Timestamp("2099-12-31T00:00:00Z")
ORDER BY IntervalEnd desc, LocksBroken desc
```

Resource pool information

The `resource_pools` system view contains information about settings of resource pools.

System view structure:

Column	Description
`Name`	Resource pool name. Type: `Utf8`. Key: `0`.
`ConcurrentQueryLimit`	Maximum number of concurrently executing queries in the resource pool. Type: `Int32`.
`QueueSize`	Maximum queue size. Type: `Int32`.
`DatabaseLoadCpuThreshold`	CPU load threshold of the entire database, in percent, after which queries are not sent for execution and remain in the queue. Type: `Double`.
`ResourceWeight`	Weights for distributing resources among pools. Type: `Double`.
`TotalCpuLimitPercentPerNode`	Percentage of available CPU that all queries on the node can use in this resource pool. Type: `Double`.
`QueryCpuLimitPercentPerNode`	Percentage of available CPU on the node for one query in the resource pool. Type: `Double`.
`QueryMemoryLimitPercentPerNode`	Percentage of available memory on the node that a query can use in this resource pool. Type: `Double`.

Example

The following query outputs information about the settings of the resource pool named `default`:

```
SELECT
    Name,
    ConcurrentQueryLimit,
    QueueSize,
    DatabaseLoadCpuThreshold,
    ResourceWeight,
    TotalCpuLimitPercentPerNode,
    QueryCpuLimitPercentPerNode,
    QueryMemoryLimitPercentPerNode
FROM `.sys/resource_pools`
WHERE Name = "default";
```

Resource pool classifier information

The `resource_pools_classifiers` system view contains information about settings of resource pool classifiers.

System view structure:

Column	Description
`Name`	Resource pool classifier name. Type: `Utf8`. Key: `0`.
`Rank`	Priority of selecting the resource pool classifier. Type: `Int64`.
`MemberName`	User or group of users that will be sent to the specified resource pool. Type: `Utf8`.
`ResourcePool`	The name of the resource pool to which queries will be sent. Type: `Utf8`.

Example

The following query outputs information about the settings of the resource pool classifier named `olap`:

```
SELECT
    Name,
    Rank,
    MemberName,
    ResourcePool
FROM `.sys/resource_pools_classifiers`
WHERE Name = "olap";
```

Users, groups, and access rights

The following system views contain information about users, access groups, user membership in groups, and access rights granted to groups or directly to users.

Information about users

The `auth_users` view contains a list of local users YDB. It does not include users authenticated through external systems such as LDAP.

Administrators have full access to this view. Regular users can only view their own data.

Table structure:

Column	Description
`Sid`	User SID. Type: `Utf8`. Key: `0`.
`IsEnabled`	Indicates whether login is allowed for this user; used for explicit blocking by an administrator. Independent of `IsLockedOut`. Type: `Bool`.
`IsLockedOut`	Indicates that this user is automatically blocked due to exceeding the number of failed authentications. Does not depend on `IsEnabled`. Type: `Bool`.
`CreatedAt`	User creation time. Type: `Timestamp`.
`LastSuccessfulAttemptAt`	Time of last successful authentication. Type: `Timestamp`.
`LastFailedAttemptAt`	Time of last failed authentication. Type: `Timestamp`.
`FailedAttemptCount`	Number of failed authentications. Type: `Uint32`.
`PasswordHash`	JSON string containing the password hash, salt, and hashing algorithm. Type: `Utf8`.

Information about groups

The `auth_groups` view contains a list of access groups.

Only administrators have access to this view.

Table structure:

Column	Description
`Sid`	Group SID. Type: `Utf8`. Key: `0`.

Information about group membership

The `auth_group_members` view contains information about membership in access groups.

Only administrators have access to this view.

Table structure:

Column	Description
`GroupSid`	Group SID. Type: `Utf8`. Key: `0`.
`MemberSid`	Group member SID. Can be either a user SID or a group SID. Type: `Utf8`. Key: `1`.

Information about access rights

The views contain a list of granted access rights.

Include two views:

- `auth_permissions`: Explicitly granted access rights.

- `auth_effective_permissions`: Effective access rights considering inheritance.

In this view, the user sees only those access objects for which they have the `ydb.granular.describe_schema` right.

Table structure:

Column	Description
`Path`	Path to the access object. Type: `Utf8`. Key: `0`.
`Sid`	SID of the access subject. Type: `Utf8`. Key: `1`.
`Permission`	Name of the access right YDB. Type: `Utf8`. Key: `2`.

Example queries

Getting explicitly granted rights on an access object - the `my_table` table:

```
SELECT *
FROM `.sys/auth_permissions`
WHERE Path = "my_table"
```

Getting effective rights on an access object - the `my_table` table:

```
SELECT *
FROM `.sys/auth_effective_permissions`
WHERE Path = "my_table"
```

Getting rights granted to user `user3`:

```
SELECT *
FROM `.sys/auth_permissions`
WHERE Sid = "user3"
```

Information about owners of access objects

The `auth_owners` view displays information about owners of access objects.

In this view, the user sees only those access objects for which they have been granted the `ydb.granular.describe_schema` right.

Table structure:

Column	Description
`Path`	Path to the access object. Type: `Utf8`. Key: `0`.
`Sid`	SID of the access object owner. Type: `Utf8`.

Streaming queries

Viewing information about streaming queries

The system view `streaming_queries` contains information about all created streaming queries.

In this view, the user sees only those streaming queries for which they have been granted the `ydb.granular.describe_schema` right.

Table structure:

Column	Description
`Path`	Full path to the query. Type: `Utf8`. Key: `0`.
`Status`	Query execution status, one of: `CREATING` - query is being created, `CREATED` - query created but not started, `STARTING` - query is starting, `RUNNING` - query is running, `STOPPING` - query is stopping, `STOPPED` - query stopped, `SUSPENDED` - query completed with error and is waiting for backoff to retry, Type: `Utf8`
`Issues`	Query execution errors in JSON format Type: `Utf8`

`Plan`	Query plan in JSON format Type: `Utf8`
`Ast`	Query AST Type: `Utf8`
`Text`	Query text Type: `Utf8`
`Run`	Whether the query is currently being run by the user Type: `Bool`
`ResourcePool`	Name of the resource pool the query was bound to (see example) Type: `Utf8`
`RetryCount`	Number of query restarts Type: `Uint64`
`LastFailAt`	Time of the last query execution error Type: `Timestamp`
`SuspendedUntil`	Time when an attempt will be made to resume a stopped query Type: `Timestamp`

Change Data Capture

With Change Data Capture (CDC), you can track changes in table data. YDB provides access to changefeeds so that data consumers can monitor changes in near real time.

Enabling and disabling CDC

CDC is represented as a data schema object: a changefeed that can be added to a table or deleted from them using the ADD CHANGEFEED and DROP CHANGEFEED directives of the YQL `ALTER TABLE` statement.

Reading data from a topic

Before reading data, add a consumer. Below is a sample command that adds a consumer named `my_consumer` to the `updates_feed` changefeed of the `table` table in the `my` directory:

```
ydb topic consumer add \
  my/table/updates_feed \
  --consumer=my_consumer
```

Next, you can use the created consumer to start tracking changes. Below is a sample command for tracking data changes in the CLI:

```
ydb topic read \
  my/table/updates_feed \
  --consumer=my_consumer \
  --format=newline-delimited \
  --wait
```

Impact on table write performance

When writing data to a table with CDC enabled, there are additional overheads for the following operations:

- Making records and saving them to a changefeed.
- Storing records in a changefeed.
- In some modes (such as `OLD_IMAGE` and `NEW_AND_OLD_IMAGES`), data needs to be pre-fetched even if a user query doesn't require this.

As a result, queries may take longer to execute and size limits for stored data may be exceeded.

In real-world use cases, enabling CDC has virtually no impact on the query execution time (whatever the mode), since almost all data required for making records is stored in the cache , while the records themselves are sent to a topic asynchronously. However, record delivery background activity slightly (by 1% to 10%) increases CPU utilization.

When creating a changefeed for a table, the number of partitions of its storage (topic) is determined based on the current number of table partitions. If the number of source table partitions changes significantly (for example, after uploading a large amount of data or as a result of intensive accesses), an imbalance occurs between the table partitions and the topic partitions. This imbalance can also result in longer execution time for queries to modify data in the table or in unnecessary storage overheads for the changefeed. You can recreate the changefeed to correct the imbalance.

Load testing

As a load generator, you can use the feature of emulating an online store built into the YDB CLI:

1. Initialize a test.
2. Add a changefeed:

```
ALTER TABLE `orders` ADD CHANGEFEED `updates` WITH (
    FORMAT = 'JSON',
    MODE = 'UPDATES'
);
```

1. Create a consumer:

```
ydb topic consumer add \
  orders/updates \
  --consumer=my_consumer
```

2. Start tracking changes:

```
ydb topic read \
  orders/updates \
  --consumer=my_consumer \
  --format=newline-delimited \
  --wait
```

3. Generate a load.

   The following changefeed appears in the CLI:

```
...
{"update":{"created":"2022-06-24T11:35:00.000000Z","customer":"Name366"},"key":[1319569999286404932]}
{"update":{"created":"2022-06-24T11:35:00.000000Z","customer":"Name3894"},"key":[452209497351143909]}
{"update":{"created":"2022-06-24T11:35:00.000000Z","customer":"Name7773"},"key":[237797889418385025 8]}
...
```

Managing YDB using Terraform

Terraform can create, delete, and modify the following objects inside a YDB cluster:

- tables
- indexes of tables
- change data capture for tables
- topics

> **Warning**
>
> Currently, the YDB provider for Terraform is under development, and its functionality will be expanded.

To get started, you need to:

1. Deploy the YDB cluster
2. Create a database (described in paragraph 1 for the appropriate type of cluster deployment)
3. Install Terraform
4. Install and configure Terraform provider for YDB

Configuring the Terraform provider to work with YDB

1. You need to download provider code
2. Build the provider by executing `$make local-build` in the root directory of the provider's code. To do this, you need to additionally install the make utility and go
   The provider will be installed in the Terraform plugins folder - `~/.terraform.d/plugins/terraform.storage.ydb.tech/...`
3. Add the provider to `~/.terraformrc` by adding the following content to the `provider_installation` section (if there was no such section yet, then create):

```
provider_installation {
  direct {
    exclude = ["terraform.storage.ydb.tech/*/*"]
  }

  filesystem_mirror {
    path    = "/PATH_TO_HOME/.terraform.d/plugins"
    include = ["terraform.storage.ydb.tech/*/*"]
  }
}
```

4. Next, we configure the YDB provider itself to work (for example, in the file `provider.tf` in the working directory):

```
terraform {
  required_providers {
    ydb = {
      source = "terraform.storage.ydb.tech/provider/ydb"
    }
  }
  required_version = ">= 0.13"
}

provider "ydb" {
  token = "<TOKEN>"
  //OR for static credentials
  user = "<USER>"
  password = "<PASSWORD>"
}
```

Where:

- `token` - specifies the access token to the database if authentication is used, for example, using a third-party IAM provider.
- `user` - the username for accessing the database in case of using authentication by username and password
- `password` - the password for accessing the database in case of using authentication by username and password

Using the Terraform provider YDB

The following commands are used to apply changes to terraform resources:

1. `terraform init` - initialization of the terraform module (performed in the terraform resource directory).
2. `terraform validate` - checking the syntax of terraform resource configuration files.
3. `terraform apply` - direct application of the terraform resource configuration.

For ease of use, it is recommended to name terraform files as follows:

1. `provider.tf` - contains the settings of the terraform provider itself.
2. `main.tf` - contains a set of resources to create.

Database connection

For all resources describing data schema objects, you must specify the database details in which they are located. To do this, provide one of the two arguments:

- The connection string `connection_string` is an expression of the form `grpc(s)://HOST:PORT/?database=/database/path`, where `grpc(s)://HOST:PORT/` endpoint, and `/database/path` is the path of the database.
  For example, `grpcs://example.com:2135?database=/Root/testdb0`.

- `database_endpoint` - used when working with the [topics] resource (#topic_resource) (analogous to `connection_string` when working with table resources).

> **Note**
>
> The user can transfer the connection string to the database using standard Terraform tools - via variables.

If you are using the creation of `ydb_table_changefeed` or `ydb_topic` resources and authorization is not enabled on the YDB server, then in the DB config config.yaml you need to specify:

```
...
pqconfig:
  require_credentials_in_new_protocol: false
  check_acl: false
```

Example of using all types of YDB Terraform provider resources

This example combines all types of resources that are available in the YDB Terraform provider:

```
variable "db-connect" {
  type = string
  default = "grpc(s)://HOST:PORT/?database=/database/path" # you need to specify the path to the database
}

resource "ydb_table" "table" {
  path        = "1/2/3/tftest"
  connection_string = var.db-connect
  column {
    name = "a"
    type = "Utf8"
  }
  column {
    name = "b"
    type = "String"
  }
  column {
    name = "ttlBase"
    type = "Uint32"
  }
  ttl {
    column_name = "ttlBase"
    expire_interval = "P7D"
    unit = "milliseconds"
  }

  primary_key = ["b", "a"]

  partitioning_settings {
    auto_partitioning_min_partitions_count = 5
    auto_partitioning_max_partitions_count = 8
    auto_partitioning_partition_size_mb    = 256
    auto_partitioning_by_load              = true
  }
}

resource "ydb_table_index" "table_index" {
  table_path        = ydb_table.table.path
  connection_string = ydb_table.table.connection_string
  name              = "my_index"
  type              = "global_sync" # "global_async"
  columns           = ["a", "b"]

  depends_on = [ydb_table.table] # link to the table creation resource
}

resource "ydb_table_changefeed" "table_changefeed" {
  table_id = ydb_table.table.id
  name     = "changefeed"
  mode     = "NEW_IMAGE"
  format   = "JSON"
  consumer {
    name = "test"
    supported_codecs = ["raw", "gzip"]
  }

  depends_on = [ydb_table.table] # link to the table creation resource
}

resource "ydb_topic" "test" {
  database_endpoint = ydb_table.table.connection_string
  name              = "1/2/test"
  supported_codecs  = ["zstd"]

  consumer {
    name             = "test-consumer3"
    starting_message_timestamp_ms = 0
    supported_codecs = ["zstd","raw"]
  }

  consumer {
    name             = "test-consumer1"
    starting_message_timestamp_ms = 2000
    supported_codecs = ["zstd"]
  }

  consumer {
    name             = "test-consumer2"
    starting_message_timestamp_ms = 0
    supported_codecs = ["zstd"]
  }
}
```

All resources of the YDB Terraform provider will be described in detail below.

String table

> **Note**
>
> Working with column-oriented tables via Terraform is not yet available.

The `ydb_table` resource is used to work with tables.

Example:

```
resource "ydb_table" "ydb_table" {
  path = "path/to/table" # path relative to the base root
  connection_string = "grpc(s)://HOST:PORT/?database=/database/path" #DB connection example
  column {
    name = "a"
    type = "Utf8"
    not_null = true
  }
  column {
    name = "b"
    type = "Uint32"
    not_null = true
  }
  column {
    name = "c"
    type = String
    not_null = false
  }
  column {
    name = "f"
    type = "Utf8"
  }
  column {
    name = "e"
    type = "String"
  }
  column {
    name = "d"
    type = "Timestamp"
  }
  primary_key = ["b", "a"]
}
```

The following arguments are supported:

- `path` - (required) is the path of the table relative to the root of the database (example - `/path/to/table`).
- `connection_string` — (required) connection string.
- `column` — (required) column properties (see the column argument).
- `family` - (optional) is a column group (see the family argument).
- `primary_key` — (required) primary key of the table that contains an ordered list of column names of the primary key.
- `ttl` — (optional) TTL (see the ttl argument).
- `partitioning_settings` — (optional) partitioning settings (see the argument partitioning_settings).
- `key_bloom_filter` — (optional) (bool) use Bloom filter for primary key, the default value is false.
- `read_replicas_settings` — (optional) settings for read replicas.

column

The `column` argument describes the column properties of the table.

> **Warning**
>
> Using Terraform, you cannot only add columns but not delete them. To delete a column, use the YDB tools, then delete the column from the resource description. When trying to apply changes to the table's columns (changing the data type or name), Terraform will not try to delete them but will try to do an update-in-place, though the changes will not be applied.

Example:

```
column {
  name     = "column_name"
  type     = "Utf8"
  family   = "some_family"
  not_null = true
}
```

- `name` - (required) is the column's name.
- `type` — (required) YQL data type columns. Simple column types are allowed. However, container types cannot be used as data types of table columns.
- `family` - (optional) is the name of the column group (see the family argument).
- `not_null` — (optional) column cannot contain `NULL`. The default value: `false`.

family

The `family` argument describes column group properties.

- `name` - (required) is the name of the column group.
- `data` — (required) storage device type for column data of this group.
- `compression` — (required) data compression codec.

Example:

```
family {
  name        = "my_family"
  data        = "ssd"
  compression = "lz4"
}
```

partitioning_settings

The `partitioning_settings` argument describes partitioning settings.

Example:

```
partitioning_settings {
  auto_partitioning_min_partitions_count = 5
  auto_partitioning_max_partitions_count = 8
  auto_partitioning_partition_size_mb    = 256
  auto_partitioning_by_load              = true
}
```

- `uniform_partitions` — (optional) the number of preallocated partitions.
- `partition_at_keys` — (optional) partitioning by primary key.
- `auto_partitioning_min_partitions_count` — (optional) minimum possible number of partitions when auto-partitioning.
- `auto_partitioning_max_partitions_count` — (optional) maximum possible number of partitions when auto-partitioning.
- `auto_partitioning_partition_size_mb` — (optional) setting the value of auto-partitioning by size in megabytes.
- `auto_partitioning_by_size_enabled` — (optional) enabling auto-partitioning by size (bool), enabled by default (true).
- `auto_partitioning_by_load` — (optional) enabling autopartition by load (bool), disabled by default (false).

See the links above for more information about the parameters and their default values.

ttl

The `ttl` argument describes the Time To Live settings.

Example:

```
ttl {
  column_name     = "column_name"
  expire_interval = "PT1H" # 1 hour
  unit = "seconds" # for numeric column types (non-ISO8601)
}
```

- `column_name` - (required) is the column name for TTL.
- `expire_interval` — (required) interval in ISO 8601 format (for example, `P1D` is an interval of 1 day, that is, 24 hours).
- `unit` — (optional) is set if the column with ttl has a numeric type. Supported values:
  - `seconds`
  - `milliseconds`
  - `microseconds`
  - `nanoseconds`

Secondary index of the table

The ydb_table_index resource is used to work with a table index.

Example:

```
resource "ydb_table_index" "ydb_table_index" {
  table_path = "path/to/table" # path relative to the base root
  connection_string = "grpc(s)://HOST:PORT/?database=/database/path" #DB connection example
  name              = "my_index"
  type              = "global_sync" # "global_async"
  columns           = ["a", "b"]
  cover             = ["c"]
}
```

The following arguments are supported:

- `table_path` - is the path of the table. Specified if `table_id` is not specified.
- `connection_string` — connection string. Specified if `table_id` is not specified.
- `table_id` - terraform-table identifier. Specify if `table_path` or `connection_string` is not specified.
- `name` - (required) is the name of the index.
- `type` - (required) is the index type global_sync | global_async.
- `columns` - (required) is an ordered list of column names participating in the index.
- `cover` - (required) is a list of additional columns for the covering index.

Change Data Capture

The `ydb_table_changefeed` resource is used to work with the change data capture of the table.

Example:

```
resource "ydb_table_changefeed" "ydb_table_changefeed" {
  table_id = ydb_table.ydb_table.id
  name     = "changefeed"
  mode     = "NEW_IMAGE"
  format   = "JSON"
}
```

The following arguments are supported:

- `table_path` - is the path of the table. Specified if `table_id` is not specified.
- `connection_string` — connection string. Specified if `table_id` is not specified.
- `table_id` — terraform-table identifier. Specify if `table_path` or `connection_string` is not specified.
- `name` - (required) is the name of the change stream.
- `mode` - (required) is the mode of operation of the change data capture.
- `format` - (required) is the format of the change data capture.
- `virtual_timestamps` — (optional) using virtual timestamps.
- `retention_period` — (optional) data storage time in ISO 8601 format.
- `consumer` - (optional) is a reader of the change data capture (see the argument #consumer).

consumer

The `consumer` argument describes the reader of the change data capture.

- `name` - (required) is the reader's name.
- `supported_codecs` — (optional) supported data codec.
- `starting_message_timestamp_ms` — (optional) timestamp in UNIX timestamp format in milliseconds, from which the reader will start reading the data.

Usage examples

Creating a table in an existing database

```
resource "ydb_table" "ydb_table" {
  # Path to the table
  path = "path/to/table" # path relative to the base root

  connection_string = "grpc(s)://HOST:PORT/?database=/database/path" #DB connection example

  column {
    name = "a"
    type = "Uint64"
    not_null = true
  }
  column {
    name     = "b"
    type     = "Uint32"
    not_null = true
  }
  column {
    name = "c"
    type = String
    not_null = false
  }
  column {
    name = "f"
    type = "Utf8"
  }
  column {
    name = "e"
    type = "String"
  }
  column {
    name = "d"
    type = "Timestamp"
  }
  # Primary key
  primary_key = [
    "a", "b"
  ]
}
```

Creating a table, index, and change stream

```
resource "ydb_table" "ydb_table" {
  # Path to the table
  path = "path/to/table" # path relative to the base root

  # ConnectionString to the database.
  connection_string = "grpc(s)://HOST:PORT/?database=/database/path" #DB connection example

  column {
    name = "a"
    type = "Uint64"
    not_null = true
  }
  column {
    name     = "b"
    type     = "Uint32"
    not_null = true
  }
  column {
    name = "c"
    type = "Utf8"
  }
  column {
    name = "f"
    type = "Utf8"
  }
  column {
    name = "e"
    type = "String"
  }
  column {
    name = "d"
    type = "Timestamp"
  }

  # Primary key
  primary_key = [
    "a", "b"
  ]

  ttl {
    column_name     = "d"
    expire_interval = "PT5S"
  }

  partitioning_settings {
    auto_partitioning_by_load = false
    auto_partitioning_partition_size_mb    = 256
    auto_partitioning_min_partitions_count = 6
    auto_partitioning_max_partitions_count = 8
  }

  read_replicas_settings = "PER_AZ:1"

  key_bloom_filter = true # Default = false
}

resource "ydb_table_changefeed" "ydb_table_changefeed" {
  table_id = ydb_table.ydb_table.id
  name = "changefeed"
  mode = "NEW_IMAGE"
  format = "JSON"

  consumer {
    name = "test_consumer"
  }

  depends_on = [ydb_table.ydb_table] # link to the table creation resource
}

resource "ydb_table_index" "ydb_table_index" {
  table_id = ydb_table.ydb_table.id
  name = "some_index"
  columns = ["c", "d"]
  cover = ["e"]
  type = "global_sync"

  depends_on = [ydb_table.ydb_table] # link to the table creation resource
}
```

Topic configuration management YDB via Terraform

The `ydb_topic` resource is used to work with topics

Note

The topic cannot be created in the root of the database; you need to specify at least one directory in the name of the topic. When trying to create a topic in the root of the database, the provider will return an error.

Description of the `ydb_topic` resource

Example:

```
resource "ydb_topic" "ydb_topic" {
  database_endpoint = "grpcs://example.com:2135/?database=/Root/testdb0" #database connection example
  name              = "test/test1"
  supported_codecs  = ["zstd"]

  consumer {
    name             = "test-consumer1"
    starting_message_timestamp_ms = 0
    supported_codecs = ["zstd","raw"]
  }

  consumer {
    name             = "test-consumer2"
    starting_message_timestamp_ms = 2000
    supported_codecs = ["zstd"]
  }

  consumer {
    name             = "test-consumer3"
    starting_message_timestamp_ms = 0
    supported_codecs = ["zstd"]
  }
}
```

The following arguments are supported:

- `name` - (required) is the name of the topic.
- `database_endpoint` - (required) is the full path to the database, for example: `"grpcs://example.com:2135/?database=/Root/testdb0"`; analogous to `connection_string` for tables.
- `retention_period_ms` - the duration of data storage in milliseconds; the default value is `86400000` (day).
- `partitions_count` - the number of partitions; the default value is `2`.
- `supported_codecs` - supported data compression codecs, the default value is `"gzip", "raw", "zstd"`.
- `consumer` - readers for the topic.

Description of the data consumer `consumer`:

- `name` - (required) is the reader's name.
- `supported_codecs` - supported data compression encodings, by default - `"gzip", "raw", "zstd"`.
- `starting_message_timestamp_ms` - timestamp in UNIX timestamp format in milliseconds, from which the reader will start reading the data; the default value is 0, which means "from the beginning".

Custom attributes in tables

You can use custom attributes to store any information and process it in your app or using the CLI.

For example, your application uses a database table. It stores versions of the table's scheme in custom attributes. You need to migrate data when the table scheme changes. To make sure that your application runs a relevant migration, rather than a previous one, when started, access the custom attributes to check the scheme version:

- The version in the attribute is `1`, and your application knows how to work with version `2`. So, you apply the `1` > `2` migration and update the attribute value with `2`.
- In the attribute, the version is `2`, and your application knows how to work with version `2`, so no migration is needed.
- The version in the attribute is `2`, and your application knows how to work with version `1`: you terminate your application with an exception, notifying the user of an attempt to run an older app version against the new data scheme.

When you use custom attributes, you no longer need to store scheme versions in a separate table.

Set a custom attribute when creating a table

Go

To set a custom attribute when creating the `series` table, pass the `scheme_version` key and the attribute value `1` in the `options.WithAttribute` option of the `CreateTable` method:

```
err := client.Do(ctx, func(ctx context.Context, s table.Session) error {
  return s.CreateTable(ctx, "episodes",
    options.WithColumn("series_id", types.Optional(types.TypeUint64)),
    options.WithColumn("season_id", types.Optional(types.TypeUint64)),
    options.WithColumn("episode_id", types.Optional(types.TypeUint64)),
    options.WithColumn("title", types.Optional(types.TypeText)),
    options.WithPrimaryKeyColumn("series_id", "season_id", "episode_id"),
    options.WithAttribute("scheme_version", "1"),
  )
})
```

Set a custom attribute for an existing table

Go

To set a custom attribute for the existing `series` table, pass the `scheme_version` key and the attribute value `1` in the `options.WithAddAttribute` option of the `AlterTable` method:

```
err = db.Table().Do(ctx,
  func(ctx context.Context, s table.Session) (err error) {
    return s.AlterTable(ctx, path.Join(db.Name(), "series"),
      options.WithAddAttribute("scheme_version", "1"),
    )
  },
)
```

CLI

To set a custom attribute for the existing `series` table, pass the `scheme_version` key and the attribute value `1` in the `--attribute` option of the ydb table attribute add command:

```
ydb table attribute add --attribute scheme_version=1 series
```

Update the custom attribute

Go

To update the custom attribute when changing the table scheme, pass the `scheme_version` key and the new attribute value of `2` in the `WithAlterAttribute` option of the `AlterTable` method:

```
err = db.Table().Do(ctx,
  func(ctx context.Context, s table.Session) (err error) {
    return s.AlterTable(ctx, path.Join(db.Name(), "series"),
      options.WithAddColumn("air_date", types.Optional(types.TypeUint64)),
      options.WithAlterAttribute("scheme_version", "2"),
    )
  },
)
```

CLI

To edit the custom attribute for the existing `series` table, pass the `scheme_version` key and the attribute value `2` in the `--attribute` option of the ydb table attribute add command:

```
ydb table attribute add --attribute scheme_version=2 series
```

View your custom attributes

Go

To retrieve the `series` table scheme, including the custom attributes, use the method `table.Session.DescribeTable()`:

```
err := c.Do(ctx,
  func(ctx context.Context, s table.Session) error {
    description, err := s.DescribeTable(ctx, path.Join(prefix, "series"))
    if err != nil {
      return err
    }
    for k, v := range description.Attributes {
      log.Println(k, "=", v)
    }
    return nil
  },
)
```

CLI

To get the data about the `series` table scheme, including the custom attributes, use the command ydb scheme describe:

```
ydb scheme describe series
```

Result:

```
...
Attributes:
┌────────────────┬─────────┐
| Name           | Value |
├────────────────┼─────────┤
| scheme_version | 2     |
└────────────────┴─────────┘
...
```

Delete the custom attribute

Go

To drop the custom attribute, pass the `scheme_version` key in the option `WithDropAttribute` of the `AlterTable` method:

```
err = db.Table().Do(ctx,
  func(ctx context.Context, s table.Session) (err error) {
    return s.AlterTable(ctx, path.Join(db.Name(), "series"),
      options.WithDropAttribute("scheme_version"),
    )
  },
)
```

CLI

To drop the custom attribute, use the `scheme_version` key in the `--attributes` option of the ydb table attribute drop command:

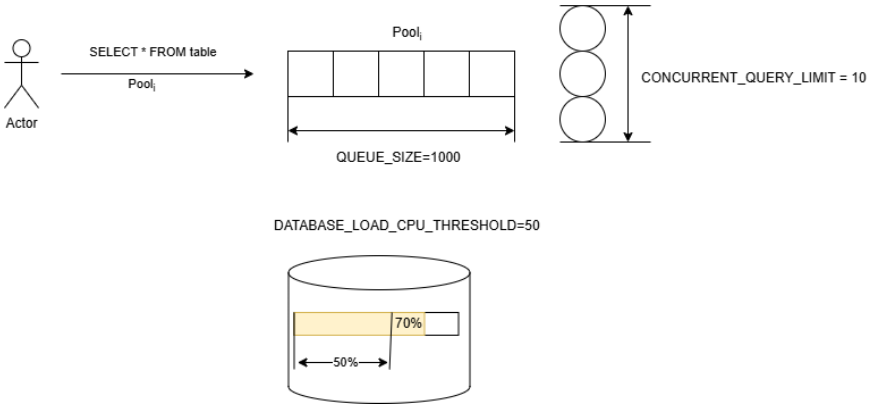
```
ydb table attribute drop --attributes scheme_version series
```

Workload Manager — resource consumption management

Resource pools allow isolating database resources between executing queries or configuring resource allocation strategies in case of oversubscription (requesting more resources than available in the system). All resource pools are equal, without any hierarchy, and affect each other only when there is a general resource shortage.

For example, one of the typical resource isolation scenarios is separating two classes of consumers:

1. A regular robot process that builds a report once a day.
2. Analysts who run ad hoc queries.



> **Warning**
>
> The resource consumption management functionality described is in Preview.

Creating a resource pool

The example below shows the syntax for creating a separate resource pool named "olap" that will run analytical queries:

```
CREATE RESOURCE POOL olap WITH (
    CONCURRENT_QUERY_LIMIT=10,
    QUEUE_SIZE=1000,
    DATABASE_LOAD_CPU_THRESHOLD=80,
    RESOURCES_WEIGHT=100,
    QUERY_CPU_LIMIT_PERCENT_PER_NODE=50,
    TOTAL_CPU_LIMIT_PERCENT_PER_NODE=70
)
```

You can find the full list of resource pool parameters in the Parameters reference. Some parameters are global for the entire database (for example, `CONCURRENT_QUERY_LIMIT`, `QUEUE_SIZE`, `DATABASE_LOAD_CPU_THRESHOLD`), while others apply only to a single compute node (for example, `QUERY_CPU_LIMIT_PERCENT_PER_NODE`, `TOTAL_CPU_LIMIT_PERCENT_PER_NODE`, `TOTAL_MEMORY_LIMIT_PERCENT_PER_NODE`). CPU can be shared among all pools in case of oversubscription on a single compute node using `RESOURCES_WEIGHT`.

Let's look at the example above to see what these parameters actually mean and how they will affect resource allocation. Suppose the YDB database has nodes with each. In total, such a database has . Then on each node, for the resource pool named `olap`, the following will be allocated:

In total, with uniform resource distribution across the entire database, the resource pool will be allocated:

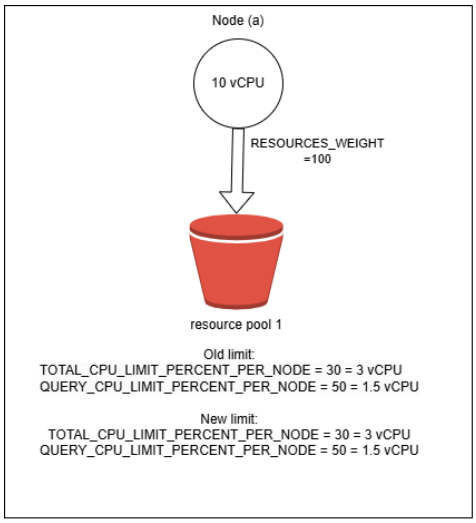
For one query in this resource pool, the following will be allocated:

How CONCURRENT_QUERY_LIMIT and QUEUE_SIZE work

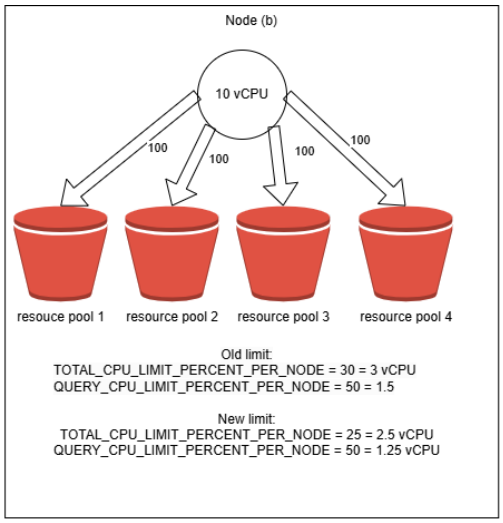
Suppose 9 queries are already running in the resource pool `olap`. When a new query arrives, it will immediately start executing in parallel with the other 9 queries. Now there will be 10 queries running in the pool. If an 11th query arrives, it will not start executing but will be placed in the waiting queue. When at least one of the 10 running queries completes, the 11th query will be taken from the queue and start executing.

If there are already queries in the queue, then when the 1001st query is sent, the client will immediately receive an error in response, and this query will not be executed. Example error:

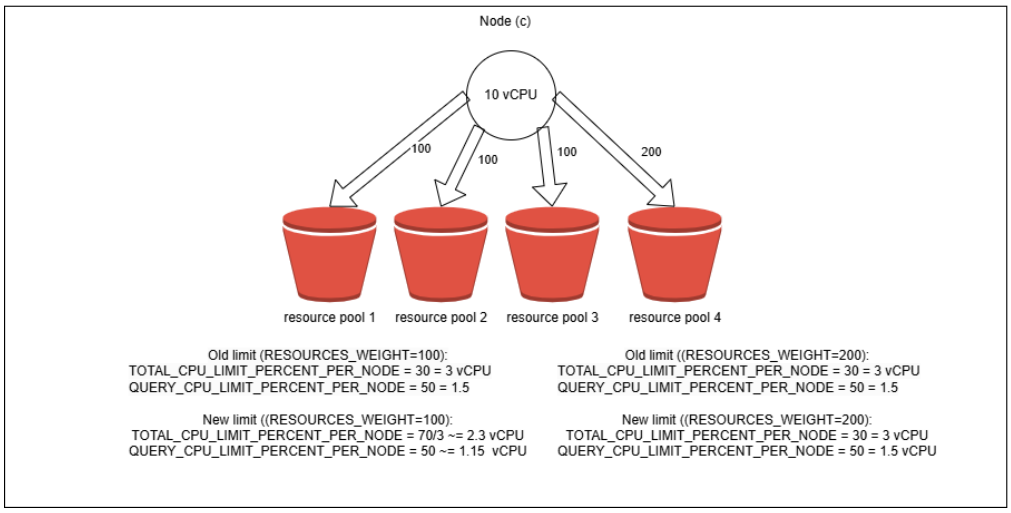
```
Issues:
<main>: Error: Request was rejected, number of local pending requests is 20, number of global delayed/running
requests is 0, sum of them is larger than allowed limit 1 (including concurrent query limit 1) for pool olap
<main>: Error: Query failed during adding/waiting in workload pool olap
```



The number of concurrently executing queries is affected not only by `CONCURRENT_QUERY_LIMIT` but also by `DATABASE_LOAD_CPU_THRESHOLD`.



How DATABASE_LOAD_CPU_THRESHOLD works



When a query enters a resource pool for which `DATABASE_LOAD_CPU_THRESHOLD` is set, 10% of the available CPU on the node is immediately reserved, based on the assumption that the query will require at least that amount of resources. Then, every 10 seconds, the consumed resources are recalculated across the entire database, allowing the initial 10% estimate to be refined. This means that if more than 10 queries arrive at a cluster node simultaneously, no more than 10 queries will be started for execution, and the rest will wait for the actual CPU consumption to be refined.

As with `CONCURRENT_QUERY_LIMIT`, when the specified load threshold is exceeded, queries are sent to the waiting queue.

Resource allocation according to RESOURCES_WEIGHT

The `RESOURCES_WEIGHT` parameter only takes effect in case of oversubscription and when there is more than one resource pool in the system. In the current implementation, `RESOURCES_WEIGHT` only affects the allocation of `vCPU` resources. When queries appear in a resource pool, it starts participating in resource allocation. For this, the pools recalculate their limits according to the Max-min fairness algorithm. The actual resource redistribution is performed on each compute node individually, as shown in the figure above.

Suppose we have a node in the system with available. The following limits are set:

- ,
- .

In this case, the resource pool will have a limit of per node and per query in this pool (figure *a*). If there are 4 such pools in the system and they all try to use maximum resources, this would amount to , which exceeds the limit of available resources on the node (). In this case, `RESOURCES_WEIGHT` takes effect, and each pool will be allocated (figure *b*).

If you need to increase the allocated resources for a specific pool, you can change its weight, for example, to 200. Then this pool will get , and the remaining pools will equally share the remaining , which amounts to per pool (figure *c*).

> **Warning**
>
> The current resource allocation algorithm may be changed in the future without backward compatibility support.

Default resource pool

Even if no resource pool has been created, the system always has a resource pool `default` that cannot be deleted. Any query executing in the system always belongs to some pool — there is no situation where a query is not attached to any resource pool. By default, the settings of the resource pool `default` are as follows:

```
CREATE RESOURCE POOL default WITH (
    CONCURRENT_QUERY_LIMIT=-1,
    QUEUE_SIZE=-1,
    DATABASE_LOAD_CPU_THRESHOLD=-1,
    RESOURCES_WEIGHT=-1,
    TOTAL_MEMORY_LIMIT_PERCENT_PER_NODE=-1,
    QUERY_CPU_LIMIT_PERCENT_PER_NODE=-1,
    TOTAL_CPU_LIMIT_PERCENT_PER_NODE=-1
)
```

This means that no restrictions are applied in the resource pool `default`: it operates independently of other pools and has no limits on consumed resources. In the resource pool `default`, you can change parameters using the ALTER RESOURCE POOL query, except for the parameters `CONCURRENT_QUERY_LIMIT`, `DATABASE_LOAD_CPU_THRESHOLD`, and `QUEUE_SIZE`. This restriction is

intentionally introduced to minimize risks associated with incorrect configuration of the default resource pool.

Resource pool ACL management

Permissions for creating, modifying, and deleting a resource pool

To create, modify, or delete a resource pool, you need to grant access permissions according to the permissions described in the reference for CREATE RESOURCE POOL. For example, to create resource pools, you need to have the `CREATE TABLE` permission on the directory `.metadata/workload_manager/pools`, which can be granted with a query of the following form:

```
GRANT CREATE TABLE ON `.metadata/workload_manager/pools` TO user1;
```

Permissions for executing a query in a resource pool

To execute a query in a pool, the user must have the access permission `SELECT` on this pool. Example of granting permissions:

```
GRANT SELECT
    ON `.metadata/workload_manager/pools/olap`
    TO `user1@domain`;
```

Creating a resource pool classifier

Resource pool classifiers allow you to specify rules by which queries will be distributed among resource pools. The example below shows a resource pool classifier that sends queries from all users to a resource pool named `olap`:

```
CREATE RESOURCE POOL CLASSIFIER olap_classifier
WITH (
    RESOURCE_POOL = 'olap',
    MEMBER_NAME = 'all-users@well-known'
);
```

- `RESOURCE_POOL` — the name of the resource pool to which the query satisfying the requirements specified in the resource pool classifier will be sent.
- `MEMBER_NAME` — a user group or user whose queries will be sent to the specified resource pool.

ACL management of the resource pool classifier

Resource pool classifiers are global for the entire database and apply to all users. To create, delete, or modify a resource pool classifier, you need to have the access permission `USE` on the entire database, which can be granted with a query of the form:

```
GRANT USE ON `/my_db` TO user1;
```

Warning

To use the classifier, the user must have access to the resource pool to which this classifier refers. If there is no such access, the classifier is skipped and the next one is checked. In future versions, this behavior may change, so do not use the lack of permissions on the pool as a control mechanism for which classifier will be triggered.

Order of resource pool classifier selection in case of conflicts

```
CREATE RESOURCE POOL CLASSIFIER olap1_classifier
WITH (
    RESOURCE_POOL = 'olap1',
    MEMBER_NAME = 'user1@domain'
);

CREATE RESOURCE POOL CLASSIFIER olap2_classifier
WITH (
    RESOURCE_POOL = 'olap2',
    MEMBER_NAME = 'user1@domain'
);
```

Suppose there are two resource pool classifiers with conflicting conditions, and user `user1@domain` matches both resource pools: `olap1` and `olap2`. If no classifier existed in the system before, then `olap1` is set for `RANK=1000`, and `olap2` for `RANK=2000`. Resource pool classifiers with a lower `RANK` value have higher priority. In this example, since `olap1` has a higher priority `RANK` than `olap2`, it will be selected.

You can also set `RANK` for resource pool classifiers when creating them using the CREATE RESOURCE POOL CLASSIFIER syntax construct, or change `RANK` for existing resource pool classifiers using ALTER RESOURCE POOL CLASSIFIER.

The system cannot have two classifiers with the same `RANK` value, which makes it possible to uniquely determine which resource pool will be selected in case of conflicting conditions.

Example of a priority resource pool

Consider an example of resource allocation between an analytics team and a conditional CEO. It is important for the CEO to have priority over the computing resources used for analytical tasks, but it is useful to allow the analytics team to utilize more cluster resources during periods when the CEO is not using them. The configuration for this scenario might look as follows:

```
CREATE RESOURCE POOL olap WITH (
    CONCURRENT_QUERY_LIMIT=20,
    QUEUE_SIZE=100,
    DATABASE_LOAD_CPU_THRESHOLD=80,
    RESOURCES_WEIGHT=20,
    QUERY_CPU_LIMIT_PERCENT_PER_NODE=80,
    TOTAL_CPU_LIMIT_PERCENT_PER_NODE=100
);

CREATE RESOURCE POOL the_ceo WITH (
    CONCURRENT_QUERY_LIMIT=20,
    QUEUE_SIZE=100,
    RESOURCES_WEIGHT=100,
    QUERY_CPU_LIMIT_PERCENT_PER_NODE=100,
    TOTAL_CPU_LIMIT_PERCENT_PER_NODE=100
);
```

In the example above, two resource pools are created: `olap` for the analytics team and `the_ceo` for the CEO.

- **Resource pool `olap`**:
  - Has a weight of 20.
  - The limit on running queries when the database is overloaded is 80% of available resources.
- **Resource pool `the_ceo`**:
  - Has a higher weight — 80.
  - Has no limit on running queries when overloaded.

A weight of 80 for `the_ceo` effectively means that when competing for resources, pool `the_ceo` will receive 4 times more priority than pool `olap`. If queries arrive in both pools, the system will recalculate the limits, and for `olap` the `TOTAL_CPU_LIMIT_PERCENT_PER_NODE` limit will be reduced to 20%, while for `the_ceo` it will be increased to 80%. This resource redistribution is based on weights, as described above.

Explicit selection of a resource pool for a query

If necessary, the user can explicitly specify in which pool a given query should be executed. Currently, this can be done as follows:

- **YDB UI** — in the query launch settings window `Query execution settings` via the `Resource pool` parameter.
- **YDB CLI** — in the `ydb sql` command with the `--resource-pool` parameter, for example, `ydb sql --resource-pool my_pool -s "SELECT 1"`.
- **YDB CLI (interactive mode)** — using the command `SET resource_pool = my_pool`, where `my_pool` is the name of the resource pool.
- **YDB CPP SDK** — in the query launch settings via the ResourcePool parameter.
- **YDB GO SDK** — in the query launch settings `ExecuteOption` via the WithResourcePool call.
- **YDB Java SDK** — in the query launch settings `ExecuteQuerySettings` via the withResourcePool call, available since version 2.3.12.
- **YDB Python SDK** — via the pool_id parameter of the `QuerySession.execute()`, `QueryTxContext.execute()` and `QuerySessionPool.execute_with_retries()` methods, available since version 3.31.2.

Diagnostics

Query plan

Detailed information about query plans can be found on the query plan structure page. To get information about the resource pool used, you need to run a command that retrieves statistics in `json-unicode` format. Example command:

```
ydb -p <profile_name> sql -s 'select 1' --stats full --format json-unicode
```

In the body of the query plan obtained using the command above, you can find useful attributes for diagnosing resource pool operation. Example of such information:

```
"Node Type" : "Query",
"Stats" : {
  "TotalDurationUs": 28795,
  "ProcessCpuTimeUs": 45,
  "Compilation": {
    "FromCache": false,
    "CpuTimeUs": 7280,
    "DurationUs": 21700
  },
  "ResourcePoolId": "default",
  "QueuedTimeUs": 0
},
"PlanNodeType" : "Query"
```

Useful attributes:

- `TotalDurationUs` — total query execution time, including queue wait time.
- `ResourcePoolId` — name of the resource pool to which the query was assigned.
- `QueuedTimeUs` — total query queue wait time.

Status of a running query

Information about how a query is processed in Workload Manager can be obtained from the system view `.sys/query_sessions`. This view contains the following fields:

- `WmPoolId (Utf8)` - ID of the pool in which the query is executed.

- `WmState` `(Utf8)` - Query status in WM.
- `WmEnterTime` `(Timestamp)` - Time when the query transitioned to PENDING or DELAYED status.
- `WmExitTime` `(Timestamp)` - Time when the query was submitted for execution.

Possible values of the WmState field:

- `NONE` - Not being processed.
- `PENDING` - Being processed (during classification/routing).
- `DELAYED` - In queue.
- `EXITED` - Submitted for execution.

The following query outputs information about all active queries in the system:

```
select
    Query,          -- Запрос
    WmPoolId,       -- Идентификатор пула
    WmState,        -- Статус запроса в WM
    WmEnterTime,    -- Время, когда запрос перешел в статус PENDING или DELAYED
    WmExitTime      -- Время, когда запрос передан на выполнение
from `.sys/query_sessions`
where State = 'EXECUTING'
```

Metrics

Information about resource pool metrics can be found in the metrics reference.

System views

Information about system views related to resource pools and resource pool classifiers can be found on the Resource pool information page.

Shared topic consumer: architecture and limitations

Shared consumer is a reading model for a topic where a consumer is assigned one or more messages, rather than an entire partition. This allows multiple consumers to process messages from one partition in parallel and use topics as message queues. A typical scenario is message exchange between microservices; reading via the Amazon SQS API works through a shared consumer.

For a general description of the model, consumer settings, DLQ policies, and message ordering, see the Shared consumer section. This article describes the internal architecture of the mechanism: how the server tracks processing state, distributes read requests across partitions, what limitations to consider when designing high-load queues, and what resource consumption the inflight creates.

Implementation specifics

For each pair of 'shared consumer — topic partition', the server maintains its own message processing state. The state consists of a continuous block of messages from the topic partition — the inflight. The first message of the inflight is a message that has not yet been processed, is being processed, or is waiting to be moved to the DLQ. If the first message is successfully processed, the beginning of the block moves to the next message. Messages for processing are only delivered from the messages in the inflight.

Up to 120,000 messages can be in the inflight of one partition. This means that if a large number of consumers (more than 120,000) read from one partition, no more than 120,000 consumers will receive messages for processing, even if there are more messages in the partition. Increasing the number of partitions in a topic increases the total inflight size — the total inflight of a topic equals the number of partitions multiplied by 120,000 messages. If you need to process a large number of messages simultaneously, you should increase the number of partitions in the topic.

If a topic consists of several partitions, read requests are evenly distributed across all partitions. It may happen that a request hits a partition that has no messages. In this case, the consumer will receive a response that there are no messages to process. If a partition has no messages to process for a long time, it is excluded from read request distribution. The partition will return to distribution as soon as messages to process appear in it.

For shared consumers with message ordering preservation, this means that if a large number of messages from one message-group-id (more than 120,000 messages) are written consecutively to a partition, the entire inflight will be occupied by messages from one message-group-id, and messages from other groups will not be delivered until messages from other groups appear in the inflight.

Fair queues

When delivering messages for reading, the server takes into account the `message-group-id` of messages in the inflight. Trying to deliver messages from different groups, the server distributes the load among writers more evenly.

This allows smoothing out peaks from individual writers: if one writer sends many more messages to the queue than others, processing of messages from 'small' writers gets priority and is not blocked by the flow from a single source.

For FIFO queues and shared consumers with message ordering preservation, the order of messages within one `message-group-id` is guaranteed: the consumer always receives the group's messages in the order they were written.

Resource consumption

The inflight state consumes RAM and disk resources. For each message in the inflight, the server stores about 32 bytes of metadata — this is not the message body, but metadata about its processing status.

RAM

The entire inflight is stored in the server's memory. To estimate memory consumption, it is convenient to calculate per million messages: **1 million messages in the inflight ≈ 32 MB** of RAM.

For example, a topic with 10 partitions and one shared consumer with a fully filled inflight (120,000 messages per partition) holds up to 1.2 million messages in inflight — about **38 MB** of memory for the service state alone. For one "shared consumer — partition" pair at maximum inflight, it accounts for about **3.8 MB**. If a topic has multiple shared consumers, memory consumption multiplies by their number.

When designing, consider:

- the more partitions and consumers, the higher the memory consumption ceiling
- the longer messages are being processed (long message processing time, slow consumers), the longer they stay in inflight and occupy memory
- increasing the number of partitions expands parallelism, but at the same time increases the total inflight volume.

Disk

Information about message status is also stored on disk — from **32 bytes per message**. Storage consists of two parts:

1. **Snapshot** — the full state of all messages in inflight is periodically written.
2. **Change log** — the server processes pending read requests in batches and, when processing each batch, appends changes to message statuses to the log.

Consequently, high read frequency and a large inflight increase the volume of disk writes. When planning cluster capacity, allocate disk resources alongside RAM — especially for topics with a large number of partitions, multiple shared consumers, and long message processing times.

For Analysts

This section provides examples and recommendations for handling analytical (OLAP) scenarios in YDB.

This section includes the following materials

- Dataset import

Related sections

- Questions and answers about analytics in YDB
- Column-Oriented Tables
- Aggregate functions

Quickstart: Loading TPC-H data from Object Storage and executing analytical queries

This quickstart describes the process of loading the TPC-H test dataset (scale factor 10, 10 GB) into YDB from external S3-compatible storage and executing analytical queries.

After completing the steps, the following will be created in the database:

- External data source `EXTERNAL DATA SOURCE`.
- External tables `EXTERNAL TABLE` for Parquet file schemas.
- YDB column-oriented tables optimized for analytical queries.

Actions include:

- Loading data from Object Storage into YDB tables using `UPSERT INTO... SELECT FROM`.
- Executing a test query (TPC-H Q0) for verification.

Prerequisites

- An existing YDB database.
- A tool for executing YQL/SQL queries (YDB UI or CLI).

Creating an external data source

In this step, an `EXTERNAL DATA SOURCE` object will be created, which is a named reference to external data storage. It contains information about the data location and access method.

`EXTERNAL DATA SOURCE` is an entity in YDB that describes a connection to external storage, such as S3-compatible Object Storage.

```
CREATE EXTERNAL DATA SOURCE IF NOT EXISTS `external/tpc` WITH (
    SOURCE_TYPE="ObjectStorage",
    LOCATION="https://storage.yandexcloud.net/tpc/",
    AUTH_METHOD="NONE"
);
```

Parameters:

- `SOURCE_TYPE="ObjectStorage"`: storage type (S3-compatible).
- `LOCATION="https://storage.yandexcloud.net/tpc/"`: bucket URL.
- `AUTH_METHOD="NONE"`: public access without authentication.

Creating external tables

In this step, schemas (columns and types) are defined for Parquet files in the external source. This allows accessing data through SQL queries in YDB, linking the logical structure with physical files.

`EXTERNAL TABLE` is a "virtual" table that describes the structure of the data located in an external source. This links the logical table schema with the physical files.

```
CREATE EXTERNAL TABLE IF NOT EXISTS `external/tpch/s10/customer` (
    c_acctbal Double NOT NULL,
    c_mktsegment String NOT NULL,
    c_phone String NOT NULL,
    c_nationkey Int32 NOT NULL,
    c_custkey Int32 NOT NULL,
    c_name String NOT NULL,
    c_comment String NOT NULL,
    c_address String NOT NULL
) WITH (
    DATA_SOURCE="external/tpc",
    LOCATION="/h/s10/parquet/customer/",
    FORMAT="parquet"
);
```

Parameters:

- `DATA_SOURCE="external/tpc"`: reference to the source.
- `LOCATION="/h/s10/parquet/customer/"`: path to files.
- `FORMAT="parquet"`: data format.

Create the remaining tables

```
CREATE EXTERNAL TABLE IF NOT EXISTS `external/tpch/s10/customer` (
    c_acctbal Double NOT NULL,
    c_mktsegment String NOT NULL,
    c_phone String NOT NULL,
    c_nationkey Int32 NOT NULL,
    c_custkey Int32 NOT NULL,
    c_name String NOT NULL,
    c_comment String NOT NULL,
    c_address String NOT NULL
) WITH (
    DATA_SOURCE="external/tpc",
    LOCATION="/h/s10/parquet/customer/",
    FORMAT="parquet"
);

CREATE EXTERNAL TABLE IF NOT EXISTS `external/tpch/s10/lineitem` (
    l_orderkey Int64 NOT NULL,
    l_partkey Int32 NOT NULL,
    l_suppkey Int32 NOT NULL,
    l_linenumber Int32 NOT NULL,
    l_quantity Double NOT NULL,
    l_extendedprice Double NOT NULL,
    l_discount Double NOT NULL,
    l_tax Double NOT NULL,
    l_returnflag String NOT NULL,
    l_linestatus String NOT NULL,
    l_shipdate Date NOT NULL,
    l_commitdate Date NOT NULL,
    l_receiptdate Date NOT NULL,
    l_shipinstruct String NOT NULL,
    l_shipmode String NOT NULL,
    l_comment String NOT NULL
) WITH (
    DATA_SOURCE="external/tpc",
    LOCATION="/h/s10/parquet/lineitem/",
    FORMAT="parquet"
);

CREATE EXTERNAL TABLE IF NOT EXISTS `external/tpch/s10/nation` (
    n_nationkey Int32 NOT NULL,
    n_name String NOT NULL,
    n_regionkey Int32 NOT NULL,
    n_comment String NOT NULL
) WITH (
    DATA_SOURCE="external/tpc",
    LOCATION="/h/s10/parquet/nation/",
    FORMAT="parquet"
);

CREATE EXTERNAL TABLE IF NOT EXISTS `external/tpch/s10/orders` (
    o_orderkey Int64 NOT NULL,
    o_custkey Int32 NOT NULL,
    o_orderstatus String NOT NULL,
    o_totalprice Double NOT NULL,
    o_orderdate Date NOT NULL,
    o_orderpriority String NOT NULL,
    o_clerk String NOT NULL,
    o_shippriority Int32 NOT NULL,
    o_comment String NOT NULL
) WITH (
    DATA_SOURCE="external/tpc",
    LOCATION="/h/s10/parquet/orders/",
    FORMAT="parquet"
);

CREATE EXTERNAL TABLE IF NOT EXISTS `external/tpch/s10/part` (
    p_partkey Int32 NOT NULL,
    p_name String NOT NULL,
    p_mfgr String NOT NULL,
    p_brand String NOT NULL,
    p_type String NOT NULL,
    p_size Int32 NOT NULL,
    p_container String NOT NULL,
    p_retailprice Double NOT NULL,
    p_comment String NOT NULL
) WITH (
    DATA_SOURCE="external/tpc",
    LOCATION="/h/s10/parquet/part/",
    FORMAT="parquet"
);

CREATE EXTERNAL TABLE IF NOT EXISTS `external/tpch/s10/partsupp` (
    ps_partkey Int32 NOT NULL,
    ps_suppkey Int32 NOT NULL,
    ps_availqty Int32 NOT NULL,
    ps_supplycost Double NOT NULL,
    ps_comment String NOT NULL
) WITH (
    DATA_SOURCE="external/tpc",
```

```
    LOCATION="/h/s10/parquet/partsupp/",
    FORMAT="parquet"
);

CREATE EXTERNAL TABLE IF NOT EXISTS `external/tpch/s10/region` (
    r_regionkey Int32 NOT NULL,
    r_name String NOT NULL,
    r_comment String NOT NULL
) WITH (
    DATA_SOURCE="external/tpc",
    LOCATION="/h/s10/parquet/region/",
    FORMAT="parquet"
);

CREATE EXTERNAL TABLE IF NOT EXISTS `external/tpch/s10/supplier` (
    s_suppkey Int32 NOT NULL,
    s_name String NOT NULL,
    s_address String NOT NULL,
    s_nationkey Int32 NOT NULL,
    s_phone String NOT NULL,
    s_acctbal Double NOT NULL,
    s_comment String NOT NULL
) WITH (
    DATA_SOURCE="external/tpc",
    LOCATION="/h/s10/parquet/supplier/",
    FORMAT="parquet"
);
```

Creating column-oriented tables

In this step, internal YDB tables are created for data storage. They use the column-oriented format and partitioning, which provides high performance for analytical queries through parallel processing.

```
CREATE TABLE IF NOT EXISTS `tpch/s10/customer` (
    c_acctbal Double NOT NULL,
    c_mktsegment String NOT NULL,
    c_phone String NOT NULL,
    c_nationkey Int32 NOT NULL,
    c_custkey Int32 NOT NULL,
    c_name String NOT NULL,
    c_comment String NOT NULL,
    c_address String NOT NULL,
    PRIMARY KEY (c_custkey)
)
PARTITION BY HASH (c_custkey)
WITH (
    STORE = COLUMN,
    PARTITION_COUNT = 64
);
```

Parameters:

- `PRIMARY KEY (c_custkey)`: table primary key.
- `PARTITION BY HASH (c_custkey)`: hash partitioning for parallelism.
- `STORE = COLUMN`: column-oriented data storage format for accelerating analytical queries.
- `PARTITION_COUNT = 64`: number of partitions for data distribution.

Create the remaining tables

```
CREATE TABLE IF NOT EXISTS `tpch/s10/customer` (
    c_acctbal Double NOT NULL,
    c_mktsegment String NOT NULL,
    c_phone String NOT NULL,
    c_nationkey Int32 NOT NULL,
    c_custkey Int32 NOT NULL,
    c_name String NOT NULL,
    c_comment String NOT NULL,
    c_address String NOT NULL,
    PRIMARY KEY (c_custkey)
)
PARTITION BY HASH (c_custkey)
WITH (
    STORE = COLUMN,
    PARTITION_COUNT = 64
);

CREATE TABLE IF NOT EXISTS `tpch/s10/lineitem` (
    l_orderkey Int64 NOT NULL,
    l_partkey Int32 NOT NULL,
    l_suppkey Int32 NOT NULL,
    l_linenumber Int32 NOT NULL,
    l_quantity Double NOT NULL,
    l_extendedprice Double NOT NULL,
    l_discount Double NOT NULL,
    l_tax Double NOT NULL,
    l_returnflag String NOT NULL,
    l_linestatus String NOT NULL,
    l_shipdate Date NOT NULL,
    l_commitdate Date NOT NULL,
    l_receiptdate Date NOT NULL,
    l_shipinstruct String NOT NULL,
    l_shipmode String NOT NULL,
    l_comment String NOT NULL,
    PRIMARY KEY (l_orderkey, l_linenumber)
)
PARTITION BY HASH (l_orderkey)
WITH (
    STORE = COLUMN,
    PARTITION_COUNT = 64
);

CREATE TABLE IF NOT EXISTS `tpch/s10/nation` (
    n_nationkey Int32 NOT NULL,
    n_name String NOT NULL,
    n_regionkey Int32 NOT NULL,
    n_comment String NOT NULL,
    PRIMARY KEY (n_nationkey)
)
PARTITION BY HASH (n_nationkey)
WITH (
    STORE = COLUMN,
    PARTITION_COUNT = 64
);

CREATE TABLE IF NOT EXISTS `tpch/s10/orders` (
    o_orderkey Int64 NOT NULL,
    o_custkey Int32 NOT NULL,
    o_orderstatus String NOT NULL,
    o_totalprice Double NOT NULL,
    o_orderdate Date NOT NULL,
    o_orderpriority String NOT NULL,
    o_clerk String NOT NULL,
    o_shippriority Int32 NOT NULL,
    o_comment String NOT NULL,
    PRIMARY KEY (o_orderkey)
)
PARTITION BY HASH (o_orderkey)
WITH (
    STORE = COLUMN,
    PARTITION_COUNT = 64
);

CREATE TABLE IF NOT EXISTS `tpch/s10/part` (
    p_partkey Int32 NOT NULL,
    p_name String NOT NULL,
    p_mfgr String NOT NULL,
    p_brand String NOT NULL,
    p_type String NOT NULL,
    p_size Int32 NOT NULL,
    p_container String NOT NULL,
    p_retailprice Double NOT NULL,
    p_comment String NOT NULL,
    PRIMARY KEY (p_partkey)
)
PARTITION BY HASH (p_partkey)
WITH (
    STORE = COLUMN,
    PARTITION_COUNT = 64
```

```
);

CREATE TABLE IF NOT EXISTS `tpch/s10/partsupp` (
    ps_partkey Int32 NOT NULL,
    ps_suppkey Int32 NOT NULL,
    ps_availqty Int32 NOT NULL,
    ps_supplycost Double NOT NULL,
    ps_comment String NOT NULL,
    PRIMARY KEY (ps_partkey, ps_suppkey)
)
PARTITION BY HASH (ps_partkey, ps_suppkey)
WITH (
    STORE = COLUMN,
    PARTITION_COUNT = 64
);

CREATE TABLE IF NOT EXISTS `tpch/s10/region` (
    r_regionkey Int32 NOT NULL,
    r_name String NOT NULL,
    r_comment String NOT NULL,
    PRIMARY KEY (r_regionkey)
)
PARTITION BY HASH (r_regionkey)
WITH (
    STORE = COLUMN,
    PARTITION_COUNT = 64
);

CREATE TABLE IF NOT EXISTS `tpch/s10/supplier` (
    s_suppkey Int32 NOT NULL,
    s_name String NOT NULL,
    s_address String NOT NULL,
    s_nationkey Int32 NOT NULL,
    s_phone String NOT NULL,
    s_acctbal Double NOT NULL,
    s_comment String NOT NULL,
    PRIMARY KEY (s_suppkey)
)
PARTITION BY HASH (s_suppkey)
WITH (
    STORE = COLUMN,
    PARTITION_COUNT = 64
);
```

Loading data into column-oriented tables

In this step, data is copied from the external storage into internal YDB tables. This provides the local storage for fast analytics. The process may take time (for 10 GB — on the order of minutes, depending on resources).

```
UPSERT INTO `tpch/s10/customer` SELECT * FROM `external/tpch/s10/customer`;
UPSERT INTO `tpch/s10/lineitem` SELECT * FROM `external/tpch/s10/lineitem`;
UPSERT INTO `tpch/s10/nation`   SELECT * FROM `external/tpch/s10/nation`;
UPSERT INTO `tpch/s10/orders`   SELECT * FROM `external/tpch/s10/orders`;
UPSERT INTO `tpch/s10/part`     SELECT * FROM `external/tpch/s10/part`;
UPSERT INTO `tpch/s10/partsupp` SELECT * FROM `external/tpch/s10/partsupp`;
UPSERT INTO `tpch/s10/region`   SELECT * FROM `external/tpch/s10/region`;
UPSERT INTO `tpch/s10/supplier` SELECT * FROM `external/tpch/s10/supplier`;
```

Executing a test analytical query

In this step, the TPC-H Q0 test query is executed to verify the correctness of data loading and performance. The query aggregates metrics from the `lineitem` table (about 6 million rows), with grouping and subsequent data sorting, demonstrating the efficiency of column-oriented tables.

```
SELECT
    l_returnflag,
    l_linestatus,
    SUM(l_quantity) AS sum_qty,
    SUM(l_extendedprice) AS sum_base_price,
    SUM(l_extendedprice * (1 - l_discount)) AS sum_disc_price,
    SUM(l_extendedprice * (1 - l_discount) * (1 + l_tax)) AS sum_charge,
    AVG(l_quantity) AS avg_qty,
    AVG(l_extendedprice) AS avg_price,
    AVG(l_discount) AS avg_disc,
    COUNT(*) AS count_order
FROM
    `tpch/s10/lineitem`
WHERE
    l_shipdate <= Date('1998-12-01') - Interval("P90D")
GROUP BY
    l_returnflag,
    l_linestatus
ORDER BY
    l_returnflag,
    l_linestatus;
```

Next steps

- Execute other queries from the TPC-H suite on the loaded tables using YDB CLI and TPC-H workload testing.
- Integration with BI systems for data visualization and analysis.

Overview

These pages describe popular datasets that you can load into YDB to familiarize yourself with the database's functionality and test various use cases.

Prerequisites

To load the datasets, you will need:

1. Installed YDB CLI
2. [Optional] Configured connection profile to YDB to avoid specifying connection parameters with every command

General Information on Data Loading

YDB supports importing data from CSV files using the command `ydb import file csv`. Example command:

```
ydb import file csv --header --null-value "" --path <table_path> <file>.csv
```

Where:

- `--header` indicates that the first row of the file contains the column names, and the actual data starts from the second row;
- `--null-value ""` specifies that an empty string in the CSV will be interpreted as a null value during data import into the table.

A table must already exist in YDB for data import. The primary way to create a table is by executing the `CREATE TABLE` YQL query. Instead of writing the query manually, you can try running the import command from a file, as shown in any example in this section, without creating the table first. In this case, the CLI will suggest a `CREATE TABLE` query, which you can use as a base, edit if necessary, and execute.

To import data into YDB, a table must be pre-created. Typically, a table is created using the YQL `CREATE TABLE` query. However, instead of crafting such a query manually, you can initiate the import command `ydb import file csv` as shown in the import examples in this section. If the table doesn't exist, the CLI will automatically suggest a `CREATE TABLE` query that you can use to create the table.

> **Selecting a Primary Key**
>
> YDB requires a primary key for the table. It significantly speeds up data loading and processing, and it also allows for deduplication: rows with identical values in the primary key columns replace each other.
>
> If the imported dataset doesn't have suitable columns for a primary key, we add a new column with row numbers and use it as the primary key, as each row number is unique within the file.

Features and Limitations

When woimporting data to YDB, consider the following points:

1. **Column Names**: Column names should not contain spaces or special characters.
2. **Data Types**:
   - Date/time strings with timezone (e.g., "2019-11-01 00:00:00 UTC") will be imported as Text type.
   - The Bool type is not supported as a column type; use Text or Int64 instead.

Available Datasets

- Chess Position Evaluations - Stockfish engine chess position evaluations
- Video Game Sales - video game sales data
- E-Commerce Behavior Data - user behavior data from an online store
- COVID-19 Open Research Dataset - open research dataset on COVID-19
- Netflix Movies and TV Shows - data on Netflix movies and shows
- Animal Crossing New Horizons Catalog - item catalog from the game

> If the imported dataset doesn't have suitable columns for a primary key, we add a new column with row numbers and use it as the primary key, as each row number is unique within the file.

Features and Limitations

When woimporting data to YDB, consider the following points:

1. **Column Names**: Column names should not contain spaces or special characters.
2. **Data Types**:
   - Date/time strings with timezone (e.g., "2019-11-01 00:00:00 UTC") will be imported as Text type.
   - The Bool type is not supported as a column type; use Text or Int64 instead.

Available Datasets

- Chess Position Evaluations - Stockfish engine chess position evaluations
- Video Game Sales - video game sales data
- E-Commerce Behavior Data - user behavior data from an online store
- COVID-19 Open Research Dataset - open research dataset on COVID-19
- Netflix Movies and TV Shows - data on Netflix movies and shows
- Animal Crossing New Horizons Catalog - item catalog from the game

Chess Position Evaluations

> **Note**
>
> This page is part of the Dataset Import section, which includes examples of loading popular datasets into YDB. Before starting, please review the general information on requirements and the import process.

The dataset includes 513 million chess position evaluations performed by the Stockfish engine for analysis on the Lichess platform.

Source: Kaggle - Chess Position Evaluations

Size: 59.66 GB

Loading Example

1. Download the `evals.csv` file from Kaggle.
2. Create a table in YDB using one of the following methods:

   YDB UI

   For more information on YDB UI.

   ```
   CREATE TABLE `evals` (
       `fen` Text NOT NULL,
       `line` Text NOT NULL,
       `depth` Uint64,
       `knodes` Uint64,
       `cp` Double,
       `mate` Double,
       PRIMARY KEY (`fen`, `line`)
   )
   WITH (
       STORE = COLUMN,
       UNIFORM_PARTITIONS = 50
   );
   ```

   YDB CLI

   ```
   ydb sql -s \
   'CREATE TABLE `evals` (
       `fen` Text NOT NULL,
       `line` Text NOT NULL,
       `depth` Uint64,
       `knodes` Uint64,
       `cp` Double,
       `mate` Double,
       PRIMARY KEY (`fen`, `line`)
   )
   WITH (
       STORE = COLUMN,
       UNIFORM_PARTITIONS = 50
   );'
   ```

3. Execute the import command:

   ```
   ydb import file csv --header --null-value "" --path evals evals.csv
   ```

Analytical Query Example

Identify positions with the highest number of moves analyzed by the Stockfish engine:

YDB UI

```
SELECT
    fen,
    MAX(depth) AS max_depth,
    SUM(knodes) AS total_knodes
FROM evals
GROUP BY fen
ORDER BY max_depth DESC
LIMIT 10;
```

YDB CLI

```
ydb sql -s \
'SELECT
    fen,
    MAX(depth) AS max_depth,
    SUM(knodes) AS total_knodes
FROM evals
GROUP BY fen
ORDER BY max_depth DESC
LIMIT 10;'
```

This query performs the following actions:

- Finds positions (represented in FEN format) with the maximum analysis depth.
- Sums the number of analyzed nodes (knodes) for each position.
- Sorts results by maximum analysis depth in descending order.
- Outputs the top 10 positions with the highest analysis depth.

Video Game Sales

> **Note**
>
> This page is part of the Dataset Import section, which includes examples of loading popular datasets into YDB. Before starting, please review the general information on requirements and the import process.

Data on video game sales.

Source: Kaggle - Video Game Sales

Size: 1.36 MB

Loading Example

1. Download and unzip the `vgsales.csv` file from Kaggle.
2. Create a table in YDB using one of the following methods:

   YDB UI

   For more information on YDB UI.

   ```
   CREATE TABLE `vgsales` (
       `Rank` Uint64 NOT NULL,
       `Name` Text NOT NULL,
       `Platform` Text NOT NULL,
       `Year` Text NOT NULL,
       `Genre` Text NOT NULL,
       `Publisher` Text NOT NULL,
       `NA_Sales` Double NOT NULL,
       `EU_Sales` Double NOT NULL,
       `JP_Sales` Double NOT NULL,
       `Other_Sales` Double NOT NULL,
       `Global_Sales` Double NOT NULL,
       PRIMARY KEY (`Rank`)
   )
   WITH (
       STORE = COLUMN
   );
   ```

   YDB CLI

   ```
   ydb sql -s \
   'CREATE TABLE `vgsales` (
       `Rank` Uint64 NOT NULL,
       `Name` Text NOT NULL,
       `Platform` Text NOT NULL,
       `Year` Text NOT NULL,
       `Genre` Text NOT NULL,
       `Publisher` Text NOT NULL,
       `NA_Sales` Double NOT NULL,
       `EU_Sales` Double NOT NULL,
       `JP_Sales` Double NOT NULL,
       `Other_Sales` Double NOT NULL,
       `Global_Sales` Double NOT NULL,
       PRIMARY KEY (`Rank`)
   )
   WITH (
       STORE = COLUMN
   );'
   ```

3. Execute the import command:

   ```
   ydb import file csv --header --null-value "" --path vgsales vgsales.csv
   ```

Analytical Query Example

To identify the publisher with the highest average game sales in North America, execute the query:

YDB UI

```
SELECT
    Publisher,
    AVG(NA_Sales) AS average_na_sales
FROM vgsales
GROUP BY Publisher
ORDER BY average_na_sales DESC
LIMIT 1;
```

YDB CLI

```
ydb sql -s \
'SELECT
    Publisher,
    AVG(NA_Sales) AS average_na_sales
FROM vgsales
GROUP BY Publisher
ORDER BY average_na_sales DESC
LIMIT 1;'
```

Result:

```
┌─────────────┬────────────────────┐
| Publisher | average_na_sales |
├─────────────┼────────────────────┤
| "Palcom"  | 3.38               |
└─────────────┴────────────────────┘
```

This query helps find the publisher with the greatest success in North America by average sales.

E-Commerce Behavior Data

> **Note**
>
> This page is part of the Dataset Import section, which includes examples of loading popular datasets into YDB. Before starting, please review the general information on requirements and the import process.

User behavior data from a multi-category online store.

Source: Kaggle - E-commerce behavior data

Size: 9 GB

Loading Example

1. Download and unzip the `2019-Nov.csv` file from Kaggle.
2. The dataset includes completely identical rows. Since YDB requires unique primary key values, add a new column named `row_id` to the file, where the key value will be equal to the row number in the original file. This prevents the removal of duplicate data. This operation can be carried out using the awk command:

```
awk 'NR==1 {print "row_id," \$0; next} {print NR-1 "," \$0}' 2019-Nov.csv > temp.csv && mv temp.csv 2019
-Nov.csv
```

3. Create a table in YDB using one of the following methods:

   YDB UI

   For more information on YDB UI.

```
CREATE TABLE `ecommerce_table` (
    `row_id` Uint64 NOT NULL,
    `event_time` Text NOT NULL,
    `event_type` Text NOT NULL,
    `product_id` Uint64 NOT NULL,
    `category_id` Uint64,
    `category_code` Text,
    `brand` Text,
    `price` Double NOT NULL,
    `user_id` Uint64 NOT NULL,
    `user_session` Text NOT NULL,
    PRIMARY KEY (`row_id`)
)
WITH (
    STORE = COLUMN,
    UNIFORM_PARTITIONS = 50
);
```

   YDB CLI

```
ydb sql -s \
'CREATE TABLE `ecommerce_table` (
    `row_id` Uint64 NOT NULL,
    `event_time` Text NOT NULL,
    `event_type` Text NOT NULL,
    `product_id` Uint64 NOT NULL,
    `category_id` Uint64,
    `category_code` Text,
    `brand` Text,
    `price` Double NOT NULL,
    `user_id` Uint64 NOT NULL,
    `user_session` Text NOT NULL,
    PRIMARY KEY (`row_id`)
)
WITH (
    STORE = COLUMN,
    UNIFORM_PARTITIONS = 50
);'
```

4. Execute the import command:

```
ydb import file csv --header --null-value "" --path ecommerce_table 2019-Nov.csv
```

Analytical Query Example

Identify the most popular product categories on November 1, 2019:

YDB UI

```
SELECT
    category_code,
    COUNT(*) AS view_count
FROM ecommerce_table
WHERE
    SUBSTRING(CAST(event_time AS String), 0, 10) = '2019-11-01'
    AND event_type = 'view'
GROUP BY category_code
ORDER BY view_count DESC
LIMIT 10;
```

YDB CLI

```
ydb sql -s \
'SELECT
    category_code,
    COUNT(*) AS view_count
FROM ecommerce_table
WHERE
    SUBSTRING(CAST(event_time AS String), 0, 10) = "2019-11-01"
    AND event_type = "view"
GROUP BY category_code
ORDER BY view_count DESC
LIMIT 10;'
```

Result:

```
┌──────────────────────────────────────┬────────────┐
| category_code                        | view_count |
├──────────────────────────────────────┼────────────┤
| null                                 | 453024     |
├──────────────────────────────────────┼────────────┤
| "electronics.smartphone"             | 360650     |
├──────────────────────────────────────┼────────────┤
| "electronics.clocks"                 | 43581      |
├──────────────────────────────────────┼────────────┤
| "computers.notebook"                 | 40878      |
├──────────────────────────────────────┼────────────┤
| "electronics.video.tv"               | 40383      |
├──────────────────────────────────────┼────────────┤
| "electronics.audio.headphone"        | 37489      |
├──────────────────────────────────────┼────────────┤
| "apparel.shoes"                      | 31013      |
├──────────────────────────────────────┼────────────┤
| "appliances.kitchen.washer"          | 28028      |
├──────────────────────────────────────┼────────────┤
| "appliances.kitchen.refrigerators"   | 27808      |
├──────────────────────────────────────┼────────────┤
| "appliances.environment.vacuum"      | 26477      |
└──────────────────────────────────────┴────────────┘
```

COVID-19 Open Research Dataset

> **Note**
>
> This page is part of the Dataset Import section, which includes examples of loading popular datasets into YDB. Before starting, please review the general information on requirements and the import process.

An open dataset of COVID-19 research.

Source: Kaggle - COVID-19 Open Research Dataset Challenge

Size: 1.65 GB (metadata.csv file)

Loading Example

1. Download and unzip the `metadata.csv` file from Kaggle.
2. The dataset includes completely identical rows. Since YDB requires unique primary key values, add a new column named `row_id` to the file, where the key value will be equal to the row number in the original file. This prevents the removal of duplicate data. This operation can be carried out using the awk command:

   ```
   awk 'NR==1 {print "row_id," \$0; next} {print NR-1 "," \$0}' metadata.csv > temp.csv && mv temp.csv meta
   data.csv
   ```

3. Create a table in YDB using one of the following methods:

   YDB UI

   For more information on YDB UI.

   ```
   CREATE TABLE `covid_research` (
       `row_id` Uint64 NOT NULL,
       `cord_uid` Text NOT NULL,
       `sha` Text NOT NULL,
       `source_x` Text NOT NULL,
       `title` Text NOT NULL,
       `doi` Text NOT NULL,
       `pmcid` Text NOT NULL,
       `pubmed_id` Text NOT NULL,
       `license` Text NOT NULL,
       `abstract` Text NOT NULL,
       `publish_time` Text NOT NULL,
       `authors` Text NOT NULL,
       `journal` Text NOT NULL,
       `mag_id` Text,
       `who_covidence_id` Text,
       `arxiv_id` Text,
       `pdf_json_files` Text NOT NULL,
       `pmc_json_files` Text NOT NULL,
       `url` Text NOT NULL,
       `s2_id` Uint64,
       PRIMARY KEY (`row_id`)
   )
   WITH (
       STORE = COLUMN
   );
   ```

   YDB CLI

   ```
   ydb sql -s \
   'CREATE TABLE `covid_research` (
       `row_id` Uint64 NOT NULL,
       `cord_uid` Text NOT NULL,
       `sha` Text NOT NULL,
       `source_x` Text NOT NULL,
       `title` Text NOT NULL,
       `doi` Text NOT NULL,
       `pmcid` Text NOT NULL,
       `pubmed_id` Text NOT NULL,
       `license` Text NOT NULL,
       `abstract` Text NOT NULL,
       `publish_time` Text NOT NULL,
       `authors` Text NOT NULL,
       `journal` Text NOT NULL,
       `mag_id` Text,
       `who_covidence_id` Text,
       `arxiv_id` Text,
       `pdf_json_files` Text NOT NULL,
       `pmc_json_files` Text NOT NULL,
       `url` Text NOT NULL,
       `s2_id` Uint64,
       PRIMARY KEY (`row_id`)
   )
   WITH (
       STORE = COLUMN
   );'
   ```

4. Execute the import command:

```
ydb import file csv --header --null-value "" --path covid_research metadata.csv
```

Analytical Query Example

Run a query to determine the journals with the highest number of publications:

YDB UI

```
SELECT
    journal,
    COUNT(*) AS publication_count
FROM covid_research
WHERE journal IS NOT NULL AND journal != ''
GROUP BY journal
ORDER BY publication_count DESC
LIMIT 10;
```

YDB CLI

```
ydb sql -s \
'SELECT
    journal,
    COUNT(*) AS publication_count
FROM covid_research
WHERE journal IS NOT NULL AND journal != ""
GROUP BY journal
ORDER BY publication_count DESC
LIMIT 10;'
```

Result:

```
┌──────────────────────────────────┬──────────────────┐
| journal                          | publication_count |
├──────────────────────────────────┼──────────────────┤
| "PLoS One"                       | 9953             |
├──────────────────────────────────┼──────────────────┤
| "bioRxiv"                        | 8961             |

```

Netflix Movies and TV Shows

> **Note**
>
> This page is part of the Dataset Import section, which includes examples of loading popular datasets into YDB. Before starting, please review the general information on requirements and the import process.

Data on movies and TV shows available on Netflix.

Source: Kaggle - Netflix Movies and TV Shows

Size: 3.4 MB

Loading Example

1. Download and unzip the `netflix_titles.csv` file from Kaggle.
2. Create a table in YDB using one of the following methods:

   YDB UI

   For more information on YDB UI.

   ```
   CREATE TABLE `netflix` (
       `show_id` Text NOT NULL,
       `type` Text NOT NULL,
       `title` Text NOT NULL,
       `director` Text NOT NULL,
       `cast` Text,
       `country` Text NOT NULL,
       `date_added` Text NOT NULL,
       `release_year` Uint64 NOT NULL,
       `rating` Text NOT NULL,
       `duration` Text NOT NULL,
       `listed_in` Text NOT NULL,
       `description` Text NOT NULL,
       PRIMARY KEY (`show_id`)
   )
   WITH (
       STORE = COLUMN
   );
   ```

   YDB CLI

   ```
   ydb sql -s \
   'CREATE TABLE `netflix` (
       `show_id` Text NOT NULL,
       `type` Text NOT NULL,
       `title` Text NOT NULL,
       `director` Text NOT NULL,
       `cast` Text,
       `country` Text NOT NULL,
       `date_added` Text NOT NULL,
       `release_year` Uint64 NOT NULL,
       `rating` Text NOT NULL,
       `duration` Text NOT NULL,
       `listed_in` Text NOT NULL,
       `description` Text NOT NULL,
       PRIMARY KEY (`show_id`)
   )
   WITH (
       STORE = COLUMN
   );'
   ```

3. Execute the import command:

   ```
   ydb import file csv --header --null-value "" --path netflix netflix_titles.csv
   ```

Analytical Query Example

Identify the top three countries with the most content added to Netflix in 2020:

YDB UI

```
SELECT
    country,
    COUNT(*) AS count
FROM netflix
WHERE
    CAST(SUBSTRING(CAST(date_added AS String), 7, 4) AS Int32) = 2020
    AND date_added IS NOT NULL
GROUP BY country
ORDER BY count DESC
LIMIT 3;
```

YDB CLI

```
ydb sql -s \
'SELECT
    country,
    COUNT(*) AS count
FROM netflix
WHERE
    CAST(SUBSTRING(CAST(date_added AS String), 7, 4) AS Int32) = 2020
    AND date_added IS NOT NULL
GROUP BY country
ORDER BY count DESC
LIMIT 3;'
```

Result:

```
┌─────────────────┬───────┐
| country         | count |
├─────────────────┼───────┤
| "United States" | 22    |
├─────────────────┼───────┤
| ""              | 7     |
├─────────────────┼───────┤
| "Canada"        | 3     |
└─────────────────┴───────┘
```

Animal Crossing New Horizons Catalog

> **Note**
>
> This page is part of the Dataset Import section, which includes examples of loading popular datasets into YDB. Before starting, please review the general information on requirements and the import process.

A catalog of items from the popular game Animal Crossing: New Horizons.

Source: Kaggle - Animal Crossing New Horizons Catalog

Size: 51 KB

Loading Example

1. Download and unzip the `accessories.csv` file from Kaggle.
2. This file includes a BOM (Byte Order Mark). However, the import command does not support files with a BOM. To resolve this, remove the BOM bytes from the beginning of the file by executing the following command:

   ```
   sed -i '1s/^\xEF\xBB\xBF//' accessories.csv
   ```

3. The column names in the file contain spaces, which are incompatible with YDB since YDB does not support spaces in column names. Replace spaces in the column names with underscores, for example, by executing the following command:

   ```
   sed -i '1s/ /_/g' accessories.csv
   ```

4. Create a table in YDB using one of the following methods:

   YDB UI

   For more information on YDB UI.

   ```
   CREATE TABLE `accessories` (
       `Name` Text NOT NULL,
       `Variation` Text NOT NULL,
       `DIY` Text NOT NULL,
       `Buy` Text NOT NULL,
       `Sell` Uint64 NOT NULL,
       `Color_1` Text NOT NULL,
       `Color_2` Text NOT NULL,
       `Size` Text NOT NULL,
       `Miles_Price` Text NOT NULL,
       `Source` Text NOT NULL,
       `Source_Notes` Text NOT NULL,
       `Seasonal_Availability` Text NOT NULL,
       `Mannequin_Piece` Text NOT NULL,
       `Version` Text NOT NULL,
       `Style` Text NOT NULL,
       `Label_Themes` Text NOT NULL,
       `Type` Text NOT NULL,
       `Villager_Equippable` Text NOT NULL,
       `Catalog` Text NOT NULL,
       `Filename` Text NOT NULL,
       `Internal_ID` Uint64 NOT NULL,
       `Unique_Entry_ID` Text NOT NULL,
       PRIMARY KEY (`Unique_Entry_ID`)
   )
   WITH (
       STORE = COLUMN
   );
   ```

YDB CLI

```
ydb sql -s \
'CREATE TABLE `accessories` (
    `Name` Text NOT NULL,
    `Variation` Text NOT NULL,
    `DIY` Text NOT NULL,
    `Buy` Text NOT NULL,
    `Sell` Uint64 NOT NULL,
    `Color_1` Text NOT NULL,
    `Color_2` Text NOT NULL,
    `Size` Text NOT NULL,
    `Miles_Price` Text NOT NULL,
    `Source` Text NOT NULL,
    `Source_Notes` Text NOT NULL,
    `Seasonal_Availability` Text NOT NULL,
    `Mannequin_Piece` Text NOT NULL,
    `Version` Text NOT NULL,
    `Style` Text NOT NULL,
    `Label_Themes` Text NOT NULL,
    `Type` Text NOT NULL,
    `Villager_Equippable` Text NOT NULL,
    `Catalog` Text NOT NULL,
    `Filename` Text NOT NULL,
    `Internal_ID` Uint64 NOT NULL,
    `Unique_Entry_ID` Text NOT NULL,
    PRIMARY KEY (`Unique_Entry_ID`)
)
WITH (
    STORE = COLUMN
);'
```

5. Execute the import command:

```
ydb import file csv --header --path accessories accessories.csv
```

Analytical Query Example

Identify the top five most popular primary colors of accessories:

YDB UI

```
SELECT
    Color_1,
    COUNT(*) AS color_count
FROM accessories
GROUP BY Color_1
ORDER BY color_count DESC
LIMIT 5;
```

YDB CLI

```
ydb sql -s \
'SELECT
    Color_1,
    COUNT(*) AS color_count
FROM accessories
GROUP BY Color_1
ORDER BY color_count DESC
LIMIT 5;'
```

Result:

```
┌──────────┬─────────────┐
| Color_1  | color_count |
├──────────┼─────────────┤
| "Black"  | 31          |
├──────────┼─────────────┤
| "Green"  | 27          |
├──────────┼─────────────┤
| "Pink"   | 20          |
├──────────┼─────────────┤
| "Red"    | 20          |
├──────────┼─────────────┤
| "Yellow" | 19          |
└──────────┴─────────────┘
```

Working with slowly changing dimensions

This section contains practical guides for implementing slowly changing dimensions (Slowly Changing Dimensions, SCD) — a popular approach to managing historical data in analytical stores.

The section describes the SCD1 and SCD2 variants:

- SCD Type 1: Old attribute values are replaced with new ones, keeping only the current state of data.
- SCD Type 2: The full history of changes is preserved by adding new records for each new attribute version.

Features of SCD1

Slowly changing dimensions (type 1) or SCD1 (Type 1) is an approach where when an attribute of the dimension changes, the old value is replaced with a new one. Only the current state of data is stored. This approach is used when:

- historical information is not required;
- it is important to have only current data;
- it is required to minimize the size of the data store;
- it is required to have a simple data structure for analytics.

Features of SCD2 and append-only approach

Slowly changing dimensions (type 2) or SCD2 (Type 2) is an approach where when an attribute of the dimension changes, a new record is created, and the old one is marked as not current. Thus, the history of changes is preserved. This approach is used when:

- it is required to track the history of data changes;
- it is required to perform data analysis with regard to time periods;
- it is important to preserve the audit trail of changes;
- it is required to have the ability to restore the state of data at a specific point in time.

Available guides

The section discusses different technical ways to implement these mechanisms:

- Using the combination of Change Data Capture (CDC) and Transfer for automatic streaming replication of changes from source tables.
  - Using the TRANSFER mechanism to implement SCD1 based on data from CDC sources in YDB
  - Using the TRANSFER mechanism to implement SCD2 based on data from CDC sources in YDB
- Using periodic YQL queries that process batches of changes from the intermediate table and merge them into the main SCD table.
  - Using the merge process to implement SCD2 in YDB

Working with slowly changing dimensions

This section contains practical guides for implementing slowly changing dimensions (Slowly Changing Dimensions, SCD) — a popular approach to managing historical data in analytical stores.

The section describes the SCD1 and SCD2 variants:

- SCD Type 1: Old attribute values are replaced with new ones, keeping only the current state of data.
- SCD Type 2: The full history of changes is preserved by adding new records for each new attribute version.

Features of SCD1

Using the TRANSFER mechanism to implement SCD1 based on data from CDC sources in YDB

This article describes the implementation of the Slowly Changing Dimensions Type 1 (SCD1) pattern in YDB.

Used tools

For delivering data to the SCD1 table, the following combination of functional capabilities of YDB will be used in this article:

1. The source table will be row-oriented for operational transactional changes;
2. The target table will be column-oriented for efficient execution of analytical queries;
3. The subscription to changes in the source table will be implemented through the Change Data Capture (CDC) mechanism;
4. The buffering of changes will be handled by an implicitly created CDC topic;
5. The automatic transfer of data from the CDC topic to the target table will be handled by transfer.

> **Warning**
>
> Transfer cannot delete rows from tables, it can only perform `UPSERT` in the target table.
> Therefore, using Transfer, only SCD1-soft can be implemented: deletion is marked with a flag and the moment of deletion is saved. If physical data cleaning is needed, it can be performed through an explicit command `DELETE`.

Create a source data table that will generate CDC events

```
CREATE TABLE source_customers (
    id Utf8 NOT NULL,
    attribute1 Utf8,
    attribute2 Utf8,
    change_time Timestamp,
    PRIMARY KEY (id)
);

ALTER TABLE `source_customers` ADD CHANGEFEED `updates` WITH (
  FORMAT = 'DEBEZIUM_JSON',
  MODE = 'NEW_AND_OLD_IMAGES'
);
```

Create a target data table in SCD1 format

```
CREATE TABLE dimension_scd1 (
    id Utf8 NOT NULL,
    attribute1 Utf8,
    attribute2 Utf8,
    is_deleted Uint8,
    last_update_timestamp Timestamp,
    PRIMARY KEY (id)
)
PARTITION BY HASH(id)
WITH (
  STORE=COLUMN
)
```

Create a transfer and lambda function to process CDC data

Features of processing CDC data in Debezium format:

- The message format contains the `payload.before` and `payload.after` fields with the state before and after the change.
- The `payload.op` field indicates the type of operation: "c" (create), "u" (update), "d" (delete).
- The `payload.ts_ms` field contains the event timestamp in milliseconds.
- When deleting (`op = "d"`), the data is in the `before` field, and when creating/updating - in the `after` field. If deletion of a non-existent row is performed, a message with the operation type `op = "d"` will be formed, but with empty `before` and `after` fields.

```
$transformation_lambda = ($msg) -> {
    $cdc_data = CAST($msg._data AS Json);

    -- Define the type of operation
    $operation = Json::ConvertToString($cdc_data.payload.op);
    $is_deleted = $operation == "d";

    -- Get data depending on the type of operation
    $data = IF($is_deleted, $cdc_data.payload.before, $cdc_data.payload.after);

    -- If the data has not come (the DELETE command has been executed on a non-existent key, then the record
will be ignored)
    return IF($data IS NOT NULL,
        <|
            id: Unwrap(CAST(Json::ConvertToString($data.id) AS Utf8)),
            attribute1: CAST(Json::ConvertToString($data.attribute1) AS Utf8),
            attribute2: CAST(Json::ConvertToString($data.attribute2) AS Utf8),
            is_deleted: CAST($is_deleted AS Uint8),
            last_update_timestamp: DateTime::FromMilliseconds(Json::ConvertToUint64($cdc_data.payload.source.
ts_ms))
        |>
    , NULL);
};

-- In this example, a high frequency of updates to the target table is configured.
-- This is done solely for clarity. For production scenarios, larger values should be set
CREATE TRANSFER dimension_scd1_cdc_transfer
  FROM `source_customers/updates` TO dimension_scd1 USING $transformation_lambda
  WITH (
    FLUSH_INTERVAL=Interval("PT1S")
  );
```

Note

The `id` column in the receiving table `dimension_scd1` is declared as `Utf8 NOT NULL`, while in Json CDC, data that cannot be converted to a string may be passed, i.e., the result of converting data from Json may be a `NULL` value. The `Unwrap` function guarantees that after its execution, there cannot be a `NULL` value or a runtime error. This ensures that the result of executing the lambda function will either be a fully correct data structure, or a runtime error.

Demonstration of work

To demonstrate the work with CDC data, data will be written to the source table in YDB, which will generate CDC events:

Inserting a new record

```
INSERT INTO source_customers (id, attribute1, attribute2)
VALUES ('CUSTOMER_1001', 'John Doe', 'New York');
```

This action will create a CDC event with the operation type `op = "c"` approximately of the following form:

```
{
  "payload":{
    "op":"c",
    "source":{
      "txId":18446744073709551615,
      "connector":"ydb",
      "version":"1.0.0",
      "step":1755868513260,
      "ts_ms":1755868513219,
      "snapshot":false
    },
    "after":{
      "attribute1":"John Doe",
      "id":"CUSTOMER_1001",
      "attribute2":"New York"
    }
  }
}
```

The content of the `dimension_scd1` table after executing the command above will be as follows:

id	attribute1	attribute2	is_deleted	last_update_timestamp
CUSTOMER_1001	John Doe	New York	0	2025-08-22T13:15:13.219000Z

Updating an existing record

```
UPSERT INTO source_customers (id, attribute1, attribute2)
VALUES ('CUSTOMER_1001', 'John Doe', 'Los Angeles');
```

This action will create a CDC event with the operation type `op = "u"` approximately of the following form:

```
{
  "payload":{
      "op":"u",
      "source":{
        "txId":18446744073709551615,
        "connector":"ydb",
        "version":"1.0.0",
        "step":1755868795050,
        "ts_ms":1755868795719,
        "snapshot":false
    },
    "after":{
      "attribute1":"John Doe",
      "id":"CUSTOMER_1001",
      "attribute2":"Los Angeles"
    },
    "before":{
      "attribute1":"John Doe",
      "id":"CUSTOMER_1001",
      "attribute2":"New York"
    }
  }
}
```

The content of the `dimension_scd1` table after executing the command above will be as follows:

id	attribute1	attribute2	is_deleted	last_update_timestamp
CUSTOMER_1001	John Doe	Los Angeles	0	2025-08-22T13:19:55.719000Z

Deleting a record

```
DELETE FROM source_customers WHERE id = 'CUSTOMER_1001';
```

This action will create a CDC event with the operation type `op = "d"` approximately of the following form:

```
{
  "payload":{
    "op":"d",
    "source":{
      "txId":18446744073709551615,
      "connector":"ydb",
      "version":"1.0.0",
      "step":1755868931000,
      "ts_ms":1755868931109,
      "snapshot":false
    },
    "before":{
      "attribute1":"John Doe",
      "id":"CUSTOMER_1001",
      "attribute2":"Los Angeles"
    }
  }
}
```

The content of the `dimension_scd1` table after executing the command above will be as follows:

id	attribute1	attribute2	is_deleted	last_update_timestamp
CUSTOMER_1001	John Doe	Los Angeles	1	2025-08-22T13:22:11.109000Z

Example of deleting data from the target table

To delete data from the target table, you can use an explicit `DELETE` command:

```
DELETE from dimension_scd1 WHERE is_deleted != 0ut
```

Using the TRANSFER mechanism to implement SCD2 based on data from CDC sources in YDB

This article describes the implementation of the Slowly Changing Dimensions Type 2 (SCD2) pattern in YDB.

Used tools

For delivering data to the SCD2 table, the following combination of functional capabilities of YDB will be used in this article:

1. The source table will be row-oriented for operational transactional changes;
2. The target table will be column-oriented for efficient execution of analytical queries;
3. The subscription to changes in the source table will be implemented through the Change Data Capture (CDC) mechanism;
4. The buffering of changes will be handled by an implicitly created CDC topic;
5. The automatic transfer of data from the CDC topic to the target table will be handled by transfer.

Create a source data table that will generate CDC events

```
CREATE TABLE source_customers (
    id Utf8 NOT NULL,
    attribute1 Utf8,
    attribute2 Utf8,
    change_time Timestamp,
    PRIMARY KEY (id)
);

ALTER TABLE `source_customers` ADD CHANGEFEED `updates` WITH (
  FORMAT = 'DEBEZIUM_JSON',
  MODE = 'NEW_AND_OLD_IMAGES'
);
```

Create a target data table in SCD2 format

```
  CREATE TABLE dimension_scd2 (
    id Utf8 NOT NULL,
    attribute1 Utf8,
    attribute2 Utf8,
    valid_from Timestamp NOT NULL,
    deleted_at Timestamp ,
    PRIMARY KEY (valid_from, id)
  )
  PARTITION BY HASH(valid_from, id)
  WITH (
    STORE=COLUMN
  )
```

Create a transfer and lambda function to process CDC data

Features of processing CDC data in Debezium format:

- When creating a record (`op = "c"`), data is taken from the `after` field, and the value of the moment of change of the record from the `changed_at` field is saved in the `valid_from` field.
- When updating a record (`op = "u"`), data is also taken from the `after` field, and the value of the moment of change of the record from the `changed_at` field is saved in the `valid_from` field.
- When deleting a record (`op = "d"`), data is taken from the `before` field, and the system moment of time of receiving information about the deletion of the record is set in the `deleted_at` field.

```
$transformation_lambda = ($msg) -> {
$cdc_data = CAST($msg._data AS Json);

-- Define the type of operation
$operation = Json::ConvertToString($cdc_data.payload.op);
$is_deleted = $operation == "d";

-- Get data depending on the type of operation
$data = IF($is_deleted, $cdc_data.payload.before, $cdc_data.payload.after);

$result =  IF($data is not NULL, <|
        id: Unwrap(CAST(Json::ConvertToString($data.id) AS Utf8)),
        attribute1: CAST(Json::ConvertToString($data.attribute1) AS Utf8),
        attribute2: CAST(Json::ConvertToString($data.attribute2) AS Utf8),
        deleted_at: IF($is_deleted, DateTime::FromMilliseconds(Json::ConvertToUint64($cdc_data.payload.sourc
e.ts_ms)), NULL),
        valid_from : Unwrap(cast(datetime::MakeDatetime(datetime::ParseIso8601(Json::ConvertToString($data.ch
ange_time))) as timestamp)),
    |>, NULL);

return $result;
};

-- In this example, a high frequency of updates to the target table is configured.
-- This is done solely for clarity. For production scenarios, larger values should be set
  CREATE TRANSFER dimension_scd2_cdc_transfer
    FROM `source_customers/updates` TO dimension_scd2 USING $transformation_lambda
    WITH (
      FLUSH_INTERVAL=Interval("PT1S")
    );
```

Note

The `id` column in the receiving table `dimension_scd2` is declared as `Utf8 NOT NULL`, while in Json CDC, data that cannot be converted to a string may be passed, i.e., the result of converting data from Json may be a `NULL` value. The `Unwrap` function guarantees that after its execution, there cannot be a `NULL` value or a runtime error. This ensures that the result of executing the lambda function will either be a fully correct data structure, or a runtime error.

Demonstration of work

To demonstrate the work with CDC data, data will be written to the source table in YDB, which will generate CDC events:

Inserting a new record

```
INSERT INTO source_customers (id, attribute1, attribute2, change_time)
VALUES ('CUSTOMER_1001', 'John Doe', 'Los Angeles', CurrentUtcTimestamp());
```

This action will create a CDC event with the operation type `op = "c"` approximately of the following form:

```
{
  "payload":{
    "op":"c",
    "source":{
      "txId":18446744073709551615,
      "connector":"ydb",
      "version":"1.0.0",
      "step":1755883683690,
      "ts_ms":1755883683652,
      "snapshot":false
    },
    "after":{
      "attribute1":"John Doe",
      "change_time":"2025-08-22T17:28:03.648313Z",
      "id":"CUSTOMER_1001",
      "attribute2":"Los Angeles"
    }
  }
}
```

The content of the `dimension_scd2` table after executing the command above will be as follows:

id	attribute1	attribute2	deleted_at	valid_from
CUSTOMER_1001	John Doe	New York	NULL	2025-08-22T17:28:03.648313Z

Updating an existing record

```
UPSERT INTO source_customers (id, attribute1, attribute2, change_time)
VALUES ('CUSTOMER_1001', 'John Doe 2', 'Los Angeles 2', CurrentUtcTimestamp());
```

This action will create a CDC event with the operation type `op = "u"` approximately of the following form:

```
{
  "payload":{
    "op":"u",
    "source":{
      "txId":18446744073709551615,
      "connector":"ydb",
      "version":"1.0.0",
      "step":1755883278000,
      "ts_ms":1755883278357,
      "snapshot":false
    },
    "after":{
      "attribute1":"John Doe 2",
      "change_time":"2025-08-22T17:31:18.357503Z",
      "id":"CUSTOMER_1001",
      "attribute2":"Los Angeles 2"
    },
    "before":{
      "attribute1":"John Doe 2",
      "change_time":"2025-08-22T17:28:03.648313Z",
      "id":"CUSTOMER_1001",
      "attribute2":"Los Angeles 2"
    }
  }
}
```

The content of the `dimension_scd2` table after executing the command above will be as follows:

id	attribute1	attribute2	deleted_at	valid_from
CUSTOMER_1001	John Doe	New York	NULL	2025-08-22T17:28:03.648313Z
CUSTOMER_1001	John Doe 2	New York 2	NULL	2025-08-22T17:31:18.357503Z

Deleting a record

```
DELETE FROM source_customers WHERE id = 'CUSTOMER_1001';
```

This action will create a CDC event with the operation type `op = "d"` approximately of the following form:

```
{
  "payload":{
    "op":"d",
    "source":{
      "txId":18446744073709551615,
      "connector":"ydb",
      "version":"1.0.0",
      "step":1755883827000,
      "ts_ms":1755883827948,
      "snapshot":false
    },
    "before":{
      "attribute1":"John Doe",
      "change_time":"2025-08-22T17:38:03.648313Z",
      "id":"CUSTOMER_1001",
      "attribute2":"Los Angeles"
    }
  }
}
```

The content of the `dimension_scd2` table after executing the command above will be as follows:

id	attribute1	attribute2	deleted_at	valid_from
CUSTOMER_1001	John Doe	New York	NULL	2025-08-22T17:28:03.648313Z
CUSTOMER_1001	John Doe 2	New York 2	NULL	2025-08-22T17:31:18.357503Z
CUSTOMER_1001	John Doe 2	New York 2	2025-08-22T17:38:03.648313Z	2025-08-22T17:38:03.648313Z

Example query to retrieve current data

To retrieve data from SCD2 append-only tables, you can use the following query, which fetches data as of `2025-08-22 19:11:30`:

```
DECLARE $as_of AS Timestamp;
$as_of = Timestamp("2025-08-22T19:11:30.000000Z");

SELECT
  id,
  data.attribute1 AS attribute1,
  data.attribute2 AS attribute2,
  data.valid_from AS valid_from,
  data.deleted_at AS deleted_at
FROM (
  SELECT
    id,
    MAX_BY(TableRow(), valid_from) AS data
  FROM dimension_scd2
  WHERE
      valid_from <= $as_of
      AND (deleted_at IS NULL OR deleted_at > $as_of)  -- The record has not yet been deleted as of time X
  GROUP BY id
)
```

Using the merge process to implement SCD2 in YDB

This article describes the implementation of the Slowly Changing Dimensions Type 2 (SCD2) pattern in YDB using the change merge process.

Tools used

To populate data into the SCD2 table in this article, the following combination of features available in YDB will be used:

1. The source table `dimension_scd_changes`, containing information about attributes, their values, and moments of data changes.
2. The target table `dimension_scd2_final` to store the resulting data.
3. An external application should periodically run a query to merge changes accumulated in the `dimension_scd_changes` table into the `dimension_scd2_final` table.
4. To deliver data from staging tables into SCD2 format, it is convenient to use the built-in YDB transfer mechanism.

> **Note**
>
> The tables `dimension_scd_changes`, `dimension_scd2_final` are given for illustration. For actual queries, you will need to adapt the structure of tables and their attributes accordingly.

Creating a table to receive all Changes `dimension_scd_changes`

```
CREATE TABLE dimension_scd_changes (
    id Utf8 NOT NULL, -- Business key
    attribute1 Utf8,  -- Data attribute
    attribute2 Utf8,  -- Data attribute
    change_time Timestamp NOT NULL, -- Moment of data change
    operation Utf8, -- Type of data change
    PRIMARY KEY (change_time, id)
)
PARTITION BY HASH(change_time, id)
WITH (
    STORE=COLUMN
)
```

Table field descriptions:

- `id` — business key of the record;
- `attribute1`, `attribute2` — dimension attributes;
- `change_time` — timestamp when the data changed;
- `operation` — type of change: `CREATE`, `UPDATE`, or `DELETE`.

The primary key is created as `PRIMARY KEY (change_time, id)` because there may be multiple changes on the same business key, and it is important to store all those changes. For details on choosing the primary key and partitioning key, see the documentation: choosing a primary key and choosing a partition key.

Creating the final SCD2 table `dimension_scd2_final`

```
CREATE TABLE dimension_scd2_final (
    id Utf8 NOT NULL, -- Business key
    attribute1 Utf8,  -- Data attribute
    attribute2 Utf8,  -- Data attribute
    valid_from Timestamp NOT NULL, -- Timestamp from which the data is valid
    valid_to Timestamp,            -- Timestamp until which the data is valid.
                                   -- If the data is currently valid, then valid_to is NULL
    is_current Uint8,              -- Indicator that the data is currently valid.
    is_deleted Uint8,              -- Indicator that the data was deleted. If deleted, is_current = FALSE
    PRIMARY KEY (valid_from, id)
)
PARTITION BY HASH(valid_from, id)
WITH(
    STORE=COLUMN
)
```

Table field descriptions:

- `id` — business key of the record;
- `attribute1`, `attribute2` — dimension attributes;
- `valid_from` — timestamp from which the record becomes valid;
- `valid_to` — timestamp until which the record was valid, or `NULL` for current records;
- `is_current` — flag indicating if the record is current (1 for current, 0 for historical);
- `is_deleted` — flag indicating if the record was deleted (1 if deleted, 0 otherwise).

The primary key is created as `PRIMARY KEY (valid_from, id)` for the same reasons as above: there may be multiple changes per key, and all those changes must be stored.

Loading data into the change table

You can use any available method to load data into the change table, as well as the automatic delivery of changes using the transfer mechanism.

Example query for explicitly loading changes:

```
UPSERT INTO dimension_scd_changes (id, attribute1, attribute2, change_time, operation)
VALUES ('CUSTOMER_1001', 'John Doe', 'Los Angeles', Unwrap(CAST('2025-08-22T17:00:00Z' as Timestamp)), 'CREAT
E');

UPSERT INTO dimension_scd_changes (id, attribute1, attribute2, change_time, operation)
VALUES ('CUSTOMER_1002', 'John Doe', 'New York', Unwrap(CAST('2025-08-22T17:00:00Z' as Timestamp)), 'CREAT
E');

UPSERT INTO dimension_scd_changes (id, attribute1, attribute2, change_time, operation)
VALUES ('CUSTOMER_1001', 'John Doe', 'San Francisco', Unwrap(CAST('2025-08-22T19:00:00Z' as Timestamp)), 'UPD
ATE');

UPSERT INTO dimension_scd_changes (id, attribute1, attribute2, change_time, operation)
VALUES ('CUSTOMER_1002', 'John Doe', 'New York', Unwrap(CAST('2025-08-22T21:00:00Z' as Timestamp)), 'DELET
E');
```

Query for applying changes in SCD2 format

A special query is used to transform data from the changes table into SCD2 format and load it into the final table. This query should be run regularly—with whatever frequency you want to update data in the final table. For automatic execution, you can use the YDB integration with Apache Airflow™:

```
-- Step 1: Read all new events from the `dimension_scd_changes` table.
-- This named expression ($changes) serves as the initial dataset for all subsequent processing in this run.
$changes = (
    SELECT
        id,
        attribute1,
        attribute2,
        change_time,
        String::AsciiToUpper(operation) AS op
    FROM dimension_scd_changes
);

-- Step 2: Filter events, keeping only those not yet present in the target table.
-- The goal of this step is to ensure read-level idempotency, avoiding reprocessing
-- of already loaded data in case of a script failure and restart.
$unprocessed_data = (
    SELECT
        chg.id AS id,
        chg.attribute1 AS attribute1,
        chg.attribute2 AS attribute2,
        chg.change_time AS change_time,
        chg.op AS op
    FROM $changes AS chg
    LEFT JOIN dimension_scd2_final AS scd
        ON chg.id = scd.id AND chg.change_time = scd.valid_from -- Look for records by each entity (id) and c
hange timestamp
    WHERE scd.id IS NULL -- Exclude rows already transferred to the dimension_scd2_final table earlier
);

-- Step 3: Find active records (`is_current=1`) in the target table that have received updates.
-- Generate "closing" versions for them, setting `valid_to` to the timestamp
-- of the earliest change from the new batch ($unprocessed_data).
$close_open_intervals = (
    SELECT
        target.id AS id,
        target.attribute1 as attribute1,
        target.attribute2 as attribute2,
        target.valid_from as valid_from,
        0ut AS is_current, -- The closing record is no longer current
        unprocessed_data.change_time AS valid_to,
        target.is_deleted as is_deleted
    FROM dimension_scd2_final AS target
    INNER JOIN (
        SELECT
            id,
            MIN(change_time) AS change_time
        FROM $unprocessed_data
        GROUP BY id
    ) AS unprocessed_data
    ON target.id = unprocessed_data.id
    WHERE target.is_current = 1ut
);

-- Step 4: Transform the stream of unprocessed events into versioned records (rows to insert).
-- Here, all necessary attributes for new versions are calculated: `valid_to`, `is_current`, `is_deleted`.
$updated_data = (
    SELECT
        t.id AS id,
        t.attribute1 AS attribute1,
        t.attribute2 AS attribute2,
        t.is_deleted AS is_deleted,
        -- Logic for the `is_current` flag: it is set to 1 only for the last
        -- record in the chain (`next_change_time IS NULL`), and only if it is not
        -- a delete operation (`is_deleted == 0`).
        IF(t.next_change_time IS NOT NULL OR t.is_deleted == 1ut, 0ut, 1ut) AS is_current,
        t.change_time AS valid_from,
        t.next_change_time AS valid_to
    FROM (
        -- Subquery calculates the delete flag (`is_deleted`)
        -- and the timestamp of the next event (`next_change_time`) using the LEAD window function.
        SELECT
            unprocessed_data.id AS id,
            unprocessed_data.attribute1 AS attribute1,
            unprocessed_data.attribute2 AS attribute2,
            unprocessed_data.op AS op,
            unprocessed_data.change_time AS change_time,
            IF(unprocessed_data.op = "DELETE", 1ut, 0ut) AS is_deleted,
            LEAD(unprocessed_data.change_time) OVER (PARTITION BY id ORDER BY unprocessed_data.change_time) A
S next_change_time
        FROM $unprocessed_data AS unprocessed_data
    ) AS t
);

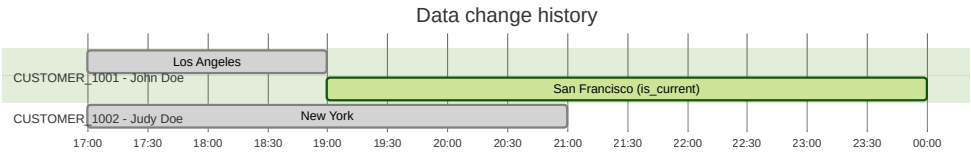
-- Step 5: Atomically apply all calculated changes to the target table.
-- UPSERT will update existing records (from $close_open_intervals) and insert new ones (from $updated_data).
UPSERT INTO dimension_scd2_final (id, attribute1, attribute2, is_current, is_deleted, valid_from, valid_to)
SELECT
    id,
    attribute1,
    attribute2,
    is_current,
```

```
    is_deleted,
    valid_from,
    valid_to
FROM $close_open_intervals
UNION ALL
SELECT
    id,
    attribute1,
    attribute2,
    is_current,
    is_deleted,
    valid_from,
    valid_to
FROM $updated_data;

-- Step 6: Clear the staging table of processed records.
DELETE FROM dimension_scd_changes ON
SELECT id, change_time FROM $changes;
```

Demonstration of work

In the example below, the entity **Customer** is considered:



- business key — field `id`,
- attributes — `attribute1` (full name) and `attribute2` (city).

At `2025-08-22 17:00` two customers are created (John in Los Angeles - with id `CUSTOMER_1001` and Judy in New York with id `CUSTOMER_1002`), at `2025-08-22 19:00` customer `CUSTOMER_1001` updates his city to San Francisco `UPDATE`, and at `2025-08-22 21:00` customer `CUSTOMER_1002` is deleted `DELETE`.

id	attribute1	attribute2	change_time	operation
CUSTOMER_1001	John Doe	Los Angeles	2025-08-22 17:00	CREATE
CUSTOMER_1002	Judy Doe	New York	2025-08-22 17:00	CREATE
CUSTOMER_1001	John Doe	San Francisco	2025-08-22 19:00	UPDATE
CUSTOMER_1002	Judy Doe	New York	2025-08-22 21:00	DELETE

The SCD2 process converts such events into interval-based record versions with the `valid_from` and `valid_to` fields. For example, `CUSTOMER_1001` will have two sequential versions: first with the city LA, then with the city SF (the current record, where `valid_to = NULL`). `CUSTOMER_1002` will have one outdated version and a final record with flags `is_deleted=1` and `is_current=0`, indicating that the user has been deleted.

Below are the original events and their corresponding versions in the final table.

id	attribute1	attribute2	valid_from	valid_to	is_current	is_deleted
CUSTOMER_1001	John Doe	Los Angeles	2025-08-22 17:00	2025-08-22 19:00	0	0
CUSTOMER_1001	John Doe	San Francisco	2025-08-22 19:00	NULL	1	0
CUSTOMER_1002	Judy Doe	New York	2025-08-22 17:00	2025-08-22 21:00	0	0
CUSTOMER_1002	Judy Doe	New York	2025-08-22 21:00	NULL	0	1

Retrieving data from the SCD2 table

Retrieving actual data

```
SELECT
    id,
    attribute1,
    attribute2,
    valid_from,
    valid_to
FROM dimension_scd2_final
WHERE is_current = 1ut;
```

Result:

id	attribute1	attribute2	valid_from	valid_to	is_current	is_deleted
CUSTOMER_1001	John Doe	San Francisco	2025-08-22 19:00	NULL	1	0

Retrieving data at a specific point in time

```
$as_of = Timestamp("2025-08-22T19:11:30.000000Z");

SELECT
    id,
    attribute1,
    attribute2,
    valid_from,
    valid_to
FROM dimension_scd2_final
WHERE valid_from <= $as_of
        AND (valid_to IS NULL OR valid_to > $as_of) -- Get records that were valid at the $as_of time
        AND is_deleted = 0ut -- Only records that are not deleted
```

Result:

id	attribute1	attribute2	valid_from	valid_to
CUSTOMER_1001	John Doe	San Francisco	2025-08-22 19:00	NULL
CUSTOMER_1002	Judy Doe	New York	2025-08-22 17:00	2025-08-22 21:00

Retrieving the history of changes for a specific record

```
SELECT
    id,
    attribute1,
    attribute2,
    valid_from,
    valid_to,
    is_current,
    is_deleted
FROM dimension_scd2_final
WHERE id = 'CUSTOMER_1001'
ORDER BY valid_from;
```

Result:

id	attribute1	attribute2	valid_from	valid_to	is_current	is_deleted
CUSTOMER_1001	John Doe	Los Angeles	2025-08-22 17:00	2025-08-22 19:00	0	0
CUSTOMER_1001	John Doe	San Francisco	2025-08-22 19:00	NULL	1	0

Known limitations

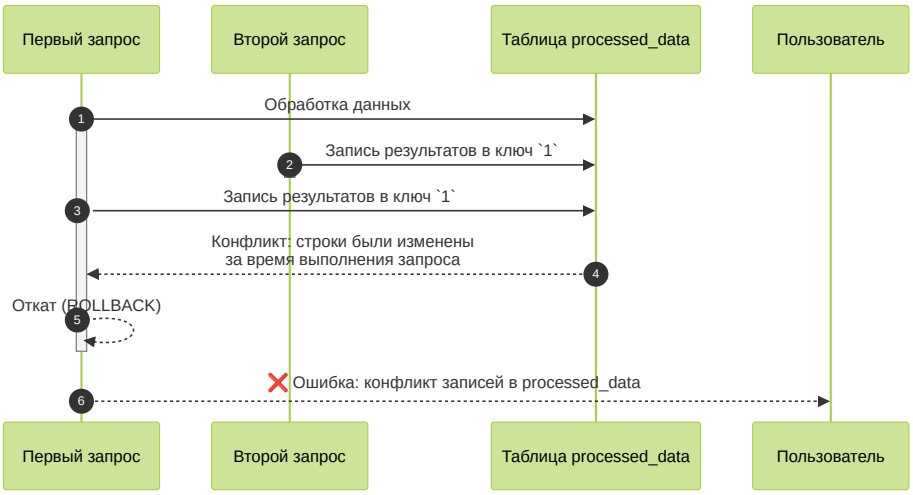
This section covers important features of YDB that you need to consider when designing applications and writing queries. For each feature, the current behavior and possible workarounds are described.

Transactions and isolation

Transaction isolation levels

YDB supports different isolation levels for row-based (OLTP) and column-based (OLAP) tables.

- Row-based tables. They support transactions with isolation levels Serializable, `Online Read-Only`, and others. This ensures strict consistency for OLTP workloads.
- Column-based tables. All operations are performed in `Serializable` mode. This guarantees that any analytical transaction works with a consistent snapshot of data, as if no further changes were occurring in the database.



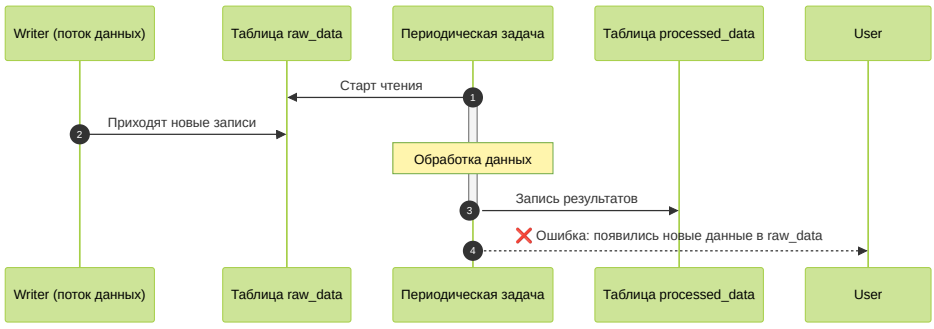
The following discusses the specifics of working with `Serializable` mode in the context of analytical (OLAP) queries.

Features of Serializable isolation with concurrent data access

The `Serializable` isolation level guarantees no read anomalies but imposes certain requirements on the design of ETL/ELT pipelines. Conflicts occur if data that a transaction has read or intends to modify has been changed by another, already completed transaction.

Write-write conflict

Two concurrent tasks attempt to write data to the same key range in the output table. The first task, which started execution but is slower, will be canceled upon commit attempt because the second, faster task has already modified those rows.



Solution options:

- **Load partitioning:** split the input data so that parallel queries write data to different tables or keys. For example, process data by day or by user IDs in separate tasks.
- **Using intermediate tables:** each task writes its result to its own temporary table. After all tasks complete, data from the temporary tables is moved to the final table in a single transaction using `INSERT INTO ... SELECT FROM`.

Read-write conflict

A long-running analytical query reads data from the `raw_data` table, into which writes are still occurring at the same time. By the time the query finishes reading and processing, the source table has already changed. YDB detects this and cancels the query to guarantee snapshot consistency.

Solution

Using intermediate tables: Create a temporary table with the required data and perform further processing with it. This fixes the data state and eliminates conflicts.

```
CREATE TABLE temp_snapshot AS SELECT * FROM raw_data WHERE ...;
-- Next, we work only with temp_snapshot
INSERT INTO processed_data SELECT process(t.*) FROM temp_snapshot AS t;
```

Modifying queries to column-based and row-based tables simultaneously are prohibited

Within a single transaction, it is impossible to perform data modification operations (DML) simultaneously for both row-based and column-based tables.

Solution

Split the logic into two sequential transactions. First, perform the operation on the row-based table, and after its successful completion, on the column-based table (or vice versa, depending on business logic).

Syntax specifics

Common table expressions (CTEs) are not supported

YQL does not support the `WITH ... AS (CTE)` syntax. Instead, it uses the named expression mechanism with variables starting with the `$` sign.

Solution

Use named expressions. This is a syntactic equivalent of CTE that allows decomposing complex queries.

A part of a query can be extracted into a separate expression and given a name starting with `$` using the named expression mechanism. Such an expression can be used multiple times within a single query. Usage is supported for both table and scalar expressions.

```
-- parameter declaration
DECLARE $days AS Int32;
$cutoff = CurrentUtcTimestamp() - $days * Interval("P1D"); -- creating a scalar named expression

-- creating a table named expression
$base = (
  SELECT *
  FROM raw_events
  WHERE event_ts >= $cutoff -- using a scalar variable
);

-- using a named expression
SELECT * FROM $base WHERE event_ts > CurrentUtcTimestamp()
```

YDB guarantees that when a named expression is used multiple times within a single transaction, the same data will be read. This is ensured by the Serializable transaction isolation level.

Lack of support for correlated subqueries

A correlated subquery is a subquery that references columns from an outer query. Such subqueries are not supported in YQL.
Most use cases of correlated subqueries can be replaced using `JOIN` and aggregate functions.
The complete support matrix and rewrite rules are available in Correlated subqueries, EXISTS, and NOT EXISTS.

EXISTS

Transformation of correlated `EXISTS` → `LEFT SEMI JOIN` or `INNER JOIN` with unique keys on the right side.

Original query:

```
SELECT a.* FROM A a WHERE EXISTS (
  SELECT 1 FROM B b WHERE b.key = a.key AND b.flag = 1
);
```

Solution with LEFT SEMI JOIN

```
$B_match = (
  SELECT key
  FROM B
  WHERE flag = 1
);

SELECT a.*
FROM A AS a
LEFT SEMI JOIN $B_match AS b
ON b.key = a.key;
```

Alternative with INNER JOIN

Deduplicate the matching keys on the right side before joining. This prevents several matching rows from duplicating a row from the left side. Applying `DISTINCT` to the left-side columns is unnecessary and can collapse equal rows from the outer input.

```
$B_match = (
  SELECT key
  FROM B
  WHERE flag = 1
  GROUP BY key
);

SELECT a.*
FROM A AS a
INNER JOIN $B_match AS b
ON b.key = a.key;
```

Subquery with aggregate

Scalar subquery with aggregate → aggregation + JOIN

Original query:

```
SELECT a.*, (SELECT MAX(ts) FROM B b WHERE b.user_id = a.user_id) AS last_ts
FROM A a;
```

Solution

```
$B_last = (
  SELECT user_id, MAX(ts) AS last_ts
  FROM B
  GROUP BY user_id
);

SELECT a.*, bl.last_ts
FROM A AS a
LEFT JOIN $B_last AS bl
ON bl.user_id = a.user_id;
```

NOT EXISTS

Transformation of correlated `NOT EXISTS` → `LEFT ONLY JOIN`.

Original query:

```
SELECT a.* FROM A a WHERE NOT EXISTS (
  SELECT 1 FROM B b WHERE b.key = a.key AND b.flag = 1
);
```

Solution

```
$B_match = (
  SELECT key
  FROM B
  WHERE flag = 1
);

SELECT a.*
FROM A AS a
LEFT ONLY JOIN $B_match AS b
ON b.key = a.key;
```

Support for equi-JOIN only

JOIN conditions can only contain the equality operator (=). Non-equi joins (>, <, >=, <=, BETWEEN) are not supported. The inequality condition can be moved to the WHERE clause after a CROSS JOIN.

> **Warning**
>
> CROSS JOIN creates a Cartesian product of tables. This approach is not recommended for large tables as it leads to an explosive growth of intermediate data volume and performance degradation. Use it only if one of the tables is very small or both tables have been pre-filtered to a small size.

Original query:

```
SELECT e.event_id, e.user_id, e.ts
FROM events AS e
JOIN periods AS p
ON e.user_id = p.user_id
 AND e.ts >= p.start_ts
```

Solution

```
SELECT e.event_id, e.user_id, e.ts
FROM events AS e
CROSS JOIN periods AS p
WHERE e.user_id = p.user_id
  AND e.ts >= p.start_ts
```

Importing data using federated queries

YDB supports federated queries to external data sources (such as ClickHouse, PostgreSQL, etc.). This mechanism is designed for fast ad-hoc analytics and on-the-fly data joining, but is not an optimal tool for bulk and regular loading of large data volumes (ETL/ELT). When using federated queries for import, you may encounter limitations on supported data types and query execution.

Solution

1. Export data from your DBMS to one of the open formats (recommended `CSV`) into a Object Storage bucket. Use the `INSERT INTO ... SELECT FROM` command to read data from an external table associated with your bucket in Object Storage. This approach allows efficient parallelization of data reading.
2. For continuous replication tasks or building complex pipelines, use standard industry tools that integrate with YDB:
   - Change Data Capture (CDC): tools like Debezium can capture changes from the transaction log of your OLTP database and deliver them to YDB.

- ETL/ELT frameworks: systems such as Apache Spark or Apache NiFi have connectors to YDB and allow building flexible and powerful data processing and loading pipelines.

List of limitations:

> **Warning**
>
> External connectors are an experimental feature of YDB. To work with external DBMS through connectors, you need to deploy fq-connector-go and explicitly enable the corresponding sources in the cluster configuration YDB. The functionality may change, so use in production is not recommended without thorough testing.

- ClickHouse
- Greenplum
- Microsoft SQL Server
- MySQL
- PostgreSQL
- YDB (federated queries between YDB databases)

```
-- Parameters (for example, as variables)
DECLARE $yc_key    AS String;
DECLARE $yc_secret AS String;

-- 1) External S3 source with Yandex Cloud endpoint
CREATE EXTERNAL DATA SOURCE s3_backup_ds
WITH (
  SOURCE_TYPE = "S3",
  LOCATION    = "https://storage.yandexcloud.net",  -- endpoint YC
  AUTH_METHOD = "AWS",
  AWS_ACCESS_KEY_ID     = $yc_key,
  AWS_SECRET_ACCESS_KEY = $yc_secret
);

-- 2) External "table" (directory with CSV in bucket)
CREATE EXTERNAL TABLE s3_my_columnstore_table_backup
WITH (
  DATA_SOURCE = "s3_backup_ds",
  LOCATION    = "s3://my-bucket/ydb-backups/processed_data/full/",  -- path in Object Storage
  FORMAT      = "CSV"
)(
  id Uint64,
  event_dt Datetime,
  value String
  -- ... other columns of your CSV table ...
);

-- 3) Export
INSERT INTO s3_my_columnstore_table_backup
SELECT * FROM my_columnstore_table;

-- 4) Data recovery
INSERT INTO my_columnstore_table
SELECT *
FROM s3_my_columnstore_table_backup;
```

Number of partitions is fixed at creation

In YDB, the number of partitions (data segments) for a columnar table is set once at creation and cannot be changed later.

Choosing the correct number of partitions is an important aspect of data schema design.

- Too few partitions: may lead to uneven load on compute nodes (hotspots) and limit query parallelism.
- Too many partitions: may create excessive load on the database management component (Scheme Shard) and increase query processing overhead.

Solution

- Initial number of partitions: for a basic estimate of the number of partitions, you can use the formula `(number of nodes * 4)`. This will maximize cluster resource utilization when executing parallel queries.
- Choose the number of partitions considering the expected growth of data volume and increase in the number of nodes in the cluster.
- The total number of partitions across all tables in a single database must not exceed **2000**.
- If you need to increase the number of partitions, you can create a new table and move data into it using the `CREATE TABLE (PRIMARY KEY (a, b)) PARTITION BY HASH(a) WITH(STORE=COLUMN, PARTITION_COUNT=96) new_table AS SELECT * FROM old_table;` query.

No secondary indexes or skip indexes

The performance of analytical queries with columnar data storage is achieved through mechanisms based on physical data organization: columnar storage, partitioning, sorting by primary key.

Solution

Pay special attention to partitioning keys and primary keys, as described in the Choosing keys for maximum column-oriented table performance section.

Mixing OLTP and OLAP in the same database is not recommended

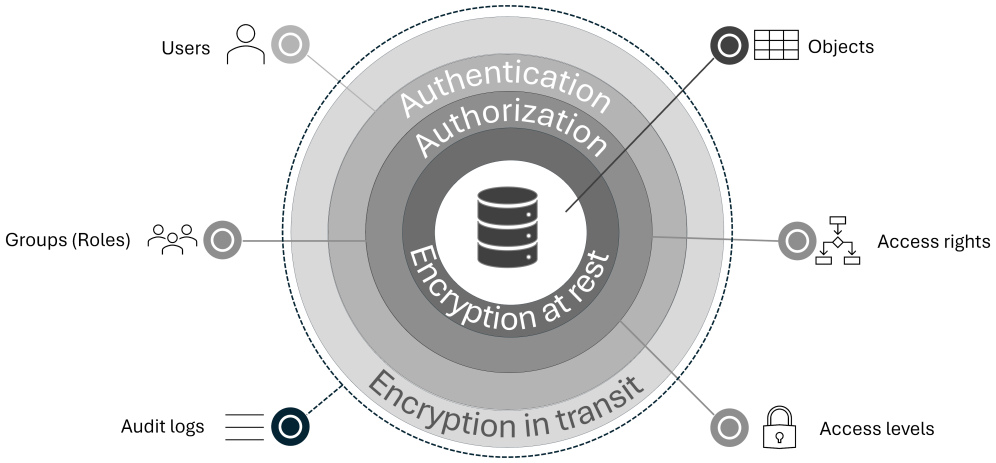
OLTP and OLAP workloads impose opposite resource requirements, and mixing them almost always leads to mutual performance degradation.

- OLTP workload (row-based tables) is a set of short, fast transactions (key-based read/write) that are latency-critical.
- OLAP workload (column-based tables) is typically long-running and resource-intensive queries that scan large volumes of data, perform aggregation, and actively consume CPU, memory, and disk I/O.

When a heavy OLAP query starts executing, it can monopolize cluster resources, causing fast OLTP queries to queue up and increasing their response time.

It is not recommended to combine OLTP and OLAP workloads in the same database. OLAP workloads can negatively affect OLTP, increasing query execution time.

Solution



To ensure stable and predictable performance for both workloads, use two separate YDB databases: one for OLTP and another for OLAP. To synchronize data between them, use the Change Data Capture (CDC) mechanism and the Data transfer service, which allows streaming changes from the OLTP database to the OLAP database.

YDB for Security Engineers

This section of YDB documentation covers security-related aspects of working with YDB. It'll be useful for compliance purposes too.

YDB security elements and concepts

Security model in YDB introduces the following concepts:

- **Access subjects**:
  - **Users**. YDB supports both internal users and external users from third-party directory services, such as LDAP and IAM systems.
  - **Groups**. YDB allows grouping users into named collections. The list of users in a group can be modified later. A group can be empty.
- **Access objects** in YDB are scheme objects (tables, views, etc) for which access rights are configured.
- **Access rights** in YDB are used to determine the list of permitted operations with access objects for a given user or group.

  Access rights represent permission for an access subject to perform a specific set of operations (create, drop, select, update, etc) in a cluster or database on a specific access object.

  Access rights can be granted to a user or a group. When a user is added to a group, the user gets the access rights that were granted to the group. When a user is removed from a group, the user loses the access rights of the group.

  For more information about access rights, see Right.
- **Access levels** in YDB are used to determine the list of additional cluster management operations permitted for a given user or group. YDB uses hierarchical access levels: database, viewer, monitoring, and administration. Higher levels automatically include all lower level privileges. In addition, there are two special non-hierarchical lists: bootstrap (for initial cluster bootstrap) and register node (for dynamic node registration).

  For more information about access levels, see Access level lists.
- **Authentication and authorization**. The access control system in YDB provides data protection in a YDB cluster. Due to the access system, only authorized access subjects (users and groups) can work with data. Access to data can be restricted.
  - **Authentication**. When a user connects to a YDB cluster, YDB first identifies the user's account. This process is called authentication. YDB supports various authentication modes. For more information, see Authentication.

    Regardless of an authentication mode, after passing authentication, a user gets a SID and an authentication token.

    - YDB cluster uses a SID for user identification. For example, a SID for a local user is the user login. SIDs for external users also include information about the system where they were created. User SIDs can also be found in system views describing the security configuration.
    - The authentication token is used by YDB nodes to authorize user access before processing user requests.

      The user can then use the received authentication token repeatedly when making requests to the YDB cluster. For more information about the authentication token and related configuration parameters, see auth_config.
  - **Authorization**. Based on the authentication data, a user then goes through authorization — a process that verifies whether a user has sufficient access rights and access levels to perform user operations.
- **Audit logs**. YDB provides audit logs that include data about all operations that attempted to change the YDB objects, such as changing access rights, creating or deleting scheme objects, whether successful or not. Audit logs are intended for people responsible for information security.
- **Encryption**. YDB is a distributed system typically running on a cluster, often spanning multiple datacenters. To protect user data, YDB provides the following technologies:
  - encryption in transit to secure data transmitted between a client and YDB, and between nodes of the YDB cluster.
  - data encryption at rest.

Authentication

Once a network connection is established, the server starts to accept client requests with authentication information for processing. The server uses it to identify the client's account and to verify access to execute the query.

> **Note**
>
> An authentication client refers to a user undergoing the authentication process when accessing YDB. Examples of clients include the SDK or CLI.

The following authentication modes are supported:

- Anonymous authentication.
- Authentication by username and password.
- LDAP authentication.
- Authentication through a third-party IAM provider, for example, Yandex Identity and Access Management.

Anonymous authentication

Anonymous authentication allows you to connect to YDB without specifying any credentials like username and password. This type of access should be used only for educational purposes in local databases that cannot be accessed over the network.

However, if a user or token is specified, the corresponding authentication mode will work with subsequent authorization.

> **Warning**
>
> Anonymous authentication should be used only for informational purposes for local databases that are not accessible over the network.

To enable anonymous authentication, use `false` in the `enforce_user_token_requirement` key of the cluster's configuration file.

Authenticating by username and password

Authentication by username and password using the YDB server is available only to local users. Authentication of external users involves third-party servers.

This access type implies that each database user has a username and password.

Only digits and lowercase Latin letters can be used in usernames. Password complexity requirements can be configured.

The username and hashed password are stored in a table inside the authentication component. The password is hashed using the Argon2 method. Only the system administrator has access to this table.

A token is returned in response to the username and password. Tokens have a default lifetime of 12 hours. To rotate tokens, the client, such as the SDK, independently sends requests to the authentication service. Tokens accelerate authentication and enhance security.

Authentication by username and password includes the following steps:

1. The client accesses the database and presents their username and password to the YDB authentication service.
2. The service validates authentication data. If the data matches, it generates a token and returns it to the authentication service.
3. The client accesses the database, presenting their token as authentication data.

To enable authentication by username and password, ensure that the `use_login_provider` and `enable_login_authentication` parameters are set to the default value of `true` in the configuration file. Besides, to disable anonymous authentication, set the `enforce_user_token_requirement` parameter to `true`.

To learn how to manage roles and users, see Authorization.

Password complexity

YDB allows configuring requirements for password complexity. If a password specified in the `CREATE USER` or `ALTER USER` command does not meet complexity requirements, the command will result in an error. By default, YDB has no password complexity requirements. A password of any length is accepted, including an empty string. A password can contain any number of digits and uppercase or lowercase letters, as well as special characters from the `!@#$%^&*()_+{}|<>?=` list. To set requirements for password complexity, define parameters in the `password_complexity` section in the configuration.

Password brute-force protection

YDB provides password brute-force protection. A user is locked out after exceeding a specified number of failed attempts to enter a password. After a certain period, the user will be unlocked and able to log in again.

By default, a user has four attempts to enter a password. If a user fails to enter the correct password in four attempts, the user will be locked out for an hour. You can change these lockout settings in the `auth_config` section of the configuration.

If necessary, a YDB cluster or database administrator can unlock a user before the lockout period expires.

Manual user lockout

YDB provides another method for disabling authentication for a user, manual user lockout by a YDB cluster or database administrator. An administrator can unlock user accounts that were previously locked manually or automatically after exceeding the number of failed attempts to enter the correct password. For more information about manual user lockout, see the `ALTER USER LOGIN/NOLOGIN` command description.

LDAP directory integration

YDB supports authentication and authorization via an LDAP directory. To use this feature, an LDAP directory service must be deployed and accessible from the YDB servers.

Examples of supported LDAP implementations include OpenLDAP and Active Directory.

Authentication through a third-party IAM provider

- **Anonymous**: Empty token passed in a request.
- **Access Token**: Fixed token set as a parameter for the client (SDK or CLI) and passed in requests.
- **Refresh Token**: OAuth token of a user's personal account set as a parameter for the client (SDK or CLI), which the client periodically sends to the IAM API in the background to rotate a token (obtain a new one) to pass in requests.
- **Service Account Key**: Service account attributes and a signature key set as parameters for the client (SDK or CLI), which the client periodically sends to the IAM API in the background to rotate a token (obtain a new one) to pass in requests.
- **Metadata**: Client (SDK or CLI) periodically accesses a local service to rotate a token (obtain a new one) to pass in requests.
- **OAuth 2.0 token exchange** - The client (SDK or CLI) exchanges a token of another type for an access token using the OAuth 2.0 token exchange protocol, then it uses the access token in YDB API requests.

Any owner of a valid token can get access to perform operations; therefore, the principal objective of the security system is to ensure that a token remains private and to protect it from being compromised.

Authentication modes with token rotation, such as **Refresh Token** and **Service Account Key**, provide a higher level of security compared to the **Access Token** mode that uses a fixed token, since only secrets with a short validity period are transmitted to the YDB server over the network.

The highest level of security and performance is provided when using the **Metadata** mode, since it eliminates the need to work with secrets when deploying an application and allows accessing the IAM system and caching a token in advance, before running the application.

When choosing the authentication mode among those supported by the server and environment, follow the recommendations below:

- **You would normally use Anonymous** on self-deployed local YDB clusters that are inaccessible over the network.
- **You would use Access Token** when other modes are not supported on server side or for setup/debugging purposes. It does not require that the client access IAM. However, if the IAM system supports an API for token rotation, fixed tokens issued by this IAM usually have a short validity period, which makes it necessary to update them manually in the IAM system on a regular basis.
- **Refresh Token** can be used when performing one-time manual operations under a personal account, for example, related to DB data maintenance, performing ad-hoc operations in the CLI, or running applications from a workstation. You can manually obtain this token from IAM once to have it last a long time and save it in an environment variable on a personal workstation to use automatically and with no additional authentication parameters on CLI launch.
- **Service Account Key** is mainly used for applications designed to run in environments where the **Metadata** mode is supported, when testing them outside these environments (for example, on a workstation). It can also be used for applications outside these environments, working as an analog of **Refresh Token** for service accounts. Unlike a personal account, service account access objects and roles can be restricted.
- **Metadata** is used when deploying applications in clouds. Currently, this mode is supported on virtual machines and in Cloud Functions Yandex.Cloud.

The token to specify in request parameters can be obtained in the IAM system that the specific YDB deployment is associated with. In particular, YDB in Yandex.Cloud uses Yandex.Passport OAuth and Yandex.Cloud service accounts. When using YDB in a corporate context, a company's standard centralized authentication system may be used.

When using modes in which the YDB client accesses the IAM system, the IAM URL that provides an API for issuing tokens can be set additionally. By default, existing SDKs and CLIs attempt to access the Yandex.Cloud IAM API hosted at `iam.api.cloud.yandex.net:443`.

Authentication

Authentication using the LDAP protocol is similar to the static credentials authentication process (using a login and password). The difference is that the LDAP directory acts as the authentication component. The LDAP directory is used solely to verify the login/password pair.

> **Note**
>
> Since the LDAP directory is an external, independent service, YDB cannot manage user accounts within it. For successful authentication, the user must already exist in the LDAP directory. The commands `CREATE USER`, `CREATE GROUP`, `ALTER USER`, `ALTER GROUP`, `DROP USER`, and `DROP GROUP` do not affect the list of users and groups in the LDAP directory. Information on managing accounts should be found in the documentation for the specific LDAP directory implementation in use.

Currently, YDB supports only one method of LDAP authentication, known as the `search+bind` method, which involves several steps. Upon receiving the username and password of the user being authenticated, a *bind* operation is performed using the credentials of a special service account specified in the ldap_authentication section. These credentials are defined by the **bind_dn** and **bind_password** configuration parameters. After the service account is successfully authenticated, a search is conducted in the LDAP directory for the user attempting to authenticate in the system. The *search* operation is performed across the entire subtree rooted at the location specified by the **base_dn** configuration parameter and uses the filter defined in the **search_filter** configuration parameter.

Once the user entry is found, YDB performs another *bind* operation using the found user's entry and the password provided earlier. The success of this second *bind* operation determines whether the user authentication is successful.

After successful authentication, a token is generated. This token is then used in place of the username and password, speeding up the authentication process and enhancing security.

> **Note**
>
> When using LDAP authentication, no user passwords are stored in YDB.

Token verification

After a user is authenticated in the system, a token is generated and verified before executing the requested operation. During the token verification process, the system determines on whose behalf the action is being requested and identifies the groups the user belongs to. For users from the LDAP directory, the token does not include information about group memberships. Therefore, after the token is verified, an additional query is made to the LDAP server to retrieve the list of groups the user is a member of.

Groups, like users, are entities that can have assigned access rights to perform operations on database schema objects and other resources. These assigned rights determine which operations a user is authorized to perform.

The process of retrieving a user's group list from an LDAP directory is similar to the steps taken during authentication. First, a *bind* operation is performed using the service user credentials specified by the **bind_dn** and **bind_password** parameters in the ldap_authentication section of the configuration file. After successful authentication, a search is conducted for the user entry associated with the previously generated token. This search uses the **search_filter** parameter. If the user still exists, the result of the *search* operation will be a list of attribute values specified by the **requested_group_attribute** parameter. If this parameter is not set, the *memberOf* attribute is used as the default for reverse group membership. The *memberOf* attribute contains the distinguished names (DNs) of the groups to which the user belongs.

Group search

By default, YDB only searches for groups in which the user is a direct member. However, by enabling the **extended_settings.enable_nested_groups_search** flag in the ldap_authentication section, YDB will attempt to retrieve groups at all levels of nesting, not just those the user directly belongs to. If YDB is configured to work with Active Directory, the Active Directory-specific matching rule LDAP_MATCHING_RULE_IN_CHAIN will be used to find all nested groups. This rule allows for the retrieval of all nested groups with a single query. For LDAP servers based on OpenLDAP, group searches will be conducted using recursive graph traversal, which generally requires multiple queries. In both Active Directory and OpenLDAP configurations, the group search is performed only within the subtree specified by the **base_dn** parameter.

Note

In the current implementation, the group names that YDB uses match the values stored in the *memberOf* attribute. These names can be long and difficult to read.

Example:

```
cn=Developers,ou=Groups,dc=mycompany,dc=net@ldap
```

Note

In the configuration file section that specifies authentication information, the refresh rate for user and group information can be set using the **refresh_time** parameter. For more detailed information about configuration files, refer to the cluster configuration section.

Warning

It should be noted that currently, YDB does not have the capability to track group renaming on the LDAP server side. Consequently, a group with a new name will not retain the rights assigned to the group under its previous name.

LDAP users and groups in YDB

Since YDB supports various methods of user authentication (login and password authentication, IAM provider usage, LDAP directory), it is often helpful to identify the specific source of authentication when handling user and group names. For all authentication types except login and password, a suffix in the format `<username>@<domain>` is appended to user and group names.

For LDAP users, the `<domain>` is determined by the **ldap_authentication_domain** configuration parameter in the configuration section. By default, this parameter is set to `ldap`, so all usernames authenticated through the LDAP directory, as well as their corresponding group names in YDB, will follow this format:

- `user1@ldap`
- `group1@ldap`
- `group2@ldap`

Warning

To indicate that the entered login should be recognized as a username from the LDAP directory, rather than for login and password authentication, you need to append the LDAP authentication domain suffix. This suffix is specified through the **ldap_authentication_domain** configuration parameter.

Below are examples of authenticating the user `user1` using the YDB CLI:

- Authentication of a user from the LDAP directory: `ydb --user user1@ldap -p ydb_profile scheme ls`
- Authentication of a user using the internal YDB mechanism: `ydb --user user1 -p ydb_profile scheme ls`

TLS connection

Depending on the specified configuration parameters, YDB can establish either an encrypted or unencrypted connection. An encrypted connection with the LDAP server is established using the TLS protocol, which is recommended for production clusters. There are two ways to enable a TLS connection:

- Automatically via the `ldaps` connection scheme.
- Using the `StartTls` LDAP protocol extension*.

When using an unencrypted connection, all data transmitted in requests to the LDAP server, including passwords, will be sent in plain text. This method is easier to set up and is more suited for experimentation or testing purposes.

LDAPS

To have YDB automatically establish an encrypted connection with the LDAP server, the **scheme** value in the configuration parameter should be set to `ldaps`. The TLS handshake will be initiated on the port specified in the configuration. If no port is specified, the default port 636 will be used for the `ldaps` scheme. The LDAP server must be configured to accept TLS connections on the specified ports.

LDAP protocol extension `StartTls`

`StartTls` is an LDAP protocol extension that enables message encryption using the TLS protocol. It allows a combination of encrypted and plain-text message transmission within a single connection to the LDAP server. YDB sends a `StartTls` request to the LDAP server to initiate a TLS connection. In YDB, enabling or disabling TLS within an active session is not supported. Therefore, once an encrypted connection is established using `StartTls`, all subsequent messages sent to the LDAP server will be encrypted. One advantage of using this extension, provided the LDAP server is appropriately configured, is the capability to initiate a TLS connection over an unencrypted port. The extension can be enabled in the `use_tls` section of the configuration file.

Authorization

Basic concepts

Authorization in YDB is based on the concepts of:

- Access object
- Access subject
- Access right
- Access control list
- Owner
- User
- Group

Regardless of the authentication method, authorization is always performed on the server side of YDB based on the stored information about access objects and rights. Access rights determine the set of operations available to perform.

Authorization is performed for each user action: the rights are not cached, as they can be revoked or granted at any time.

User

To create, alter, and delete users in YDB, the following commands are available:

- CREATE USER
- ALTER USER
- DROP USER

> **Note**
>
> The scope of the commands `CREATE USER`, `ALTER USER`, and `DROP USER` does not extend to external user directories. Keep this in mind if users with third-party authentication (e.g., LDAP) are connecting to YDB. For example, the `CREATE USER` command does not create a user in the LDAP directory. Learn more about YDB's interaction with the LDAP directory.

> **Note**
>
> There is a separate user `root` with maximum rights. It is created during the initial deployment of the cluster, during which a password must be set immediately. It is not recommended to use this account long-term; instead, users with limited rights should be created.
>
> More about initial deployment:
>
> - Ansible
> - Kubernetes
> - Manually

YDB allows working with users from different directories and systems, and they differ by SID using a suffix.

The suffix `@<subsystem>` identifies the "user source" or "auth domain", within which the uniqueness of all `login` is guaranteed. For example, in the case of LDAP authentication, user names will be `user1@ldap` and `user2@ldap`.
If a `login` without a suffix is specified, it implies users directly created in the YDB cluster.

SID

See SID.

Group

Any user can be included in or excluded from a certain access group. Once a user is included in a group, they receive all the rights to database objects that were provided to the access group.
With access groups in YDB, business roles for user applications can be implemented by pre-configuring the required access rights to the necessary objects.

> **Note**
>
> An access group can be empty when it does not include any users.
>
> Access groups can be nested.

To create, alter, and delete groups, the following types of YQL queries are available:

- CREATE GROUP
- ALTER GROUP
- DROP GROUP

Right

Rights in YDB are tied not to the subject, but to the access object.

Each access object has a list of permissions — ACL (Access Control List) — it stores all the rights provided to access subjects (users and groups) for the object.

By default, rights are inherited from parents to descendants in the access objects tree.

The following types of YQL queries are used for managing rights:

- GRANT.

- REVOKE.

The following CLI commands are used for managing rights:

- chown
- grant
- revoke
- set
- clear
- clear-inheritance
- set-inheritance

The following CLI commands are used to view the ACL of an access object:

- describe
- list

Object Owner

Each access object has an owner. By default, it becomes the access subject who created the access object.

> **Note**
>
> For the owner, permission lists on this access object are not checked.
>
> They have a full set of rights on the object.

An object owner exists for the entire cluster and each database.

The owner can be changed using the CLI command `chown`.

The owner of an object can be viewed using the CLI command `describe`.

Access level lists

In addition to access control lists that control access to specific scheme objects, YDB uses access level lists to define hierarchical access levels for cluster-wide operations.

For operations where both access control lists and access level lists are checked, both checks are applied together: an action is allowed only if both checks allow it, and denied if either check fails. For other operations, only the corresponding check mechanism is used.

Hierarchy of access levels

Access level lists form a hierarchy (used by the YDB UI, viewer, and many other cluster-wide actions; ordered from lower to higher privileges):

- `database_allowed_sids` (`Database`) - access to operations within a specific database scope
- `viewer_allowed_sids` (`Viewer`) - read-only access to cluster-wide state
- `monitoring_allowed_sids` (`Monitoring`) - access to operational actions in YDB UI
- `administration_allowed_sids` (`Administration`) - administrative actions on the cluster and databases

Higher levels automatically include all lower level privileges, so a subject only needs to appear in one list. For example, presence in `administration_allowed_sids` automatically grants `monitoring`, `viewer`, and `database` privileges.
See Access level descriptions for details.

Additionally, there are two separate access level lists for specific operations:

- `bootstrap_allowed_sids` — allows cluster bootstrap operations
- `register_dynamic_node_allowed_sids` — allows node registration in the cluster

Access level descriptions

Access level lists are configured in the security configuration and determine privileges for:

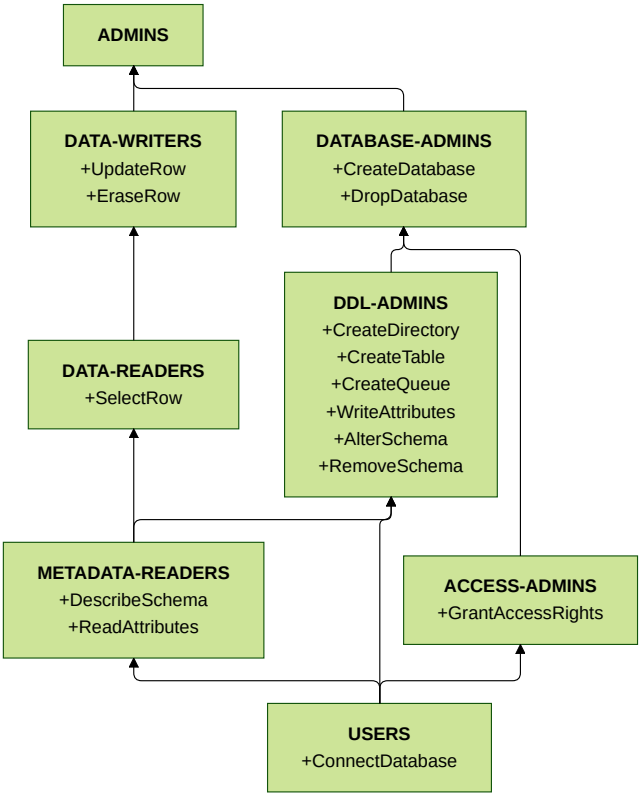
- **Database** (presence in `database_allowed_sids`) — access only within a specific database scope. Subjects can open YDB UI and work with that database data, but cannot run cluster-wide requests (for example, listing cluster nodes). Requests without a specified database are forbidden.
- **Viewer** (presence in `viewer_allowed_sids`) — read-only access to cluster-wide state: subjects can open YDB UI pages and diagnostics, but cannot run actions that change system state.
- **Monitoring** (presence in `monitoring_allowed_sids`) — access to operational actions in YDB UI, including actions that can change system state. For example, backup, database restore, or executing YQL statements from YDB UI.
- **Administration** (presence in `administration_allowed_sids`) — Full administrative access to the cluster and its databases. Also used for config changes, scheme operations requiring admin privileges, and other administrative checks.
- **Register node** (presence in `register_dynamic_node_allowed_sids`) — a separate (non-hierarchical) level for dynamic node registration in the cluster. It does not automatically grant `database` / `viewer` / `monitoring` / `administration` privileges. For technical reasons, if this list is configured (non-empty), it must include `root@builtin`.
- **Bootstrap** (presence in `bootstrap_allowed_sids`) — a separate (non-hierarchical) level only for cluster bootstrap operations. It is used in an uninitialized state, when the authentication subsystem is not yet functional. Bootstrap is allowed if the subject is in `bootstrap_allowed_sids` or `administration_allowed_sids`; `bootstrap` by itself does not grant full administrative privileges.

Initial cluster security configuration

Initial security is configured automatically when the YDB cluster starts for the first time.

During this process YDB adds a superuser and a set of roles for user access management.

> **Note**
>
> For information about overriding and skipping initial security configuration, see the following sections:
>
> - Skipping initial security configuration
> - Overriding initial security configuration



Roles

Role	Description
`ADMINS`	Provides unlimited access rights for the entire YDB cluster scheme.
`DATABASE-ADMINS`	Provides access rights to manage databases, their scheme, and scheme access rights. No data access.
`ACCESS-ADMINS`	Provides access rights to manage scheme access rights. No data access.
`DDL-ADMINS`	Provides access rights to manage the scheme. No data access.
`DATA-WRITERS`	Provides access rights for scheme objects, including reading and modifying data.
`DATA-READERS`	Provides access rights for scheme objects and reading data.
`METADATA-READERS`	Provides access rights for scheme objects. No data access.
`USERS`	Provides access rights for databases. This is a common group for all users.

Groups

Roles in YDB are implemented as a hierarchy of user groups and a set of access rights for these groups. Access rights for the groups are granted on the cluster scheme root.

Groups can be nested, and a child group inherits the access rights of its parent group:

For example, users in the `DATA-WRITERS` group are allowed to:

- View the scheme — `METADATA-READERS`
- Read data — `DATA-READERS`
- Change data — `DATA-WRITERS`

Users in the `DDL-ADMINS` group are allowed to:

- View the scheme — `METADATA-READERS`
- Change the scheme — `DDL-ADMINS`

Users in the `ADMINS` group are allowed to perform all operations on the scheme and data.

Superuser

A superuser belongs to the `ADMINS` and `USERS` groups and has full access rights to the cluster scheme.

By default, a superuser is the `root` user with an empty password.

A group for all users

The `USERS` group is a common group for all local users. When you add new users, they are automatically added to the `USERS` group.

For more information about managing groups and users, see Authorization.

Overriding initial security configuration

You can override the initial security configuration with a custom set of users, groups, and access rights.

To specify custom users, groups, and access rights to be created during the initial security configuration, define the `default_users`, `default_groups`, or `default_access` parameters in the `security_config` section in the cluster configuration file.

Skipping initial security configuration

You can skip initial security configuration by setting the `security_config.disable_builtin_security` parameter to `true`.

Audit log

An audit log is a stream of records that document the operation of the YDB cluster. Unlike technical logs, which help detect failures and troubleshoot issues, the audit log provides data relevant to security. It serves as a source of information that answers the questions: who did what, when, and from where.

A single audit log record may look like this:

```
{"@timestamp":"2025-11-03T18:07:39.056211Z","@log_type":"audit","operation":"ExecuteQueryRequest","databas
e":"/my_dir/db1","status":"SUCCESS","subject":"serviceaccount@as","remote_address":"ipv6:[xxxx:xxx:xxx:xxx:x:
xxxx:xxx:xxxx]"}
```

Examples of typical audit log events:

- Data access through DML requests.
- Schema or configuration management operations.
- Changes to permissions or access-control settings.
- Administrative user actions.

The `audit_config` section in the cluster configuration defines which audit logs are collected, how they need to be serialized and where they are delivered. See the audit log configuration section for details.

Key concepts

Audit events

An *audit event* is a record in the audit log that captures a single security-relevant action. Every event includes attributes that describe different aspects of the event. The common attributes are listed in the Common attributes section.

Audit event sources

An *audit event source* is a YDB service or subsystem that can emit audit events. Each source is identified by a unique identifier (UID) and may expose additional attributes specific to the component. Some sources require extra configuration, such as feature flags, before the source starts emitting events. See the Audit event sources overview for details.

Log classes

Audit events are grouped into *log classes* that represent broad categories of operations. You can enable or disable logging for each class in configuration and, if necessary, tailor the configuration per class. The available log classes are:

Log class	Description
`ClusterAdmin`	Cluster administration requests.
`DatabaseAdmin`	Database administration requests.
`Login`	Login requests.
`NodeRegistration`	Node registration.
`Ddl`	DDL requests.
`Dml`	DML requests.
`Operations`	Asynchronous remote procedure call (RPC) operations that require polling to track the result.
`ExportImport`	Export and import data operations.
`Acl`	Access Control List (ACL) operations.
`AuditHeartbeat`	Synthetic heartbeat messages that confirm audit logging remains operational.
`Default`	Default settings for any component that doesn't have a configuration entry.

At the moment, not all audit event sources categorize events into log classes. For most of them, the basic configuration is sufficient to capture their events. See the Audit event sources overview section for details.

Log phases

Some audit event sources divide the request processing into stages. *Logging phase* indicates the processing stages at which audit logging records events. Specifying logging phases is useful when you need fine-grained visibility into request execution and want to capture events before and after critical processing steps. The available log phases are:

Log phase	Description
`Received`	A request is received and the initial checks and authentication are made. The `status` attribute is set to `IN-PROCESS`. This phase is disabled by default; you must include `Received` in `log_class_config.log_phase` to enable it.
`Completed`	A request is completely finished. The `status` attribute is set to `SUCCESS` or `ERROR`. This phase is enabled by default when `log_class_config.log_phase` is not set.

Audit log destinations

Audit log destination is a target where the audit log stream can be delivered.

You can currently configure the following destinations for the audit log:

- A file on each YDB cluster node.
- An agent for delivering Unified Agent metrics.
- The standard error stream, `stderr`.

You can use any of the listed destinations or their combinations. See the audit log configuration for details.

If you forward the stream to a file, file-system permissions control access to the audit log. Saving the audit log to a file is recommended for production installations.

For test installations, forward the audit log to the standard error stream (`stderr`). Further stream processing depends on the YDB cluster logging settings.

Audit event sources overview

The table below summarizes the built-in audit event sources. Use it to identify which source emits the events you need and how to enable those events.

Source / UID	What it records	Configuration requirements
Schemeshard `schemeshard`	Schema operations, ACL modifications, and user management actions.	Included in the basic audit configuration.
gRPC services `grpc-proxy`	Non-internal requests handled by YDB gRPC endpoints.	Enable the relevant log classes and optional log phases.
gRPC connection `grpc-conn`	Client connection and disconnection events.	Enable the `enable_grpc_audit` feature flag.
gRPC authentication `grpc-login`	gRPC authentication attempts.	Enable the `Login` class in `log_class_config` .
Monitoring service `monitoring`	HTTP requests handled by the monitoring endpoint.	Enable the `ClusterAdmin` class in `log_class_config` .
Heartbeat `audit`	Synthetic heartbeat events proving that audit logging is alive.	Enable the `AuditHeartbeat` class in `log_class_config` and optionally adjust heartbeat settings.
BlobStorage Controller `bsc`	Console-driven BlobStorage Controller configuration changes.	Included in the basic audit configuration.
Distconf `distconf`	Distributed configuration updates.	Included in the basic audit configuration.
Web login `web-login`	Interactions with the web console authentication widget.	Included in the basic audit configuration.
Console `console`	Database lifecycle operations and dynamic configuration changes.	Included in the basic audit configuration.

Audit event attributes

Audit log event attributes are divided into two groups:

- Common attributes present in many *audit event sources* and always carry the same meaning.
- Attributes specific to the source that generates the event.

In this section, you will find a reference guide to the attributes in audit events. It covers both common attributes and source-specific ones. For each source, its UID, recorded operations, and configuration requirements are also provided.

Common attributes

The table below lists the common attributes.

Attribute	Description
`subject`	Event source SID if mandatory authentication is enabled, or `{none}` otherwise.
`sanitized_token`	A partially masked authentication token that was used to execute the request. Can be used to link related events while keeping the original credentials hidden. If authentication was not performed, the value will be `{none}` .
`operation`	Operation name (for example, `ALTER DATABASE` , `CREATE TABLE`).
`component`	Unique identifier (UID) of the *audit event source*.
`status`	Operation completion status. Acceptable values: • `SUCCESS` : The operation completed successfully. • `ERROR` : The operation failed. • `IN-PROCESS` : The operation is in progress.
`reason`	Error message.
`request_id`	Unique ID of the request that invoked the operation. You can use the `request_id` to differentiate events related to different operations and link the events together to build a single audit-related operation context.
`remote_address`	IP of the client that delivered the request.
`detailed_status`	The status delivered by a YDB *audit event source*.
`database`	Database path (for example, `/my_dir/db`).
`cloud_id`	Cloud identifier of the YDB database.

`folder_id`	Folder identifier of the YDB cluster or database.
`resource_id`	Resource identifier of the YDB database. *Optional.*

Schemeshard

UID: `schemeshard`.
Logged operations: Schema operations triggered by DDL queries, ACL modifications, and user management operations.
How to enable: Only basic audit configuration required.

The table below lists additional attributes specific to the `Schemeshard` source.

Attribute	Description
Common schemeshard attributes	**>**
`tx_id`	Unique transaction ID. This ID can be used to differentiate events related to different operations. *Required.*
`paths`	List of paths in the database that are changed by the operation (for example, `[/my_dir/db/table-a, /my_dir/db/table-b]`). *Optional.*
Ownership and permission attributes	**>**
`new_owner`	SID of the new owner of the object when ownership is transferred.
`acl_add`	List of added permissions in short notation (for example, `[+R:someuser]`).
`acl_remove`	List of revoked permissions in short notation (for example, `[-R:someuser]`).
Custom attributes	**>**
`user_attrs_add`	List of custom attributes added when creating objects or updating attributes (for example, `[attr_name1: A, attr_name2: B]`).
`user_attrs_remove`	List of custom attributes removed when creating objects or updating attributes (for example, `[attr_name1, attr_name2]`).
Login/Auth specific	**>**
`login_user`	User name recorded by login operations.
`login_group`	Group name recorded by login operations.
`login_member`	Membership changes.
`login_user_change`	Changes applied to user settings.
`login_user_level`	Privilege level of the user recorded by audit events. This attribute only uses the `admin` value.
Import/Export operation attributes	**>**
`id`	Unique identifier for export or import operations.
`uid`	User-defined label for operations.
`start_time`	Operation start time in ISO 8601 format.
`end_time`	Operation end time in ISO 8601 format.
`last_login`	User's last successful login time in ISO 8601 format.
Export-specific	**>**
`export_type`	Export destination. Possible values: `yt`, `s3`.
`export_item_count`	Number of exported items.
`export_yt_prefix`	YT destination path prefix.
`export_s3_bucket`	S3 bucket used for exports.
`export_s3_prefix`	S3 destination prefix.
Import-specific	**>**
`import_type`	Import source type. It's always `s3`.
`import_item_count`	Number of imported items.
`import_s3_bucket`	S3 bucket used for imports.
`import_s3_prefix`	S3 source prefix.

gRPC services

UID: `grpc-proxy`.
Logged operations: All non-internal gRPC requests.
How to enable: Requires specifying log classes in audit configuration.
Log classes: Depends on the RPC request type: `Ddl`, `Dml`, `Operations`, `ClusterAdmin`, `DatabaseAdmin`, or other classes.
Log phases: `Received`, `Completed`.

The table below lists additional attributes specific to the `gRPC services` source.

Attribute	Description
Common gRPC attributes	**>**
`grpc_method`	RPC method name. *Optional.*
`request`	Sanitized representation of the incoming request. *Optional.*
`start_time`	Operation start time in ISO 8601 format. *Required.*
`end_time`	Operation end time in ISO 8601 format. *Optional.*
Transaction attributes	**>**
`tx_id`	Transaction identifier.
`begin_tx`	Flag set to `1` when the request starts a new transaction.
`commit_tx`	Shows whether the request commits the transaction. Possible values: `true`, `false`.
Request fields	**>**
`query_text`	Sanitized YQL query text.
`prepared_query_id`	Identifier of a prepared query.
`program_text`	MiniKQL program sent with the request.
`schema_changes`	Description of schema modifications requested in the operation.
`table`	Full table path.
`row_count`	Number of rows processed by a bulk upsert request.
`tablet_id`	Tablet identifier.

gRPC connection

UID: `grpc-conn`.
Logged operations: Connection state changes (connect/disconnect).
How to enable: Enable the `enable_grpc_audit` feature flag.

This source uses only common attributes.

gRPC authentication

UID: `grpc-login`.
Logged operations: gRPC authentication.
How to enable: Requires specifying log classes in audit configuration.
Log classes: `Login`.
Log phases: `Completed`.

The table below lists additional attributes specific to the `gRPC authentication` source.

Attribute	Description
`login_user`	User name. *Required.*
`login_user_level`	Privilege level of the user recorded by audit events. This attribute only uses the `admin` value. *Optional.*

Monitoring service

UID: `monitoring`.
Logged operations: HTTP requests handled by the monitoring service.
How to enable: Requires specifying log classes in audit configuration.
Log classes: `ClusterAdmin`.
Log phases: `Received`, `Completed`.

The table below lists additional attributes specific to the `Monitoring service` source.

Attribute	Description
`method`	HTTP request method. For example `POST`, `GET`. *Required.*

`url`	Request path without query parameters. *Required.*
`params`	Raw query parameters. *Optional.*
`body`	Request body (truncated to 2 MB with the `TRUNCATED_BY_YDB` suffix). *Optional.*

Heartbeat

UID: `audit`.
Logged operations: Periodic audit heartbeat messages.
How to enable: Enable this source by specifying log classes in audit configuration.
Log classes: `AuditHeartbeat`.
Log phases: `Completed`.

The table below lists additional attributes specific to the `Heartbeat` source.

Attribute	Description
`node_id`	Node identifier where the event occurred. *Required.*

BlobStorage Controller

UID: `bsc`.
Logged operations: Configuration replacement requests (`TEvControllerReplaceConfigRequest`) emitted by the console.
How to enable: Only basic audit configuration required.

The table below lists additional attributes specific to the `BlobStorage Controller` source.

Attribute	Description
`old_config`	Snapshot of the previous BlobStorage Controller configuration in YAML form. *Optional.*
`new_config`	Snapshot of the configuration that replaced the previous one. *Optional.*

Distconf

UID: `distconf`.
Logged operations: Distributed configuration changes.
How to enable: Only basic audit configuration required.

The table below lists additional attributes specific to the `Distconf` source.

Attribute	Description
`old_config`	Snapshot of the configuration that was active before the distributed update was accepted. Distconf serializes it in YAML. *Required.*
`new_config`	Snapshot of the configuration that Distconf committed after the change. *Required.*

Web login

UID: `web-login`.
Logged operations: Tracks interactions with the YDB web console authentication widget.
How to enable: Only basic audit configuration required.

This source uses only common attributes.

Console

UID: `console`.
Logged operations: Database lifecycle operations and dynamic configuration changes.
How to enable: Only basic audit configuration required.

The table below lists additional attributes specific to the `Console` source.

Attribute	Description
`old_config`	Snapshot of the configuration that was in effect before the console request was applied. *Optional.*
`new_config`	Snapshot of the configuration that the console applied. *Optional.*

Audit log configuration

Enabling audit log

Audit logging works cluster-wide. For the *basic configuration*, add the `audit_config` section to the cluster configuration and specify one or more stream destinations (`file_backend`, `unified_agent_backend`, `stderr_backend`):

```
audit_config:
  file_backend:
    format: audit_log_format
    file_path: "path_to_log_file"
  unified_agent_backend:
    format: audit_log_format
    log_name: session_meta_log_name
  stderr_backend:
    format: audit_log_format
```

Audit config parameters

All fields are optional.

Field	Description
`stderr_backend`	Forward the audit log to the standard error stream (`stderr`). See the backend settings for details.
`file_backend`	Write the audit log to a file at each cluster node. See the backend settings for details.
`unified_agent_backend`	Stream the audit log to the Unified Agent. In addition, you need to define the `uaclient_config` section in the cluster configuration. See the backend settings for details.
`log_class_config`	An array of audit rules for different log classes. See the log class configuration.
`heartbeat`	Optional heartbeat configuration. See the heartbeat settings.

Backend settings

Each backend supports the following fields:

Field	Description
`format`	Audit log format. The default value is `JSON`. See Log format for details. *Optional.*
`file_path`	Path to the file that the audit log will be streamed to. If the path and the file are missing, they will be created on each node at cluster startup. If the file exists, the data will be appended to it. Only for `file_backend`. *Required.*
`log_name`	The session metadata delivered with the message. Using the metadata, you can redirect the log stream to one or more child channels based on the condition: `_log_name: "session_meta_log_name"`. Only for `unified_agent_backend`. *Optional.*
`log_json_envelope`	JSON template that wraps each log record. The template must contain the `%message%` placeholder, which is replaced with the serialized audit record. See the Envelope format. *Optional.*

Log format

The `format` field specifies the serialization format for audit events. The supported formats are:

Format	Description
`JSON`	Each audit event is serialized as a single-line JSON object preceded by an ISO 8601 timestamp. Example: `<time>: {"k1": "v1", "k2": "v2", ...}` *`k1`, `k2`, ..., `kn` represent audit log attributes; `v1`, `v2`, ..., `vn` represent their values.*
`TXT`	Each audit event is serialized as a single-line text string in the `key=value` format, preceded by an ISO 8601 timestamp. Example: `<time>: k1=v1, k2=v2, ...` *`k1`, `k2`, ..., `kn` represent audit log attributes; `v1`, `v2`, ..., `vn` represent their values.*
`JSON_LOG_COMPATIBLE`	Each audit event is serialized as a single-line JSON object suitable for output to destinations shared with debug logs. The object contains the `@timestamp` field with the ISO 8601 timestamp and the `@log_type` field set to `audit`. Example: `{"@timestamp": "<ISO 8601 time>", "@log_type": "audit", "k1": "v1", "k2": "v2", ...}` *`@timestamp` stores the ISO 8601 timestamp; `k1`, `k2`, ..., `kn` represent audit log attributes; `v1`, `v2`, ..., `vn` represent their values.*

Envelope format

Backends can wrap audit events into a custom envelope before delivering them to the backend by specifying the `log_json_envelope` field. The template must contain the `%message%` placeholder, which is replaced with the serialized audit record in the selected format.

For example, the following configuration outputs audit events to `stderr` in JSON format, wrapped in a custom envelope:

```
audit_config:
  stderr_backend:
    format: JSON
    log_json_envelope: '{"audit": %message%, "source": "ydb-audit-log"}'
```

See the Example with Envelope JSON section for output details.

Log class configuration

Each entry in `log_class_config` accepts the following fields:

Field	Description
`log_class`	Class name to configure. Uses values from the log classes list. The `log_class_config` list must not contain two classes with the same name. *Required.*
`enable_logging`	Enables audit event emission for the selected log class. Disabled by default. *Optional.*
`exclude_account_type`	Array of account type (`Anonymous` , `User` , `Service` , `ServiceImpersonatedFromUser`) that should exclude events even if logging is enabled. *Optional.*
`log_phase`	Array of request processing phases to log. See the Log phases. *Optional.*

Heartbeat settings

Heartbeat events help you monitor the health of the audit logging subsystem. They allow you to create alerts for missing audit events without false positives during periods of no activity.

`heartbeat.interval_seconds` controls how often audit heartbeat events are written. A value of `0` disables heartbeat messages.

Config samples

Simple configuration. Below is a simple configuration that saves the audit log text to a file in `TXT` format.

```
audit_config:
  file_backend:
    format: TXT
    file_path: "/var/log/ydb-audit.log"
```

Advanced configuration. The following configuration demonstrates more advanced settings:

- It sends the audit log to Unified Agent in `TXT` format with the `audit` label and also outputs it to `stderr` in `JSON` format.
- The `Default` settings enable logging for all classes in the `Completed` phase.
- Additionally, `ClusterAdmin` is configured to log the `Received` phase, and `DatabaseAdmin` is configured to exclude events from anonymous users:

```
audit_config:
  unified_agent_backend:
    format: TXT
    log_name: audit
  stderr_backend:
    format: JSON
  log_class_config:
    - log_class: ClusterAdmin
      enable_logging: true
      log_phase: [Received, Completed]
    - log_class: DatabaseAdmin
      enable_logging: true
      log_phase: [Completed]
      exclude_account_type: [Anonymous]
    - log_class: Default
      enable_logging: true
  heartbeat:
    interval_seconds: 60
```

Examples

The following tabs show the same audit log event written using different backend settings.

JSON

The `JSON` format produces entries like:

```
2023-03-14T10:41:36.485788Z: {"paths":"[/my_dir/db1/some_dir]","tx_id":"281474976775658","database":"/my_dir/db1","remote_address":"ipv6:[xxxx:xxx:xxx:xxx:x:xxxx:xxx:xxxx]:xxxxx","status":"SUCCESS","subject":"{none}","sanitized_token":"{none}", "detailed_status":"StatusAccepted","operation":"MODIFY ACL","component":"schemeshard","acl_add":"[+(ConnDB):subject:-]"}
2023-03-13T20:07:30.927210Z: {"reason":"Check failed: path: '/my_dir/db1/some_dir', error: path exist, request accepts it (id: [OwnerId: 72075186224037889, LocalPathId: 3], type: EPathTypeDir, state: EPathStateNoChanges)","paths":"[/my_dir/db1/some_dir]","tx_id":"844424930216970","database":"/my_dir/db1","remote_address":"ipv6:[xxxx:xxx:xxx:xxx:x:xxxx:xxx:xxxx]:xxxxx","status":"SUCCESS","subject":"{none}","sanitized_token":"{none}","detailed_status":"StatusAlreadyExists","operation":"CREATE DIRECTORY","component":"schemeshard"}
2025-11-03T18:07:39.056211Z: {"@log_type":"audit","begin_tx":1,"commit_tx":1,"component":"grpc-proxy","database":"/my_dir/db1","detailed_status":"SUCCESS","end_time":"2025-11-03T18:07:39.056204Z","grpc_method":"Ydb.Query.V1.QueryService/ExecuteQuery","operation":"ExecuteQueryRequest","query_text":"SELECT * FROM `my_row_table`;","remote_address":"ipv6:[xxxx:xxx:xxx:xxx:x:xxxx:xxx:xxxx]","sanitized_token":"xxxxxxxx.**","start_time":"2025-11-03T18:07:39.054863Z","status":"SUCCESS","subject":"serviceaccount@as"}
2025-11-03T17:41:44.203214Z: {"component":"monitoring","remote_address":"ipv6:[xxxx:xxx:xxx:xxx:x:xxxx:xxx:xxxx]","operation":"HTTP REQUEST","method":"POST","url":"/viewer/query","params":"base64=false&schema=multipart","body":"{\"query\":\"SELECT * FROM `my_row_table`;\",\"database\":\"/local\",\"action\":\"execute-query\",\"syntax\":\"yql_v1\"}","status":"IN-PROCESS","reason":"Execute"}
```

TXT

The `TXT` format produces entries like:

```
2023-03-14T10:41:36.485788Z: component=schemeshard, tx_id=281474976775658, remote_address=ipv6:[xxxx:xxx:xxx:xxx:x:xxxx:xxx:xxxx]:xxxxx, subject={none}, database=/my_dir/db1, operation=MODIFY ACL, paths=[/my_dir/db1/some_dir], status=SUCCESS, detailed_status=StatusSuccess, acl_add=[+(ConnDB):subject:-]
2023-03-13T20:07:30.927210Z: component=schemeshard, tx_id=281474976775657, remote_address=ipv6:[xxxx:xxx:xxx:xxx:x:xxxx:xxx:xxxx]:xxxxx, subject={none}, database=/my_dir/db1, operation=CREATE DIRECTORY, paths=[/my_dir/db1/some_dir], status=SUCCESS, detailed_status=StatusAlreadyExists, reason=Check failed: path: '/my_dir/db1/some_dir', error: path exist, request accepts it (id: [OwnerId: 72075186224037889, LocalPathId: 3], type: EPathTypeDir, state: EPathStateNoChanges)
2025-11-03T18:07:39.056211Z: component=grpc-proxy, tx_id=281474976775656, remote_address=ipv6:[xxxx:xxx:xxx:xxx:x:xxxx:xxx:xxxx]:xxxxx, subject=serviceaccount@as, database=/my_dir/db1, operation=ExecuteQueryRequest, query_text=SELECT * FROM `my_row_table`; status=SUCCESS, detailed_status=StatusSuccess, begin_tx=1, commit_tx=1, end_time=2025-11-03T18:07:39.056204Z, grpc_method=Ydb.Query.V1.QueryService/ExecuteQuery, sanitized_token=xxxxxxxx.**, start_time=2025-11-03T18:07:39.054863Z
2025-11-03T17:41:44.203214Z: component=monitoring, remote_address=ipv6:[xxxx:xxx:xxx:xxx:x:xxxx:xxx:xxxx], operation=HTTP REQUEST, method=POST, url=/viewer/query, params=base64=false&schema=multipart, body={"query":"SELECT * FROM `my_row_table`;","database":"/local","action":"execute-query","syntax":"yql_v1"}, status=IN-PROCESS, reason=Execute
```

JSON_LOG_COMPATIBLE

The `JSON_LOG_COMPATIBLE` format produces entries like:

```
{"@timestamp":"2023-03-14T10:41:36.485788Z","@log_type":"audit","paths":"[/my_dir/db1/some_dir]","tx_id":"281474976775658","database":"/my_dir/db1","remote_address":"ipv6:[xxxx:xxx:xxx:xxx:x:xxxx:xxx:xxxx]:xxxxx","status":"SUCCESS","subject":"{none}","detailed_status":"StatusAccepted","operation":"MODIFY ACL","component":"schemeshard","acl_add":"[+(ConnDB):subject:-]"}
{"@timestamp":"2023-03-13T20:07:30.927210Z","@log_type":"audit","reason":"Check failed: path: '/my_dir/db1/some_dir', error: path exist, request accepts it (id: [OwnerId: 72075186224037889, LocalPathId: 3], type: EPathTypeDir, state: EPathStateNoChanges)","paths":"[/my_dir/db1/some_dir]","tx_id":"844424930216970","database":"/my_dir/db1","remote_address":"ipv6:[xxxx:xxx:xxx:xxx:x:xxxx:xxx:xxxx]:xxxxx","status":"SUCCESS","subject":"{none}","detailed_status":"StatusAlreadyExists","operation":"CREATE DIRECTORY","component":"schemeshard"}
{"@timestamp":"2025-11-03T18:07:39.056211Z","@log_type":"audit","begin_tx":1,"commit_tx":1,"component":"grpc-proxy","database":"/my_dir/db1","detailed_status":"SUCCESS","end_time":"2025-11-03T18:07:39.056204Z","grpc_method":"Ydb.Query.V1.QueryService/ExecuteQuery","operation":"ExecuteQueryRequest","query_text":"SELECT * FROM `my_row_table`;","remote_address":"ipv6:[xxxx:xxx:xxx:xxx:x:xxxx:xxx:xxxx]","start_time":"2025-11-03T18:07:39.054863Z","status":"SUCCESS","subject":"serviceaccount@as","sanitized_token":"xxxxxxxx.**"}
{"@timestamp":"2025-11-03T17:41:44.203214Z","@log_type":"audit","component":"monitoring","remote_address":"ipv6:[xxxx:xxx:xxx:xxx:x:xxxx:xxx:xxxx]","operation":"HTTP REQUEST","method":"POST","url":"/viewer/query","params":"base64=false&schema=multipart","body":"{\"query\":\"SELECT * FROM `my_row_table`;\",\"database\":\"/local\",\"action\":\"execute-query\",\"syntax\":\"yql_v1\"}","status":"IN-PROCESS","reason":"Execute"}
```

Envelope JSON

The JSON envelope template `{"audit": %message%, "source": "ydb-audit-log"}` produces entries like:

```
{"audit":"2023-03-14T10:41:36.485788Z: {\"paths\":\"[/my_dir/db1/some_dir]\",\"tx_id\":\"281474976775658\",\"database\":\"/my_dir/db1\",\"remote_address\":\"ipv6:[xxxx:xxx:xxx:xxx:x:xxxx:xxx:xxxx]:xxxxx\",\"status\":\"SUCCESS\",\"subject\":\"{none}\",\"detailed_status\":\"StatusAccepted\",\"operation\":\"MODIFY ACL\",\"component\":\"schemeshard\",\"acl_add\":\"[+(ConnDB):subject:-]\"}\n","source":"ydb-audit-log"}
{"audit":"2023-03-13T20:07:30.927210Z: {\"reason\":\"Check failed: path: '/my_dir/db1/some_dir', error: path exist, request accepts it (id: [OwnerId: 72075186224037889, LocalPathId: 3], type: EPathTypeDir, state: EPathStateNoChanges)\",\"paths\":\"[/my_dir/db1/some_dir]\",\"tx_id\":\"844424930216970\",\"database\":\"/my_dir/db1\",\"remote_address\":\"ipv6:[xxxx:xxx:xxx:xxx:x:xxxx:xxx:xxxx]:xxxxx\",\"status\":\"SUCCESS\",\"subject\":\"{none}\",\"detailed_status\":\"StatusAlreadyExists\",\"operation\":\"CREATE DIRECTORY\",\"component\":\"schemeshard\"}\n","source":"ydb-audit-log"}
{"audit":"2025-11-03T18:07:39.056211Z: {\"@log_type\":\"audit\",\"begin_tx\":1,\"commit_tx\":1,\"component\":\"grpc-proxy\",\"database\":\"/my_dir/db1\",\"detailed_status\":\"SUCCESS\",\"end_time\":\"2025-11-03T18:07:39.056204Z\",\"grpc_method\":\"Ydb.Query.V1.QueryService/ExecuteQuery\",\"operation\":\"ExecuteQueryRequest\",\"query_text\":\"SELECT * FROM `my_row_table`;\",\"remote_address\":\"ipv6:[xxxx:xxx:xxx:xxx:x:xxxx:xxx:xxxx]:xxxxx\",\"sanitized_token\":\"xxxxxxxx.**\",\"start_time\":\"2025-11-03T18:07:39.054863Z\",\"status\":\"SUCCESS\",\"subject\":\"serviceaccount@as\"}\n","source":"ydb-audit-log"}
{"audit":"2025-11-03T17:41:44.203214Z: {\"component\":\"monitoring\",\"remote_address\":\"ipv6:[xxxx:xxx:xxx:xxx:x:xxxx:xxx:xxxx]\",\"operation\":\"HTTP REQUEST\",\"method\":\"POST\",\"url\":\"/viewer/query\",\"params\":\"base64=false&schema=multipart\",\"body\":\"{\\\"query\\\":\\\"SELECT * FROM `my_row_table`;\\\",\\\"database\\\":\\\"/local\\\",\\\"action\\\":\\\"execute-query\\\",\\\"syntax\\\":\\\"yql_v1\\\"}\",\"status\":\"IN-PROCESS\",\"reason\":\"Execute\"}\n","source":"ydb-audit-log"}
```

Pretty-JSON

The same audit log entry formatted for readability:

```
{
  "paths": "[/my_dir/db1/some_dir]",
  "tx_id": "281474976775658",
  "database": "/my_dir/db1",
  "remote_address": "ipv6:[xxxx:xxx:xxx:xxx:x:xxxx:xxx:xxxx]:xxxxx",
  "status": "SUCCESS",
  "subject": "{none}",
  "detailed_status": "StatusAccepted",
  "operation": "MODIFY ACL",
  "component": "schemeshard",
  "acl_add": "[+(ConnDB):subject:-]"
}
```

Encryption in YDB

YDB provides two main approaches for user data encryption:

- Data at rest encryption
- Data in transit encryption

It is recommended to use both of them simultaneously in any production environments that handle sensitive data.

Data at rest encryption

YDB supports transparent data encryption at the DS proxy level using the ChaCha8 algorithm. YDB includes two implementations of this algorithm, which switch depending on the availability of the AVX-512F instruction set.

By default, data at rest encryption is disabled. For instructions on enabling it, refer to the Blob Storage Configuration section.

For more details on the implementation, refer to ydb/core/blobstorage/dsproxy/dsproxy_encrypt.cpp and ydb/core/blobstorage/crypto.

Data in transit encryption

As YDB is a distributed system typically running on a cluster, often spanning multiple datacenters or availability zones, user data is routinely transferred over the network. Various protocols can be involved, and each can be configured to run over TLS. Below is a list of protocols supported by YDB:

- Interconnect, a specialized protocol for all communication between YDB nodes.
- YDB as a server:
  - gRPC for external communication with client applications designed to work natively with YDB via the SDK or CLI.
  - Kafka wire protocol for external communication with client applications initially designed to work with Apache Kafka.
  - HTTP for running the YDB UI, exposing metrics, and other miscellaneous endpoints.
- YDB as a client:
  - LDAP for user authentication.
  - Federated queries, a feature that allows YDB to query various external data sources. Some sources are queried directly from the `ydbd` process, while others are proxied via a separate connector process.
  - Tracing data sent to an external collector via gRPC.
- In asynchronous replication between two YDB databases, one serves as a client to the other.

By default, data in transit encryption is disabled and must be enabled separately for each protocol. They can either share the same set of TLS certificates or use dedicated ones. For instructions on how to enable TLS, refer to the tls section.

Short access control notation

When describing or logging the permissions granted to users (e.g., in the audit log records), a special short notation for access control may be used. The notation can vary slightly depending on the list of permissions and their inheritance from child objects.

Notation format

Each entry begins with a `+` sign and consists of 2 or 3 attributes listed through the `:` symbol.
These attributes are:

- List of permissions. If there are multiple, they are wrapped in round brackets and separated by `|`. *Mandatory.*
- SID of the subject granted permissions. *Mandatory.*
- Inheritance type. *Optional.*

When the inheritance type is not specified, it means that permission wasn't inherited.

Examples

- `+R:subject:O`
- `+W:subject`
- `+(SR|UR):subject`
- `+(SR|ConnDB):subject:OC+`

List of permissions

A short abbreviation is used to record each permission.

Permission Groups

Permission groups are unions of several permissions. Where possible, one of the groups will be indicated in the short notation.
For example, `+R:subject` — permission to read.

Group	Description
`L`	(list) enumeration. It consists of permissions to read ACL attributes and describe objects.
`R`	(read) reading. It consists of permissions to enumerate and read from a table and a topic.
`W`	(write) writing. It consists of permissions to update and delete table records, write ACL attributes, create subdirectories, create tables, and topics, modify and delete objects, and change user attributes.
`U`	(use) use. It consists of permissions for reading, writing, granting access rights, and sending requests to the database.
`UL`	(use legacy) obsolete version of use. It consists of permissions for reading, writing, and granting access rights.
`M`	(manage) management. It consists of permissions to create and delete databases.
`F`	(full) all rights. It consists of permissions for use and management.
`FL`	(full legacy) obsolete version of all rights. It consists of permissions for use (obsolete) and management.

Simple Permissions

If there's no matching permission group, the list of permissions will be provided in parentheses separated by the vertical bar `|` symbol.

For example, `+(SR|UR):subject` — permission for reading and updating table records.

Permission	Description
`SR`	(select row) reading from the table
`UR`	(update row) updating table records
`ER`	(erase row) deleting table records
`RA`	(read attributes) reading ACL attributes
`WA`	(write attributes) writing ACL attributes
`CD`	(create directory) creating subdirectory
`CT`	(create table) creating table
`CQ`	(create queue) creating queue
`RS`	(remove schema) deleting objects
`DS`	(describe schema) describing objects, listing directories content
`AS`	(alter schema) modifying objects
`CDB`	(create database) creating database
`DDB`	(drop database) deleting database
`GAR`	(grant access rights) granting access rights (not exceeding their own)
`WUA`	(write user attributes) changing user attributes

`ConnDB`	(connect database) connecting and sending requests to the database

Inheritance Types

One or more inheritance flags can be used to describe the passing of permissions to child objects.

Flag	Description
`-`	without inheritance
`O`	this entry will be inherited by child objects
`C`	this entry will be inherited by child containers
`+`	this entry will be used only for inheritance and will not be used for access checking on the current object

YDB Development

This section contains guidelines for YDB developers and contributors.

- Working on a change
- Build and test using Ya Make build system
- Releases

Development process: working on a change for YDB

This section contains a step-by-step scenario which helps you complete necessary configuration steps, and learn how to bring a change to the YDB project. This scenario does not have to be strictly followed, you may develop your own approach based on the provided information.

Set up the environment

GitHub account

You need to have a GitHub account to suggest any changes to the YDB source code. Register at GitHub if haven't done it yet.

SSH key pair

- To connect to GitHub, you can use ssh or a token. The recommended method is ssh keys.
- If you don't have keys yet, create new keys. Full instructions are on this GitHub page.

Remote development

If you are developing on a remote host, you can use the key from your laptop. Configure SSH agent forwarding using GitHub's guide.

Git CLI

You need to have the `git` command-line utility installed to run commands from the console. Visit the Downloads page of the official website for installation instructions.

To install it under Linux/Ubuntu run:

```
sudo apt-get update
sudo apt-get install git
```

Build dependencies

You need to have some libraries installed on the development machine.

To install it under Linux/Ubuntu run:

```
sudo apt-get update
sudo apt-get install libidn11-dev libaio-dev libc6-dev
```

GitHub CLI (optional)

Using GitHub CLI enables you to create Pull Requests and manage repositories from a command line. You can also use GitHub UI for such actions.

Install GitHub CLI as described at the home page. For Linux Ubuntu, you can go directly to the installation instructions.

Run authentication configuration:

```
gh auth login
```

You will be asked several questions interactively, answer them as follows:

Question	Answer
What account do you want to log into?	**GitHub.com**
What is your preferred protocol for Git operations?	**SSH**
Upload your SSH public key to your GitHub account?	Choose a file with a public key (extention `.pub`) of those created on the "Create SSH key pair" step, for instance `/home/user/.ssh/id_ed25519.pub`
Title for your SSH key	**GitHub CLI** (leave default)
How would you like to authenticate GitHub CLI	**Paste your authentication token**

After the last answer, you will be asked for a token which you can generate in the GitHub UI:

> **Tip**
>
> You can generate a Personal Access Token here.
> The minimum required scopes are 'repo', 'read:org', 'admin:public_key'.

Open the https://github.com/settings/tokens, click on "Generate new token" / "Classic", tick FOUR boxes:

- **Box** `workflow`
- Three others as adivised in the tip: "repo", "admin:public_key" and "read:org" (under "admin:org")

And copy-paste the shown token to complete the GitHub CLI configuration.

Fork and clone repository

YDB official repository is https://github.com/ydb-platform/ydb, located under the YDB organization account `ydb-platform`.

To work on the YDB code changes, you need to create a fork repository under your GitHub account. Create a fork by pressing the `Fork` button on the official YDB repository page.

After your fork is set up, create a local git repository with two remotes:

- `official`: official YDB repository, for main and stable branches
- `fork`: your YDB repository fork, for your development branches

```
mkdir -p ~/ydbwork
cd ~/ydbwork
git clone -o official git@github.com:ydb-platform/ydb.git
```

```
cd ydb
git remote add fork git@github.com:{your_github_user_name}/ydb.git
```

Once completed, you have a YDB Git repository set up in `~/ydbwork/ydb`.

Forking a repository is an instant action, however cloning to the local machine takes some time to transfer about 650 MB of repository data over the network.

Next, let's configure the default `git push` behavior:

```
git config push.default current
git config push.autoSetupRemote true
```

This way, `git push {remote}` command will automatically set upstream for the current branch to the `{remote}` and consecutive `git push` commands will only push current branch.

If you intend to use GitHub CLI, then set `ydb-platform/ydb` as a default repository for GitHub CLI:

```
gh repo set-default ydb-platform/ydb
```

Configure commit authorship

Run the following command to set up your name and email for commits pushed using Git (replace example name and email with your real ones):

```
git config --global user.name "Marco Polo"
git config --global user.email "marco@ydb.tech"
```

Working on a feature

To start working on a feature, ensure the steps specified in the Setup the environment section above are completed.

Refresh trunk

Usually you need a fresh revision to branch from. Sync your local `main` branch by running the following command in the repository:

If your current local branch is `main`:

```
git pull --ff-only official main
```

If your current local branch is not `main`:

```
cd ~/ydbwork/ydb
git fetch official main:main
```

This command updates your local `main` branch without checking it out.

Create a development branch

Create a development branch using Git (replace "feature42" with a name for your new branch):

```
git checkout -b feature42
```

Make changes and commits

Edit files locally, use standard Git commands to add files, verify status, make commits, and push changes to your fork repository:

```
git add .
git status
```

```
git commit -m "Implemented feature 42"
git push fork
```

Consecutive pushes do not require an upstream or a branch name:

```
git push
```

Create a pull request to the official repository

When the changes are completed and locally tested (see Ya Build and Test), create Pull Request.

GitHub UI

Visit your branch's page on GitHub.com (`https://github.com/{your_github_user_name}/ydb/tree/{branch_name}`), press `Contribute` and then `Open Pull Request` .
You can also use the link in the `git push` output to open a Pull Request:

```
...
remote: Resolving deltas: 100% (1/1), completed with 1 local object.
remote:
remote: Create a pull request for '{branch_name}' on GitHub by visiting:
remote:      https://github.com/{your_github_user_name}/test/pull/new/{branch_name}
...
```

GitHub CLI

Install and configure GitHub CLI.

```
cd ~/ydbwork/ydb
```

```
gh pr create --title "Feature 42 implemented"
```

After answering some questions, the Pull Request will be created and you will get a link to its page on GitHub.com.

Precommit checks

Prior to merging, the precommit checks are run for the Pull Request.

For changes in the YDB code, precommit checks build YDB artifacts, and run tests as described in `ya.make` files. Build and test run on a specific commit which merges your changes to the current `main` branch. If there are merge conflicts, build/test checks cannot be run, and you need to rebase your changes as described below.

You can see the checks status on the Pull Request page. Also, key information for YDB build/test checks progress and status is published to the comments of the Pull Ruquest.

If you are not a member of the YDB team, build/test checks do not run until a team member reviews your changes and approves the PR for tests by assigning a label `ok-to-test` .

Checks are restarted every time you push changes to the pull request, cancelling the previous run if it's still in progress. Each iteration of checks produces its own comment on the pull request page, so you can see the history of checks.

If you are a member of the YDB team, you can also restart checks on a new merge commit without pushing. To do so, add label `rebase-and-check` to the PR.

Test results

You can click on the test amounts in different sections of the test results comment to get to the simple HTML test report. In this report you can see which tests have been failed/passed, and get to their logs.

Test history

Each time when tests are run by the YDB CI, their results are uploaded to the test history application. There's a link "Test history" in the comment with test results heading to the page with the relevant run in this application.

In the "Test History" YDB team members can browse test runs, search for tests, see the logs, and compare them between different test runs. If some test is failed in a particular precommit check, it can be seen in its history if this failure had been introduced by the change, or the test had been broken/flaky earlier.

Review and merge

The Pull Request can be merged after obtaining an approval from the YDB team member. Comments are used for communication. Finally a reviewer from the YDB team clicks on the 'Merge' button.

Update changes

If there's a Pull Request opened for some development branch in your repository, it will update every time you push to that branch, restarting the checks.

Rebase changes

If you have conflicts on the Pull Request, you may rebase your changes on top of the actual trunk from the official repository. To do so, refresh main branch state on your local machine, and run the rebase command:

```
# Assuming your active branch is your development branch
git fetch official main:main
git rebase main
```

Cherry-picking fixes to the stable branch

When required to cherry-pick a fix to the stable branch, first branch off of the stable branch:

```
git fetch official
git checkout -b "cherry-pick-fix42" official/stable-24-1
```

Then cherry-pick the fix and push the branch to your fork:

```
git cherry-pick {fixes_commit_hash}
git push fork
```

And then create a PR from your branch with the cherry-picked fix to the stable branch. It is done similarly to opening a PR to `main`, but make sure to double-check the target branch.

If you are using GitHub CLI, pass `-B` argument to specify the target branch:

```
gh pr create --title "Title" -B stable-24-1
```

Build and test YDB using Ya Make

Ya Make is a build and test system used historically for YDB development. Initially designed for C++, now it supports number of programming languages including Java, Go, and Python.

Ya Make build configuration language is a primary one for YDB, with a `ya.make` file in each directory representing Ya Make targets.

Setup the development environment as described in Working on a change - Setup environment arcticle to work with `Ya Make`.

Running Ya commands

There's a `ya` script in the YDB repository root to run `Ya Make` commands from the console. You can add it to the PATH evniromnet variable to enable launching without specifiying a full path. For Linux/Bash and GitHub repo cloned to `~/ydbwork/ydb` you can use the following command:

```
echo "alias ya='~/ydbwork/ydb/ya'" >> ~/.bashrc
source ~/.bashrc
```

Run `ya` without parameters to get help:

```
$ ya
Yet another build tool.

Usage: ya [--precise] [--profile] [--error-file ERROR_FILE] [--keep-tmp] [--no-logs] [--no-report] [--no-tmp-
dir] [--print-path] [--version] [-v] [--diag] [--help] <SUBCOMMAND> [OPTION]...

Options:
...

Available subcommands:
...
```

You can get detailed help on any subcommand launching it with a `--help` flag, for instance:

```
$ ya make --help
Build and run tests
To see more help use -hh/-hhh

Usage:
  ya make [OPTION]... [TARGET]...

Examples:
  ya make -r               Build current directory in release mode
  ya make -t -j16 library  Build and test library with 16 threads
  ya make --checkout -j0   Checkout absent directories without build

Options:
...
```

The `ya` script downloads required platform-specific artifacts when started, and caches them locally. Periodically, the script is updated with the links to the new versions of the artifacts.

Setup IDE

If you're using IDE for development, there's a command `ya ide` which helps you create a project with configured tools. The following IDEs are supported: goland, idea, pycharm, venv, vscode (multilanguage, clangd, go, py).

Go to the directory in the source code which you need to be a root of your project. Run the `ya ide` command specifying the IDE name, and the target directory to write the IDE project configuration in a `-P` parameter. For instance, to work on the YQL library changes in vscode you can run the following command:

```
cd ~/ydbwork/ydb/library/yql
ya ide vscode -P=~/ydbwork/vscode/yqllib
```

Now you can open the `~/ydbwork/vscode/yqllib/ide.code-workspace` from vscode.

Build a target

There are 3 basic types of targets in `Ya Make`: Program, Test, and Library. To build a target run `ya make` with the directory name. For instance, to build a YDB CLI run:

```
cd ~/ydbwork/ydb
ya make ydb/apps/ydb
```

You can also run `ya make` from inside a target directory without parameters:

```
cd ~/ydbwork/ydb/ydb/apps/ydb
ya make
```

Run tests

Running a `ya test` command in some directory will build all test binaries located inside its subdirectories, and start tests.

For instance, to run YDB Core small tests run:

```
cd ~/ydbwork/ydb
ya test ydb/core
```

To run medium and large tests, add options `-tt` and `-ttt` to the `ya test` call, respectively.

Logging

Purpose

YDB uses **structured logging** for events that occur in the system. Structured logging means that in the log (operation journal), the textual description of events is separated from the parameters of those events, and the parameter values themselves are stored and processed independently of each other. For example, if a file read error occurs, its description is text like "Unable to read file", while the parameters are the file path, system error code, textual description of the system error, and so on.

Separating event descriptions from their parameters can subsequently be used for efficient message search, statistics collection, optimized log storage, and other tasks.

Basic tools for writing messages to the log

In most cases, the following conditions are met when writing messages to the log:

1. The source code is contained in some `.cpp` file (logging from header files is supported but discussed further).
2. In one `.cpp` file, all messages are written on behalf of the same component. Therefore, at the beginning of the file (but after all `#include` directives), the `YDB_LOG_THIS_FILE_COMPONENT` macro must be defined, which sets the component code for the entire file.

> **Note**
>
> Logging in YDB assumes that the system consists of a large number of internal components, each of which has its own unique code assigned. You can find the full list of components and their codes on GitHub.
>
> When writing a message to the log, the component code on whose behalf the message is written must be explicitly or implicitly specified. Subsequently, the component name is always output to the log and can be used to search or filter log contents.
>
> In addition, each component can have its own logging settings.

Example:

```
#define YDB_LOG_THIS_FILE_COMPONENT NKikimrServices::STATESTORAGE
```

> **Warning**
>
> The build system may combine multiple `.cpp` files into a single compilation unit using `JOIN_SRCS`, which includes them via `#include` directives. Therefore, it is strongly recommended to undefine the macro at the end of each source file:
>
> ```
> #undef YDB_LOG_THIS_FILE_COMPONENT
> ```
>
> Otherwise, the definition of the `YDB_LOG_THIS_FILE_COMPONENT` macro may propagate to multiple source files.

3. Logging occurs during the operation of an actor, and the `NActors::TlsActivationContext` variable is available for working with the context (in particular, for sending messages to the logging actor).

> **Warning**
>
> If at least one of the three listed conditions is not met, you should use extended logging tools.

Further in this `.cpp` file, the following macros can be used for logging messages:

Macro	Message level
`YDB_LOG_EMERG(message, ...values...)`	Possible system failure (for example, cluster failure).
`YDB_LOG_ALERT(message, ...values...)`	Possible system degradation, system components may fail.
`YDB_LOG_CRIT(message, ...values...)`	Critical state.
`YDB_LOG_ERROR(message, ...values...)`	Non-critical error.
`YDB_LOG_WARN(message, ...values...)`	Warning that should be responded to and fixed if it is not temporary.
`YDB_LOG_NOTICE(message, ...values...)`	An event significant for the system or user has occurred.
`YDB_LOG_INFO(message, ...values...)`	Debug information for statistics collection.
`YDB_LOG_DEBUG(message, ...values...)`	Debug information for developers.
`YDB_LOG_TRACE(message, ...values...)`	Very detailed debug information.

The following parameters are specified in the arguments of the listed macros:

- `message` — text message;
- `...values...` — optional parameters. Each parameter is specified as a `{name, value}` pair, where `name` is a text string with the parameter name, and `value` is the parameter value.

Examples of writing messages to the log:

1. Message without parameters:

```
YDB_LOG_INFO("Module started");
```

2. Message with parameters:

```
YDB_LOG_ERROR("Unable to open file",
    {"sourceFilePath", filename},
    {"errorCode", err});
```

Dynamic determination of message level

In some cases, the message level is determined dynamically at runtime. Then you should use a macro that accepts the message level as an argument. The macro syntax is:

```
YDB_LOG(prio, message, ...values...);
```

Usage example:

```
auto prio = NActors::NLog::PRI_ERROR;
...
YDB_LOG(prio, "Unable to open file",
    {"sourceFilePath", filename},
    {"errorCode", err});
```

Extended tools for writing messages to the log

Logging core

The lowest-level tool for writing messages to the log is the `YDB_LOG_CTX_COMP` macro. It checks the need for logging (according to settings), forms the text message, attaches optional parameters to it, and then sends all this information to the logging actor. Next, the logging actor processes the received message according to its current settings (for example, writes it to a file or syslog).

> **Note**
>
> All other logging tools (including basic logging tools) are built on the basis of the `YDB_LOG_CTX_COMP` macro.

The full syntax of the logging macro is as follows:

```
YDB_LOG_CTX_COMP(ctx, prio, comp, message, ...values...)
```

The following parameters are specified in the macro call arguments:

- `ctx` — actor execution context (needed to send the message to the logging actor);
- `prio` — message logging level (corresponds to logging levels);
- `comp` — component identifier;
- `message` — text message;
- `...values...` — optional parameters. Each parameter is specified as a `{name, value}` pair, where `name` is a text string with the parameter name, and `value` is the parameter value.

In the examples below, `EXAMPLE_COMP_CODE` denotes the logging component code. In real code, specify an existing component instead, for example `NKikimrServices::STATESTORAGE`.

Examples of writing a message to the log

1. Message without parameters:

```
YDB_LOG_CTX_COMP(ctx, PRI_INFO, EXAMPLE_COMP_CODE, "Module started");
```

2. Message with parameters:

```
YDB_LOG_CTX_COMP(ctx, PRI_ERROR, EXAMPLE_COMP_CODE, "Unable to open file",
    {"sourceFilePath", filename},
    {"errorCode", err});
```

In this example, a message with the text `Unable to open file` and two parameters is written: `sourceFilePath` (the value is taken from the `filename` variable) and `errorCode` (the value is taken from the `err` variable). The execution context `ctx` is used to send the message to the logging actor, and `EXAMPLE_COMP_CODE` is passed as the component code.

The `YDB_LOG_CTX_COMP` macro implies dynamic determination of the message level and passing it as an argument. By analogy with basic logging tools, there are a number of macros that do not require passing the message level as an argument.

Macros without specifying the message level as an argument

Macro	Message level
`YDB_LOG_EMERG_CTX_COMP`	Possible system failure (for example, cluster failure).
`YDB_LOG_ALERT_CTX_COMP`	Possible system degradation, system components may fail.

`YDB_LOG_CRIT_CTX_COMP`	Critical state.
`YDB_LOG_ERROR_CTX_COMP`	Non-critical error.
`YDB_LOG_WARN_CTX_COMP`	Warning that should be responded to and fixed if it is not temporary.
`YDB_LOG_NOTICE_CTX_COMP`	An event significant for the system or user has occurred.
`YDB_LOG_INFO_CTX_COMP`	Debug information for statistics collection.
`YDB_LOG_DEBUG_CTX_COMP`	Debug information for developers.
`YDB_LOG_TRACE_CTX_COMP`	Very detailed debug information.

The macros listed in the table do not require specifying the `prio` argument.

Example:

```
YDB_LOG_ERROR_CTX_COMP(ctx, EXAMPLE_COMP_CODE, "Unable to open file",
    {"sourceFilePath", filename},
    {"errorCode", err});
```

Many other macros discussed below are based on the `YDB_LOG_CTX_COMP` macro. Their names are constructed according to the following scheme:

1. The macro name always starts with `YDB_LOG`.
2. If the macro does not require specifying the message level, then the message level name is added to the macro name with an underscore character.
3. If the macro requires specifying the execution context, then `_CTX` is added to the macro name.
4. If the macro requires specifying the component, then `_COMP` is added to the macro name.

Using the standard execution context

In most cases, the execution context available through the global variable `NActors::TlsActivationContext` is used to send messages to the logging actor. To avoid visually overloading the source code with references to this global variable, an additional `YDB_LOG_COMP` macro has been introduced, which always uses `NActors::TlsActivationContext` and does not require specifying the `CTX` parameter.

Example:

```
YDB_LOG_COMP(PRI_ERROR, EXAMPLE_COMP_CODE, "Unable to open file",
    {"sourceFilePath", filename},
    {"errorCode", err});
```

> **Note**
>
> The construction of the `YDB_LOG_COMP` macro name fully fits the basic macro naming principle discussed in the logging core.

In this example, the standard execution context is used, and logging occurs on behalf of the component with code `EXAMPLE_COMP_CODE`.

Macros without specifying the message level as an argument

Macro	Message level
`YDB_LOG_EMERG_COMP`	Possible system failure (for example, cluster failure).
`YDB_LOG_ALERT_COMP`	Possible system degradation, system components may fail.
`YDB_LOG_CRIT_COMP`	Critical state.
`YDB_LOG_ERROR_COMP`	Non-critical error.
`YDB_LOG_WARN_COMP`	Warning that should be responded to and fixed if it is not temporary.
`YDB_LOG_NOTICE_COMP`	An event significant for the system or user has occurred.
`YDB_LOG_INFO_COMP`	Debug information for statistics collection.
`YDB_LOG_DEBUG_COMP`	Debug information for developers.
`YDB_LOG_TRACE_COMP`	Very detailed debug information.

Example:

```
YDB_LOG_ERROR_COMP(EXAMPLE_COMP_CODE, "Unable to open file",
    {"sourceFilePath", filename},
    {"errorCode", err});
```

Using the default component

The same mechanism is used as in basic logging tools:

1. At the beginning of the file (but after all `#include` directives), the `YDB_LOG_THIS_FILE_COMPONENT` macro must be defined. It sets the component code for the entire file.

> **Warning**
>
> The build system may combine multiple `.cpp` files into a single compilation unit using `JOIN_SRCS`, which includes them via `#include` directives. Therefore, it is strongly recommended to undefine the macro at the end of each source file:
>
> ```
> #undef YDB_LOG_THIS_FILE_COMPONENT
> ```
>
> Otherwise, the definition of the `YDB_LOG_THIS_FILE_COMPONENT` macro may propagate to multiple source files.

2. Further in the file, logging macros that do not require specifying the component code should be used. They are similar to those already discussed, but their name does not contain the `_COMP` string.

Example:

```
#define YDB_LOG_THIS_FILE_COMPONENT EXAMPLE_COMP_CODE
...
YDB_LOG_CTX(ctx, PRI_ERROR, "Unable to open file",
    {"sourceFilePath", filename},
    {"errorCode", err});
```

Macros without specifying the message level as an argument

Macro	Message level
`YDB_LOG_EMERG_CTX`	Possible system failure (for example, cluster failure).
`YDB_LOG_ALERT_CTX`	Possible system degradation, system components may fail.
`YDB_LOG_CRIT_CTX`	Critical state.
`YDB_LOG_ERROR_CTX`	Non-critical error.
`YDB_LOG_WARN_CTX`	Warning that should be responded to and fixed if it is not temporary.
`YDB_LOG_NOTICE_CTX`	An event significant for the system or user has occurred.
`YDB_LOG_INFO_CTX`	Debug information for statistics collection.
`YDB_LOG_DEBUG_CTX`	Debug information for developers.
`YDB_LOG_TRACE_CTX`	Very detailed debug information.

Example:

```
#define YDB_LOG_THIS_FILE_COMPONENT EXAMPLE_COMP_CODE
...
YDB_LOG_ERROR_CTX(ctx, "Unable to open file",
    {"sourceFilePath", filename},
    {"errorCode", err});
```

Logging in header files

> **Warning**
>
> It is strongly discouraged to define the `YDB_LOG_THIS_FILE_COMPONENT` macro in header files, as this can lead to the following consequences:
>
> 1. Complex logic for determining the component code (it is not obvious which header file the `YDB_LOG_THIS_FILE_COMPONENT` definition comes from).
> 2. Compilation errors (in different files, the `YDB_LOG_THIS_FILE_COMPONENT` macro may be defined differently).

If logging is needed in a header file, macros that require explicit specification of the component code should be used:

1. `YDB_LOG_CTX_COMP` — requires explicit specification of the message level, execution context, and component code.
2. `YDB_LOG_XXXX_CTX_COMP` — does not require specifying the message level.
3. `YDB_LOG_COMP` — uses the standard execution context.
4. `YDB_LOG_XXXX_COMP` — uses the standard execution context and does not require specifying the message level.

Constructing messages

Reusable sets of attached parameters

If the same set of parameters is attached to different messages, then to avoid code duplication, you can create this parameter set in advance and then reuse it when logging various events. The `YDB_LOG_CREATE_MESSAGE` macro is intended for this purpose. It accepts a set of parameters (as `{name, value}` pairs) as arguments and returns an object that can subsequently be used when sending messages to the log.

Example

```
#define YDB_LOG_THIS_FILE_COMPONENT EXAMPLE_COMP_CODE
...
void MyFunction(const std::string& filename) {
    ...
    // Create message parameters
    auto context = YDB_LOG_CREATE_MESSAGE(
        {"sourceFilePath", filename});
    ...
    if (err != 0) {
        YDB_LOG_ERROR("MyFunction failed",
            context,                            // Use message parameters
            {"errorCode", err});
        return;
    }
    ...
    YDB_LOG_NOTICE("MyFunction succeeded",
        context);                               // Use message parameters
}
```

The result of calling the `YDB_LOG_CREATE_MESSAGE` macro is an instance of the `TStructuredMessage` class. This instance stores the set of parameters included in it, their names, types, and values. Instances of the `TStructuredMessage` class can be stored in local and global variables, copied, passed, and so on.

> **Note**
>
> The `TStructuredMessage` class can be considered a specialized container for storing `{name, value}` pairs attached to log messages.

Operations for modifying a previously created parameter set are supported:

1. Adding and updating.

Example

```
YDB_LOG_UPDATE_MESSAGE(context,
    {"socket", socketNum});
```

2. Removing parameters.

Example

```
context.RemoveValue("socket");
```

Nested parameter sets

It is possible to create nested sets of attached parameters. To do this, when logging a message (or creating another parameter set), a previously created value set (i.e., an instance of the `TStructuredMessage` class) must be specified as the value in the `{name, value}` pair. Then all parameters from the `value` set will be automatically added to the resulting message (or the created value set), but with the prefix specified in `name` added to the parameter names, with `.` as the separator.

Example

```
#define YDB_LOG_THIS_FILE_COMPONENT EXAMPLE_COMP_CODE
...
void MyFunction() {
    // Create message parameters
    auto context = YDB_LOG_CREATE_MESSAGE(
        {"operationName", "read"},
        {"sourceFilePath", filename});
    ...
    if (err != 0) {
        YDB_LOG_ERROR("MyFunction failed",
            {"details", context},                       // Use message parameters
            {"errorCode", err});
        return;
    }
    ...
}
```

In this example, the parameters `details.operationName`, `details.sourceFilePath`, and `errorCode` will be attached to the message with the text `MyFunction failed`.

Logging contexts

Forming and reusing sets of attached parameters is inconvenient in the following cases:

1. These sets need to be specified when logging a large number of messages.
2. These sets need to be passed to all called functions so that they can be specified there when logging messages.

You can simplify the source code by using a **logging context** — a set of parameters that will be automatically attached to all messages sent to the log in the given execution thread. To do this, call the `YDB_LOG_CREATE_CONTEXT` macro and pass it `{name, value}` pairs (the same way as when sending messages to the log or creating reusable sets), as well as previously created `TStructuredMessage` objects. The parameters listed in `YDB_LOG_CREATE_CONTEXT` are added during logging in the code block where this macro is called, as well as in nested code blocks and all called functions.

Example of using a logging context

```
#define YDB_LOG_THIS_FILE_COMPONENT EXAMPLE_COMP_CODE
...
void MyFunction() {
    YDB_LOG_CREATE_CONTEXT(
        {"sourceFilePath", filename});
    ...
    if (errorCode != 0) {
        YDB_LOG_ERROR("MyFunction failed",     // The sourceFilePath and errorCode parameters will be att
ached to the message
            {"errorCode", errorCode});
        return;
    }
    ...
    YDB_LOG_NOTICE("MyFunction succeeded");    // The sourceFilePath parameter will be attached to the me
ssage
}
```

The `sourceFilePath` parameter will be attached to all messages logged in this execution thread in the `MyFunction` function and the functions it calls, up to the point of exiting the `MyFunction` function.

Logging contexts are organized as a stack. If a logging context is configured, it is stored at the top of the stack. Each execution thread has its own stack of logging contexts.

When `YDB_LOG_CREATE_CONTEXT` is called, the following actions occur:

1. A new parameter set is created (as when calling `YDB_LOG_CREATE_MESSAGE`), containing all parameters from the existing context, as well as parameters directly specified in the `YDB_LOG_CREATE_CONTEXT` macro.
2. The new parameter set is placed on the top of the stack and thus becomes the current logging context in the given execution thread.
3. When writing a message to the log (calling the `YDB_LOG_CTX_COMP` macro or similar), parameters from the top of the logging context stack are automatically attached to the message, and the parameters specified in the logging macro are written on top of this set.
4. The top of the stack will be automatically removed when exiting the current block, thus returning to the previously configured context.

To add parameters to the current context or update their values, use the `YDB_LOG_UPDATE_CONTEXT` macro:

```
YDB_LOG_UPDATE_CONTEXT({"requestId", requestId});
```

Multiple parameters and their values can be specified in the `YDB_LOG_UPDATE_CONTEXT` macro. If the specified parameters already exist in the context, their values will be updated. If the specified parameters are absent from the context, their values will be added to the context.

To remove parameters from the current context, pass their names to `YDB_LOG_REMOVE_CONTEXT`:

```
YDB_LOG_REMOVE_CONTEXT("requestId");
```

The `YDB_LOG_UPDATE_CONTEXT` and `YDB_LOG_REMOVE_CONTEXT` macros can be called any number of times. They modify only the current context (that is, the top of the context stack), but do not create new contexts and do not affect other contexts located lower in the context stack.

Recommendations for log content

Security

It is forbidden to write passwords, access tokens, encryption keys, connection strings, and personal data to the log. If a value is needed for diagnostics, the sensitive part must be removed, masked, or replaced with an irreversible hash before passing it to the macro.

Coding style

The following coding style is recommended when using logging macros:

1. All mandatory information (execution context, component code, message level, and message text) is placed on one line.
2. Each `{name, value}` pair is placed on a separate line.

Example of writing a message with multiple parameters:

```
    YDB_LOG_DEBUG("Handle TEvNodeWardenNotifyConfigMismatch",
        {"clusterStateGeneration", ClusterStateGeneration},
        {"msgGeneration", msgGeneration},
        {"clusterStateGuid", ClusterStateGuid},
        {"msgGuid", msgGuid});
```

Text message style

The following style for writing message texts is recommended:

1. The text is a meaningful (and preferably correct) sentence in English that speaks about some event inside the system, with the following requirements:
    - the text starts with a capital letter;
    - if the text is a separate sentence, no period is placed at the end of the message;
    - if the text consists of several sentences, they are separated by periods, but no period is placed after the last sentence.
2. The text may contain class and function names. If an actor logs the fact of receiving some message, a good practice is to log with the text `Handle <event class name>`.
3. Messages are fixed text without dynamically formed fragments.
4. All dynamic information known only at runtime should be placed as attached parameters.

To align message texts and parameter names, there is a simple empirical rule:

> If you take the message text and add the parameter values to it in the form `(name=value, name=value, ... )`, you should get a meaningful, complete, unambiguous, and human-understandable text message.

Example of aligned message text and parameter names

```
YDB_LOG_ERROR_CTX(ctx, "Unable to open file",
    {"sourceFilePath", filename},
    {"errorCode", err});
```

The expected event description looks like this (message parameters are listed in alphabetical order):

```
Unable to open file (errorCode = ..., sourceFilePath = ...)
```

General recommendations for naming individual parameters

The style of naming individual parameters is based on two basic principles:

1. In the context of a specific message, the parameter value should be interpreted simply and unambiguously.

Good

```
YDB_LOG_ERROR("Response timeout elapsed",
    {"nodeHostName", hostName},
    {"requestNum", requestNum},
    {"waitAtPosixTime", startTime},
    {"timeoutMs", timeout});
```

Bad

```
YDB_LOG_ERROR("Response timeout elapsed",
    {"node", hostName},
    {"request", requestNum},
    {"wait", startTime},
    {"timeout", timeout});
```

If you use the previously mentioned rule for aligning message texts and parameter names, you get the sentence `Response timeout elapsed (node=<string>, request=<number>, wait=<number>, timeout=<number>)`, where it will be unclear: is the `node` value a host name or some internal node identifier? Is the `request` value a sequence number or a numeric identifier? What is `wait` and how should this value be interpreted? In what units is the `wait` value specified?

2. Semantically similar parameters should have the same names, since different naming of the same concepts makes it difficult to search for log entries. For example, it is undesirable to denote a transaction identifier as `txId` in some messages and as `transactionId` in others.

Good

```
YDB_LOG_INFO("Started transaction",
    {"txId", transactionId});
...
YDB_LOG_INFO("Transaction modifies table",
    {"queryId", queryId},
    {"txId", transactionId});
...
YDB_LOG_INFO("Query commits transaction",
    {"queryId", queryId},
    {"txId", transactionId});
...
```

Bad

```
YDB_LOG_INFO("Started transaction",
    {"id", transactionId});
...
YDB_LOG_INFO("Transaction modifies table",
    {"id", queryId},
    {"transactionId", transactionId});
...
YDB_LOG_INFO("Query commits transaction",
    {"id", queryId},
    {"txId", transactionId});
...
```

In this example, the transaction identifier is written to parameters with different names (`id`, `transactionId`, and `txId`), and at the same time, the parameter named `id` stores identifiers of completely different entities each time.

3. Parameter names are written in `camelCase`.

Specific recommendations for naming individual parameters

The following recommendations are aimed at fulfilling the two principles mentioned above:

1. It is undesirable to use individual common words (`id`, `item`, `value`, `path`, `child`, `parent`, `min`, `max`, etc.) as parameter names — this complicates searching log entries. For example, the word `id` denotes an identifier, but it is completely unclear which entity it refers to, although in the context of a specific message, the meaning of this parameter may be perfectly clear.

Good

```
YDB_LOG_INFO("Started transaction",
    {"txId", ...});
...
YDB_LOG_INFO("Received query",
    {"queryId", ...});
...
YDB_LOG_INFO("Sent request to actor",
    {"actorId", ...});
```

Bad

```
YDB_LOG_INFO("Started transaction",
    {"id", ...});
...
YDB_LOG_INFO("Received query",
    {"id", ...});
...
YDB_LOG_INFO("Sent request to actor",
    {"id", ...});
```

2. Parameter names should consist of several words, with the last word being the main one, and each preceding word clarifying the meaning of the following one. For example:

- `actorId` — actor identifier;
- `operationId` — operation identifier;
- `operationName` — operation name;
- `operationSessionId` — identifier of the session within which the operation is performed.

Good

```
YDB_LOG_INFO("Copy data to another shard",
    {"srcShardId", ...},
    {"dstShardId", ...});
```

Bad

```
YDB_LOG_INFO("Copy data to another shard",
    {"srcId", ...},
    {"dstShard", ...});
```

Here it is unclear both what entity the `srcId` parameter is an identifier of, and how to interpret the `dstShard` value (is it an identifier, a name, or something else).

3. Rules for denoting individual entities and collections:

- a separate mention of an entity name in the singular implies that the parameter value contains a description of that entity. For example, `table` is a description of a table (however, in this case, it is better to add a suffix, that is, `tableId` clearly indicates that the parameter contains a table identifier, `tableName` — a table name, `tableDesc` — a table description, etc.);
- a separate mention of an entity name in the plural implies that the parameter value contains a description of a collection of entities. For example, `tables` is a description of several tables (but not their count);
- a separate mention of an entity name in the plural with the addition of `Count` implies that the parameter value contains the number of elements in the collection. For example, `tablesCount` — the number of tables;
- it is undesirable to add `Size` instead of `Count` to the parameter name to denote the number of elements in a collection. For example, the parameter name `totalFilesSize` makes it unclear whether we are talking about the number of files or their total

size.

Good

```
YDB_LOG_INFO("Backup volumes progress",
    {"currentVolumeNum", ...},
    {"volumesCount", ...},
    {"volumesSizeBytes", ...});
```

Bad

```
YDB_LOG_INFO("Backup volumes progress",
    {"currentVolume", ...},
    {"volumes", ...});
```

4. If a commonly accepted abbreviation or term in YDB is used in a parameter name, it should be written in the case in which it is conventionally used. Examples of such parameter names:

- `VDiskId` — VDisk identifier (written not as `vdiskId`);
- `PDiskId` — PDisk identifier (written not as `pdiskId`);
- etc.

5. Popular abbreviations are allowed (`idx` instead of `index`, `msg` instead of `message`, `tx` instead of `transaction`, etc.).
6. If a parameter contains a numeric value, it is desirable to add a suffix to the parameter name:

- `Id`, if the number is an identifier (but not as `ID`);
- the name of the units of measurement (for example, for memory volumes — `Byte`, `KByte`, `MByte`, for time — `Ms`, `Sec`, `Min`, for indicating percentage fractions of something — `Percent`, and so on). If a non-standard unit of measurement is used, it is desirable to use the preposition `In` (for example, `bufferSizeInBlocks`);

Good

```
YDB_LOG_INFO("Table dump progress",
    {"tableId", ...},
    {"dumpedRecordsCount", ...},
    {"dumpedSizeBytes", ...},
    {"totalSizeBytes", ...});
```

Bad

```
YDB_LOG_INFO("Table dump progress",
    {"table", ...},
    {"dumpedRecords", ...},
    {"dumpedSize", ...},
    {"totalSize", ...});
```

7. If a numeric parameter value is more convenient for a person to analyze not in decimal form, it is better to specify this value as a character string and supplement it with commonly accepted characters (for example, a hexadecimal representation should have the prefix `0x`, and a binary one should have the prefix `0b`, etc.). A good practice is to supplement the parameter name with the suffix `Hex` or similar.

Good

```
unsigned flags;
...
YDB_LOG_INFO("Invalid access rights to file",
    {"filename", ...},
    {"aclFlags", flags},
    {"aclFlagsOct", ToOct(flags)});         // Make flags as "0XXXXX" string
```

Bad

```
unsigned flags;
...
YDB_LOG_INFO("Invalid access rights to file",
    {"filename", ...},
    {"aclFlags", flags});
```

8. If a parameter contains textual information, it is desirable to add a suffix to the parameter name that makes it easier to interpret the parameter value (for example, `Name`, `Desc`, `Json`, `Base64`, etc.).
9. Local variable naming rules can be applied to parameter names (for example, for boolean flags, add `is`, `has`, or similar to the beginning of the parameter name).

Commonly accepted parameter names

There are commonly accepted parameter names that are desirable to use.

Name	Parameter content
`actorClassName`	Name of the class in which the actor is implemented.
`actorStateName`	Actor state.

`backtrace`	Exception occurrence stack (result of the `TBackTrace::FromCurrentException().PrintToString()` function).
`ev`	Description of the message being processed by the actor.
`evType`	Type of the message being processed by the actor.
`exception`	Description of the occurred C++ exception.
`selfId`	Identifier of the actor processing the message.

Methodology for enriching logs with contextual information

The following methodology is proposed for enriching events that a specific actor writes to the log.

Step 1. The actor should implement a function that forms the current logging context as a set of parameters attached to logged messages.

Implementation example

```
TStructuredMessage GetLogContext() const {
    return YDB_LOG_CREATE_MESSAGE(
        {"actorClassName", "TFileReader"},
        {"selfId", SelfId()},
        {"sourceFilePath", filename});
}
```

> Instead of the name `GetLogContext`, `GetLogPrefix` or similar can be used. In principle, this may not even be a function, but a class field created in the constructor and modified during the actor's operation.

Step 2. Setting up the context at "entry points". Each actor has a small set of functions that can be called by the actor system core. These include:

1. The `Bootstrap` function.
2. Message processing functions (found by the `STATEFN` macro or similar).
3. Other virtual functions that the actor overrides (they are easily found by the `override` keyword).

Then, in the first line of each such function, the logging context should be configured using the `YDB_LOG_CREATE_CONTEXT` macro.

Example of context configuration

```
STATEFN(StateWork) {
    YDB_LOG_CREATE_CONTEXT(GetLogContext());
    switch (ev->GetTypeRewrite()) {
        ...
    }
}
```

Manage YDB Releases

There are two products based on the source code from the YDB repository with independent release cycles:

- YDB server
- YDB command-line interface (CLI)

YDB Server Release Cycle

Release Numbers and Schedule

YDB server version consists of three numbers separated by dots:

1. The last two digits of calendar year of the release
2. Major release ordinal number in a given year
3. Minor release ordinal number for a given major release

Thus, YDB server major version is a combination of the first two numbers (for example, `23.3`), and the full version is a combination of all three (for example, `23.3.5`).

YDB server release schedule typically includes 4 major releases per year, so the release `YY.1` is the first one, and `YY.4` is the last one for a year `YY`. The number of minor releases is not fixed, and may vary from one major release to another.

Compatibility

YDB maintains compatibility between major versions to ensure a cluster can operate while its nodes run two adjacent major versions of the YDB server executable. You may refer the Updating YDB article to learn more about the cluster upgrade procedure.

Given the above compatibility target, major releases go in pairs: odd numbered releases add new functionality switched off by feature flags, and even numbered releases enable that functionality by default.

For instance, release `23.1` comes with the new functionality switched off. It can be incrementally rolled out to a cluster running `22.4`, without downtime. As soon as the whole cluster runs `23.1` nodes, you can manually toggle feature flags to test new functionality and later further upgrade it to `23.2` to fully leverage this new functionality.

Release Branches and Tags

A release cycle for an odd major release starts by a member of a YDB Release team forking a new branch from the `main` branch. Major release branch name starts with prefix `stable-`, followed with the major version with dots replaced by dashes (for example, `stable-23-1`).

A release cycle for an even major release starts by branching from the preceding odd major version branch. The branch follows the same naming convention.

All major version releases, both odd and even, go through the comprehensive testing process producing a number of minor versions. Each minor version is created by tagging a relevant commit of the release branch with a full version number. So, there can be tags `24.1.1`, `24.1.2` etc. on the `stable-24-1` branch. As soon as a minor version proves its quality, we consider it as stable, and register a Release on GitHub linked to its tag, add it to downloads and changelog documentation pages, etc. Thus, there can be more that one stable release for a major version.

Testing

Release testing is iterative. Each iteration starts by assigning a tag to a commit on the release branch, specifying a minor version to be tested. For example, the minor version tag `23.3.5` marks a 5th testing iteration for the major release `23.3`.

A tag can be considered to be either "candidate" or "stable". Initially, the first tag is created in the release branch right after its creation. This tag is considered as "candidate".

During a testing iteration, code from release branches undergoes an extensive testing including deployment on UAT, prestable, and production environments of companies using YDB. To perform such testing, YDB code from a GitHub release tag is imported into the corporate context of a given user, following its internal policies and standards. Then it's built, deployed to the necessary environments, and thoroughly tested.

Based on a list of uncovered problems, the YDB Release team decides if the current minor release can be promoted to be called "stable", or a new testing iteration must be started over with a new minor release tag. In fact, as soon as a critical problem is discovered during testing, developers fix it in the `main` branch, and backport changes to the release branch right away. So, by the time testing iteration finishes, there will be a new tag and a new testing iteration if there are some new commits on top of the current tag.

Stable Release

If testing iteration proves the quality of a minor release, the YDB Release team prepares the release notes, and publishes the YDB server release on both the GitHub Releases and Downloads pages, therefore declaring it as "stable".

YDB CLI (Command-Line Interface) Release Cycle

Release Numbers and Schedule

YDB CLI version consists of three numbers separated by dots:

1. Major release ordinal number (currently, `2`)
2. Minor release ordinal number for a given major release
3. Patch number

For example, `2.8.0` is the 2nd major release, 8th minor, without additional patches.

There's no schedule for the YDB CLI minor releases, a new release comes as soon as there's some new valuable functionality. Initially, every new minor release has `0` as a patch number. If there are critical bugs found in that version, or some minor part of functionality did not catch it as planned, a patch can be released, incrementing only the patch number, like it was for `2.1.1`.

In general, release cycle for YDB CLI is much simpler and shorter than for the server, producing more frequent releases.

Release Tags

Tags for YDB CLI are assigned on the `main` branch by a member of the YDB Release team after running tests for some revision. To distinguish from the YDB server tags, YDB CLI tags have a `CLI_` prefix before the version number, for example CLI_2.8.0.

Stable Release

To declare a YDB CLI tag as stable, a member of the YDB Release team prepares the release notes, and publishes the release on the GitHub Releases and Downloads pages.

Contributing to YDB documentation

YDB follows the "Documentation as Code" approach, meaning that the YDB documentation is developed using similar techniques and tools as its main C++ source code.

The documentation source code consists of Markdown files and YAML configuration files located in the ydb/docs folder of the primary YDB GitHub repository. The compiler for this source code is an open-source tool called Diplodoc. See its documentation for details on its Markdown syntax flavor, configuration options, extensions, and more.

The process of suggesting changes to the documentation source code is mostly similar to changing any other YDB source code, so most of Development process: working on a change for YDB applies. The main additional considerations are:

- Extra precommit checks run for pull requests to the documentation. One of these checks posts a comment with a link to an online preview of the changes or a list of errors.
- The code review process includes additional steps. See Review process for YDB documentation and YDB documentation style guide.
- For small changes like fixing a typo, you can use the "Edit this file" feature in the GitHub web interface. Each documentation page has an "Edit on GitHub" link (represented by a pencil icon in the top-right corner) that directs you to the page's source code in the GitHub web interface.

After a pull request to the documentation is merged into the `main` branch, the CI/CD pipeline automatically deploys it to the YDB website. Documentation is also automatically deployed for stable YDB server versions from `git` branches named `stable-*`, where these versions are developed. If C++ code and documentation for a feature were committed separately and a new stable branch was forked between these commits, backporting some changes to the stable branch might be necessary. The same applies to typo fixes and other "bug fixes" to the documentation content. See Manage YDB Releases for more details on the YDB release process.

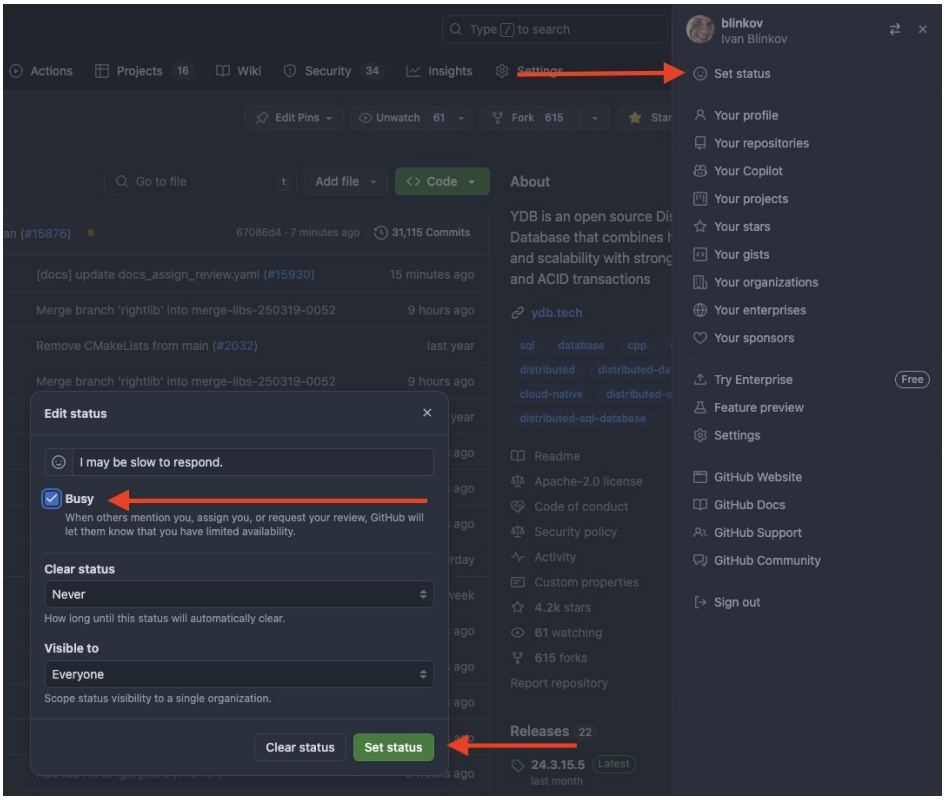
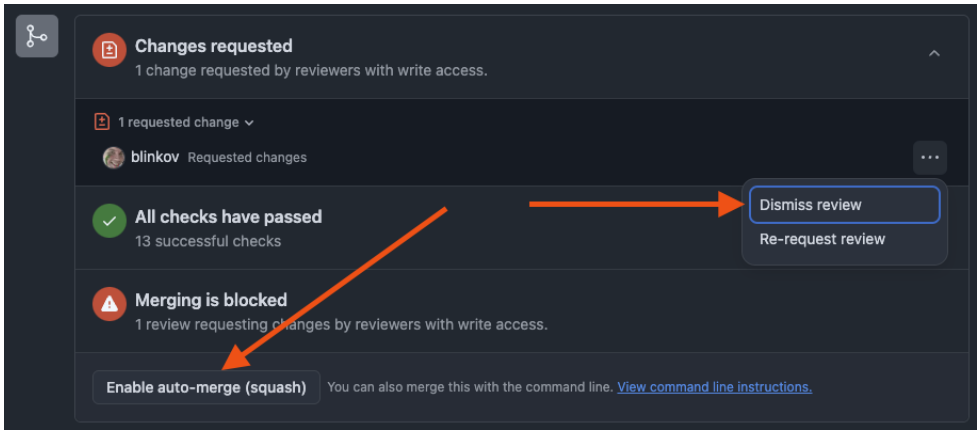
Review process for YDB documentation

Building on the high-level overview in Contributing to YDB documentation, this article dives deeper into what happens during the documentation pull request review stage.



Roles

- **Author** — the person suggesting a change to the documentation.
- **Primary reviewer** — the person thoroughly inspecting the suggested change according to the checklist.
- **Final reviewer** — the person double-checking the change using the same checklist and approving the pull request on GitHub.



Process

1. **Author** opens a GitHub pull request with suggested changes to the ydb/docs folder. Following the style guide from the beginning makes the review process smoother.
2. **Author** ensures the pull request is in a reviewable state by meeting all of the following criteria:
   2.1. The pull request has `* Documentation` as the only changelog category. If done correctly, automation marks the pull request with a "documentation" label.
   2.2. The pull request is *not* marked as a draft.
   2.3. The suggested change builds successfully, and automation has posted a comment with a preview link (instead of errors). The preview shows the changed content as expected.
3. *(optional)* **Author** shares a link to the pull request in a community or documentation-related chat for extra visibility.
4. A **primary reviewer** gets automatically assigned or picks the pull request from the inbound list via the "assign yourself" button, and then provides the initial set of feedback and suggestions.

   Temporarily excluding yourself from automatic assignment if you're a primary reviewer

5. The **author** and **primary reviewer** iterate until the suggested change passes the checklist. The **primary reviewer** provides feedback via comments on the pull request, while the **author** addresses them. The expected turnaround time for each review iteration is two business days, up to a few weeks in case of force majeure. Additionally, the **primary reviewer** periodically checks pull requests assigned to them and clarifies the status with authors if nothing happens for several business days (in GitHub comments, plus in personal communication if possible).
6. Once the **primary reviewer** confirms that the pull request meets the checklist requirements, they:
   - Enable auto-merge for the pull request. If the target branch of the pull request differs from `main`, the auto-merge feature will not be available: in this case, the **primary reviewer** should manually click the "Squash and merge" button after approval by the **final reviewer** in step 7.

- Dismiss their stale review with a "lgtm" comment.

- The **primary reviewer** passes the process to the **final reviewer** for additional review with a fresh set of eyes. This typically happens via a direct personal message, but since whole step 6 is done simultaneously, this event is still visible in the pull request itself through the previous sub-steps (enabled auto-merge and/or dismissed review from the **primary reviewer**).

7. Depending on the **final reviewer**'s verdict:
   - If the **final reviewer** approves, the pull request starts meeting one of the mandatory conditions for merging. Thus, if the build is still passing, GitHub's auto-merge likely merges the pull request automatically. Otherwise, any issues must be addressed manually.
   - If the **final reviewer** provides additional feedback or suggestions, the process returns to step 5.
8. If auto-merge was not enabled in step 6, the **primary reviewer** clicks the "Squash and merge" button.
9. After the content lands in the `main` branch, it will be automatically published to the official YDB website via CI/CD.
10. YDB documentation is multilingual, and **authors** are expected to provide synchronized changes for all supported languages (currently English and Russian), if applicable. If the **author** does not know all required languages, using an LLM or machine translation is acceptable. The translation timing depends on complexity:
    - For simple changes, it's usually best to translate at the beginning and go through the review process with a single pull request covering all languages.
    - For complex changes likely requiring multiple review iterations, it's acceptable to first complete the review process in one language and then start a separate translation pull request after approval.

Checklist

If the PR is new content for the main branch

- [ ] The text is understandable for the article's target audience.
- [ ] The text is technically accurate.
- [ ] The text is grammatically correct, with no punctuation, spelling, or typographical errors.
- [ ] Terminology is consistent. The first mention of each term used in the article is a link to its explanation in the YDB glossary or a well-known source like Wikipedia.
- [ ] Each new article is correctly placed in the documentation structure.
- [ ] Each article follows a single genre and aligns with its place in the documentation structure.
- [ ] Each new article includes links to all relevant existing documentation pages, either inline or in a "See also" section.
- [ ] Relevant existing articles are updated with links to new articles.
- [ ] All new articles are listed in YAML files with table of contents and their folder's `index.md`.
- [ ] All renamed or moved articles are reflected in redirects.yaml.
- [ ] The article's voice, tone, and style match the rest of the documentation or, at a minimum, remain consistent within the article.

> **Tip**
>
> This checklist is a condensed version of YDB documentation style guide and serves as a reminder. Feel free to copy-paste it into the pull request description and check off items as you go. Refer to the full style guide for initial understanding and additional details.

If the PR is a backport to a stable branch

The documentation content is independently published on the website from multiple Git branches. Similar to source code development, `main` is the documentation for upcoming releases, while the documentation for each specific YDB release is published from a stable branch. For example, YDB v25.1 corresponds to the `stable-25-1` branch. If the documentation content needs to be cherry-picked from `main` to a stable branch, a separate PR is created with `stable-***` as the target branch. The review process for such PRs is different, as the content has already been reviewed when it was merged into `main`. Use the following checklist instead:

- [ ] The backport PR mentions identifiers or links to one or more PRs where this content was introduced in the `main` branch.
- [ ] The content of the backport PR matches the original PRs to `main`. The content has been correctly moved if there was a structural refactoring between branches.
- [ ] The PR compiles correctly, the preview generates without errors or warnings, and the content appears in the correct locations.
- [ ] There are no merge artifacts such as duplicate content, `>>>>>>>`-like Git markers, or similar issues.
- [ ] The feature appears to be available in the corresponding YDB release. Double-check with the author or feature owner if unsure.

What documentation review is not

Testing

Documentation review is not a replacement for testing. If the documentation includes instructions, the **author** is responsible for ensuring their correctness, implementing automated tests to maintain accuracy over time, etc.

The **primary reviewer** and/or **final reviewer** may choose to follow the instructions to see how they work in practice, but this is not mandatory.

Technical design review

Documentation review is not a technical design review. Documentation is typically written for mostly completed features, so significant changes to product behavior are rarely possible at this stage. However, the **primary reviewer** and/or **final reviewer** may highlight any inconsistencies, odd behaviors, or usability concerns. It is the **author**'s responsibility to address them immediately if possible or consider them for future iterations of the feature being described.

YDB documentation style guide

The YDB documentation style guide is designed to help writers create clear, consistent, and developer-friendly documentation.

Core principles

- **Target audience understanding:**
  - Before starting a new article or improving an existing one, take a moment to narrow down its target audience. Consider their specific role (application developers, DevOps engineers, security engineers, etc.), technical background, and familiarity with the subject and YDB in general.
  - Ensure the text is understandable to the article's intended audience.
- **Clear language:**
  - Use plain, simple language that directly communicates ideas.
  - Avoid complicated phrases that might be challenging for non-native speakers.
  - Avoid jargon and slang unless they are industry-standard.
- **Consistent terminology:**
  - For each uncommon term in the article, ensure that the first usage links to an explanation:
    - For YDB-specific terms, link to the YDB glossary. If the glossary lists multiple synonyms for the term, use the primary one from the glossary header. If the glossary entry is missing, add it.
    - For generic terms that some readers might not know, link to their Wikipedia page or a similar well-known source. Avoid linking to blog posts, social media, or random third-party articles.
  - If there's an abbreviation, spell it out in full the first time it appears in the article and explicitly show the abbreviation in parentheses. For example, Structured Query Language (SQL).
- **Structured content:**
  - Each article should have only *one* goal for the reader to achieve. If the text pursues multiple goals, it likely needs to be split into multiple articles. If possible, explicitly state this goal at the beginning of the article and reiterate it at the end.
  - Each article should follow only one genre. If not, it likely needs to be split into multiple articles.
  - Organize articles with clear headings, subheadings, bullet lists, notes, tables, and code blocks to help readers quickly navigate the information.
  - Follow the overall documentation structure when creating new articles.

Voice and tone

- **Conversational.** Aim for a tone that feels like a knowledgeable friend explaining concepts in an approachable manner.
- **Friendly and respectful.** Maintain a balance of professionalism and warmth that invites engagement.
- **Inclusive language.** Write in a neutral and respectful way, avoiding biased or exclusive language.
- **Context-dependent.** Adjust your tone based on the type of content. For tutorials, be more encouraging; for reference material, be more concise.
- **Active voice.** Prefer active constructions to ensure clarity and immediacy, making instructions easier to follow.

Language-specific

Ensure that text follows proper language rules with no typos, grammar, punctuation, or spelling issues. Additionally, follow these YDB-specific rules.

English-only

- Use the serial comma where appropriate.
- Use title case for headers, preferably following the Chicago Manual of Style rules.
- Use double quotes (`"`).

Russian-only

- Use `ё` where appropriate.
- Use guillemets for quotes (`«` and `»`).
- Use `—` for long dashes.
- Use semicolons for bullet and numbered lists where appropriate, i.e., for all items except the last one, unless items contain multiple sentences.
- Do *not* use title case for headers.

Formatting and structure

- **Clear hierarchy.** Use headings and subheadings to define sections and make the document easy to scan.
- **Lists and bullet points.** Use bullet points or numbered lists to break down steps, features, or recommendations.
- **Visual highlights.** If there's an important warning, information, or tip, highlight it using a `{% note info %} ... {% endnote %}` tag. For smaller inline highlights, sparingly use **bold** or *italic*.
- **Code and samples.** When including code, use proper syntax highlighting, formatting, and comments to ensure readability. Show example output for queries and CLI commands. Use `code blocks` for everything likely to appear in a console or IDE, but not for visual highlights.
- **File naming.** Use dashes instead of underscores for spaces in new file and folder names (e.g., `new-folder/new-file.md` instead of `new_folder/new_file.md`). However, underscores are acceptable in keywords that should be written specifically with underscores, such as in setting names.
- **Linking and references.**
  - Provide clear and descriptive links to related resources or additional documentation.
  - Links internal to documentation should always include a `.md` suffix and always be relative (that is, no `https://ydb.tech` prefix); otherwise, link consistency checking doesn't work, and they will eventually start leading to 404 errors. Internal links shouldn't contain `?version=...` , `?revision=...` , or similar parameters.
  - Instead of repeating the target's header for internal links, use `[{#T}](path/to/an/article.md)` .
- **No copy-pasting.** If a piece of information needs to be displayed more than once, create a separate Markdown file in the `_includes` folder, then add it to all necessary places via the `include` feature instead of duplicating content by copying and pasting.
- **Markdown syntax style.** YDB documentation uses an automated linter for Markdown files. Refer to .yfmlint for the up-to-date list of enforced rules.

- **Variable usage.** The YDB documentation has a configuration file, presets.yaml, that lists variables to prevent typos or conditionally hide content. Use these variables when appropriate, particularly `YDB` instead of `YDB`.
- **Diagrams.** Prefer built-in Mermaid diagrams when possible. If using an external tool, submit the source file in the same `_assets` folder near the image for future edits. Ensure diagrams look good in both light and dark modes.
- **Proper article placement.** New articles should be correctly placed in the documentation structure.
- **Genre consistency.** Articles should not mix multiple genres, and the genre should match the article's place in the documentation structure.

Documentation integration

- **Cross-referencing.** Include links to all relevant existing documentation pages, either inline or in a "See also" section at the end.
- **Bidirectional linking.** Update relevant existing articles with links to new articles.
- **Index inclusion.** Mention all articles in table of contents (`toc_i.yaml` or `toc_p.yaml`) and their folder's `index.md` .
- **Source code links.** Link directly to source files on GitHub when relevant. If the target is likely to change significantly over time, use a link to a specific commit or stable branch.
- **Glossary links:**
  - When a YDB-specific term is mentioned in an article for the first time, make it a clickable link to the related glossary entry.
  - If there's a separate detailed article covering the same topic as a glossary term, link to it from the glossary term description.

Usage and flexibility

- **Guidelines, not rigid rules.** This style guide offers recommendations to improve clarity and consistency, but flexibility is allowed when deviations benefit the content.
- **Supplementary resources.** Writers are encouraged to consult external style guides (e.g., The Chicago Manual of Style, Merriam-Webster) when in doubt.
- **Updates.** This guide is meant to evolve with the rest of the content over time. If you contribute to YDB documentation frequently, check back periodically for updates.

Things to avoid

- Jargon and slang.
- Using "we".
- Jokes and other emotional content.
- Excessively long sentences.
- Unrelated topics and references, such as culture, religion, or politics.
- Overly detailed implementation specifics (except in YDB Development, YDB Server changelog, and Videos).
- Reusing third-party content without written permission or a compatible open-source license explicitly allowing it.
- HTML inside Markdown, except as a workaround for missing visual styles.

- YDB documentation genres

YDB Documentation Structure

This article complements YDB documentation style guide. It explains the current top-level folders of the documentation and what kind of content belongs in each. As a rule of thumb, most top-level sections focus either on a specific target audience (if named "For ...") or on a specific genre.

- Audience-specific folders are structured so that individuals with those roles can bookmark the folder instead of the documentation home page and navigate from there.
- Genre-specific folders are mainly designed to be found as needed through the built-in documentation search, third-party search engines, or LLMs.

Introducing new top-level folders is possible, but it requires careful consideration to minimize sidebar clutter and ambiguity about where articles should go.

General Rules

- YDB documentation is multilingual, and the file structure for each language must be consistent for the language switcher to function correctly. The file content should also be as close as possible between languages. The only exception is the Public materials folder, which intentionally contains different content for different languages. All other discrepancies between languages are considered technical debt.
- Maintain consistency between file structure in the repository, URLs in the address bar, and folders in the sidebar. Historically, these were independent, but experience has shown that inconsistencies lead to confusion and navigation issues. The documentation is gradually transitioning to a unified structure.
- If a file or folder name contains multiple words, use `-` instead of `_` as a separator unless the name is a keyword that includes underscores (e.g., configuration section names).
- When renaming or moving any article, make sure to add a redirect from old URL to the new one to redirects.yaml.

List of top-level folders

- **Quick start.** A single guide for beginners explaining how to set up a single-node YDB server and run initial queries.
- **Concepts.** A high-level theoretical overview of YDB as a technology, covering its features, terminology, and architecture. Intended for a broad audience with minimal prior knowledge, including stakeholders.
- **For DevOps.** A folder for DevOps engineers responsible for setting up and running YDB clusters. Most content consists of practical guides for specific cluster-related tasks. Since YDB supports multiple deployment options, guides that differ based on deployment method are placed in respective subfolders (Ansible, Kubernetes, or Manual), each following a consistent internal structure. Role-specific theoretical information is also included here.
- **For Application Developers.** A folder for application developers working with YDB. Primarily consists of practical guides and some theory.
- **For Security Engineers.** A folder for security engineers responsible for securing and auditing YDB clusters and applications that interact with them. Contains mostly practical guides and some role-specific theory.
- **For Contributors.** A folder for YDB core team members and external contributors. It explains various YDB development processes and provides deeper insights into how some components work. Mostly theory with some practical guides.
- **Reference.** A detailed reference section covering various aspects of YDB, designed to be found as needed or discovered via inbound links. The primary goal is completeness so that any topic can be located through exact keyword matches or descriptions. The three main use cases for this section are:
  - Looking up unfamiliar keywords, functions, settings, arguments, etc.
  - Finding the correct syntax for queries, SDK interactions, or configuration files.
  - Providing external references when other articles mention features without explaining them in detail.
- **Recipes.** Mini-guides explaining specific tasks with YDB, often with examples and code snippets. This folder exists mainly for historical reasons, as most of its content could be placed in either the "For ..." folders or "Questions and answers."
- **Troubleshooting.** A mix of theory on potential issues related to YDB and applications working with them, as well as practical guides for diagnosing and resolving them.
- **Questions and answers.** A StackOverflow-style section with frequently asked questions. Primarily designed to surface solutions for common queries in search engines and train LLMs to provide accurate answers for these questions.
- **Public materials.** A collection of links to videos and articles about YDB. Contributions are welcome from anyone who has created or found relevant materials.
- **Downloads.** A collection of links to download YDB binaries.
- **Changelog.** Release notes for each new version of the YDB server and other related binaries.

YDB documentation genres

This article complements YDB documentation style guide by describing the main genres used in YDB documentation. Understanding these genres helps contributors place new content in the appropriate section and maintain a consistent structure.

Theory

Primary goal for the reader: build a solid knowledge foundation by understanding the fundamental concepts, architecture, and principles behind YDB.

- Introduces key concepts and terminology
- Explains how things work both from the user's perspective and under the hood
- Provides high-level overviews of system components
- Helps users understand the "why" behind design decisions
- Can be targeted at either a broad audience with minimal prior knowledge or a specific role
- Can include diagrams and other visualizations to help convey information

Theory documentation is primarily found in the "Concepts" section but also appears in role-specific folders when the theoretical information is relevant only to a particular audience.

Guide

Primary goal for the reader: accomplish a specific practical task or implement a particular solution with YDB by following instructions.

Guides are practical, step-by-step instructions that help users accomplish a specific goal with YDB. Each article in this genre:

- Provides a clear goal and sequential instructions to achieve it
- Includes concrete examples and commands
- Focuses on practical implementation
- Addresses specific use cases or scenarios
- Can include screenshots to illustrate steps

Guides are primarily found in role-specific folders like "For DevOps", "For Application Developers", and "For Security Engineers", as well as in the "Troubleshooting" section.

Reference

Primary goal for the reader: find additional information about a specific niche topic related to YDB.

Reference documentation provides comprehensive, detailed information about YDB components, queries, APIs, configuration options, CLI commands, UI pages, and more. This genre:

- Aims for completeness and precision
- Serves as a lookup resource for specific details
- Documents all available options, parameters, and settings
- Is organized for quick information retrieval via a search engine or LLM
- Includes syntax, data types, parameters, return values, defaults, configuration, and examples

Reference documentation is designed to be found as needed and is the most detailed level of documentation. It's particularly useful when users need specific information about functions, settings, or keywords. This content is primarily found in the "Reference" section.

FAQ

Primary goal for the reader: quickly find answers to common questions encountered when working with YDB.

Frequently Asked Questions (FAQ) documentation answers common questions about YDB in a direct question-and-answer format. This genre:

- Addresses specific, commonly asked questions
- Provides concise, focused answers
- Is organized by topic or category
- Helps users quickly find solutions to common problems
- Is optimized for search engine or LLM discovery

FAQ content is primarily found in the "Questions and answers" section and is designed to help users who are searching for specific solutions to common situations.

Recipe

Primary goal for the reader: implement a specific, focused solution to a common issue or use case with YDB.

Recipes are short, focused mini-guides that demonstrate how to accomplish specific tasks with YDB. This genre:

- Provides concise solutions to specific problems
- Includes code snippets and examples
- Focuses on practical implementation
- Is more targeted and narrower in scope than full-fledged guides
- Often follows a problem-solution format

Recipes are primarily found in the "Recipes" section, though similar content may also appear in role-specific folders.

Release notes

Primary goal for the reader: stay informed about new features, improvements, bug fixes, and breaking changes in YDB releases.

Release notes document changes, improvements, and fixes in each new version of YDB. This genre:

- Lists new features and enhancements
- Documents bug fixes and resolved issues
- Highlights breaking changes and deprecations

- Provides upgrade instructions when necessary
- Is organized chronologically by version number

Release notes are found in the "Changelog" section and help users understand what has changed between versions and decide whether to upgrade.

Collection of links

Primary goal for the reader: discover additional resources, learning materials, and external content related to YDB.

Collections of links provide curated lists of resources related to YDB. This genre:

- Aggregates related external or internal resources
- Provides brief descriptions of each linked resource
- May be organized by topic, format, or relevance
- Helps users discover additional learning materials
- Can include videos, articles, downloads, and other content

Collections of links are primarily found in the "Public materials" and "Downloads" sections, serving as gateways to external resources about YDB.

Documenting features controlled by feature flags

Documenting experimental functionality controlled by feature flags requires a conditional warning on every page describing it. The warning explains the risks and remains visible while the relevant flag is disabled by default in the YDB version whose documentation is being built.

A disabled flag does not necessarily identify an experimental feature. If a flag controls a stable capability that only some users need, document it as an ordinary setting. Confirm the experimental status and the connection between the capability and its flag with the feature owner.

Add a warning

Place the warning at the beginning of the page or section describing the experimental feature. If the feature appears on several pages, add the warning to each one. Documentation changes for experimental functionality are incomplete without this warning.

For a flag in `NKikimrConfig.TFeatureFlags`, use this snippet:

```
{% if feature_flags.enable_xxx == false %}
{% note warning "Experimental feature" %}

This feature is under development and is disabled by default by the [`enable_xxx`](../../reference/configuration/feature_flags.md) flag. Its behavior may change without backward compatibility, and the feature may never become generally available. Enabling the flag may cause errors, cluster instability, or make it impossible to change the YDB version. Do not enable this flag in production clusters. [Learn more](../../reference/configuration/feature_flags.md#experimental).

{% endnote %}
{% endif %}
```

Replace `enable_xxx` with the actual flag's snake_case name in both the condition and the warning text. Adjust the relative links: the example paths are relative to this article. Use the same flag in the Russian page and the corresponding warning text:

```
{% if feature_flags.enable_xxx == false %}
{% note warning "Экспериментальная функциональность" %}

Функциональность находится в разработке и по умолчанию выключена флагом [`enable_xxx`](../../reference/configuration/feature_flags.md). Её поведение может измениться без сохранения обратной совместимости, а сама функциональность может так и не стать общедоступной. Включение флага может привести к ошибкам, нестабильной работе кластера или невозможности сменить версию YDB. Не включайте флаг в production-кластерах. [Подробнее](../../reference/configuration/feature_flags.md#experimental).

{% endnote %}
{% endif %}
```

If availability depends on several flags, make the condition match the implementation's guards. Do not choose a flag solely because its name resembles the feature name.

Choose the variable

Flags are defined in more than `ydb/core/protos/feature_flags.proto`. For other sources, the variable includes the type name so that identically named fields from different messages remain distinct.

Source	Example variable
`NKikimrConfig.TFeatureFlags`	`feature_flags.enable_xxx`
`NKikimrConfig.TTableServiceConfig`	`proto_flags.NKikimrConfig.TTableServiceConfig.enable_stream_write`
Nested protobuf messages	`proto_flags.<package>.<message>.<nested_message>.<snake_case_field>`
Registered C++ structs	`compile_time_flags.NActors.NFeatures.TCommonFeatureFlags.probe_spin_cycles`

Package and type names keep their original case; field names use snake_case. For example, `EnableStreamWrite` becomes `enable_stream_write`. C++ namespace components are separated by dots in documentation variables.

For a service-config flag, replace the snippet's condition with one using the appropriate protobuf type. For example:

```
{% if proto_flags.NKikimrConfig.TTableServiceConfig.enable_stream_write == false %}
<!-- Place the warning for the corresponding experimental feature here. -->
{% endif %}
```

The generator covers registered protobuf sources and their imports, including service configuration, PQ, Blob Storage, authentication, FQ, NBS, and other messages. The registry is `ydb/docs/tools/feature_flags/sources.json`. Register a source if it is neither listed nor included through imports. For a new C++ source, also check the GitHub workflow build-trigger filters.

A field in the generated inventory does not necessarily control an experimental cluster feature:

- `Ydb.FeatureFlag.Status` represents a public API parameter's state. `STATUS_UNSPECIFIED` is not equivalent to `false`.
- Viewer fields describe an API response, and physical-query fields describe query-plan data. Their protobuf defaults do not determine feature availability on a cluster.
- Only literal `constexpr bool` values are read for C++ flags. Computed expressions become `null`: the generator does not execute C++ or determine the configuration of a particular binary build.

For these sources, establish the value's meaning and its connection to the user-facing capability first. Do not apply the boolean condition automatically.

How builds work

Before Diplodoc runs, the generator reads source code from the same checkout as the documentation and adds defaults to the `default` preset in `ydb/docs/presets.yaml`. Consequently, `main` documentation uses values from `main`, while stable-version documentation uses the corresponding stable branch.

Variable value	Result of `== false`
`false`	The warning is visible.
`true`	The warning is hidden.
`null`, including a registered deleted flag	The warning is hidden.
Unknown flag or type name	Reference validation fails the build.

The absence of a warning does not itself prove that a feature is ready: `null` can also mean an unresolved value. Check the feature's implementation and documentation to establish its status.

The generator reads defaults from protobuf schemas and supported C++ literals. These values do not replace checking a running cluster's configuration and do not include defaults assigned separately by application code.

Do not edit or commit the generated block in `presets.yaml`. When backporting documentation, carry the snippet with the correct flag name; values are generated from the target branch's source code.

Validate the change

From the repository root, install the dependencies and run the generator:

```
python3 -m pip install -r ydb/docs/tools/feature_flags/requirements.txt
python3 ydb/docs/tools/feature_flags/generate.py --catalog feature-flag-defaults.json
```

The generator validates flag names in conditions and creates `feature-flag-defaults.json` with source paths, types, and values. CI exposes this inventory as the `feature-flag-defaults` artifact.

Check both PR previews. Confirm that the Russian and English pages use the same flag and condition, that the warning matches the experimental status, and that links point to the reference article and its `#experimental` section. For local builds, follow the instructions in `ydb/docs/README.md`.

When a flag is removed

When removing a protobuf field, reserve its original name with `reserved`. The generator assigns `null` to the corresponding variable, so a warning guarded by `== false` is no longer displayed.

If the name cannot be retained in protobuf, such as when an entire message or a C++ field is removed, add the reference to `retired_references` in `sources.json`. The entry identifies the variable namespace, original type, and snake_case field name. For example, for a removed service-config field:

```
{
  "namespace": "proto_flags",
  "message": "NKikimrConfig.TTableServiceConfig",
  "field": "enable_removed_example"
}
```

A `feature_flags` entry does not need a type name. For `compile_time_flags`, use the fully qualified C++ struct name with `::` separators. Active fields cannot be marked retired. Do not use the registry to bypass a spelling error: unknown references must be caught during the build.

After removing a flag, check that the feature description remains accurate. Remove obsolete snippets during the next page update. If the feature is still experimental, use its current flag in the condition or keep an unconditional warning.

Nodes

A single YDB installation consists of a *cluster* that is divided into *nodes*. A node is an individual process in the system, usually `ydbd`. Each node is part of the cluster and can exchange data with other nodes via *Interconnect*. Each node has its own ID, typically called `NodeId`. The `NodeId` is a 20-bit integer equal to or greater than 1. `NodeId` 0 is reserved for internal purposes and usually indicates the current node or no node at all.

A number of services run on each node and are implemented via *actors*.

Nodes can be either static or dynamic.

A static node configuration, which includes their complete list with the address for connecting via Interconnect, is stored in a configuration file and is read once when the process starts. The set of static nodes changes very rarely, typically during cluster expansion or when moving nodes from one physical machine to another. To change the set of static nodes, you must apply the updated configuration to **every** node and then perform a rolling restart of the entire cluster.

Dynamic nodes are not known in advance and are added to the system as new processes are started. This may occur, for example, when new tenants are created in YDB installations as a database. When a dynamic node is registered, its process first connects to one of the static nodes via gRPC, transmits information about itself through a special service called *Node Broker*, and receives a `NodeId` to use when logging into the system. The mechanism for assigning nodes is somewhat similar to DHCP in the context of distributing IP addresses.

Tablets

Special microservices called tablets run on each node. Each tablet is a singleton that has a specific type and ID. It means that only one tablet with a specific ID can run in the cluster at any given time. A tablet can launch on any suitable node. A generation is an important property of a tablet that increases with each subsequent launch.

> **Note**
>
> The distributed nature of the system and various issues, such as network partitioning problems, may result in a situation when the same tablet is actually running on two different nodes simultaneously. However, the distributed storage guarantees that only one of the duplicate tablets will successfully complete operations that change its state, and that the generation in which each successful operation runs will not decrease over time.

For cluster-level system tablets, the node on which the tablet runs is chosen by a Bootstrapper, which implements distributed consensus. User tablets are managed by a special tablet called Hive. Hive ensures that all tablets are running, distributes tablets across nodes, and manages tablet channels between storage groups.

You can find out on which node the tablet in the current generation is running through the *StateStorage* service. To send messages to tablets, use a special set of libraries named *tablet pipe*. With this, knowing the ID of the target tablet, you can easily send the desired message to it.

A tablet can be divided into two parts: the basic tablet and the user logic.

The basic tablet is a set of tables, each of which may consist of one or more key columns of an arbitrary type and a set of data columns. Each table may have its own schema. Additionally, tables can be created and deleted while the tablet is running. The basic tablet interface allows you to perform read and update operations on these tables.

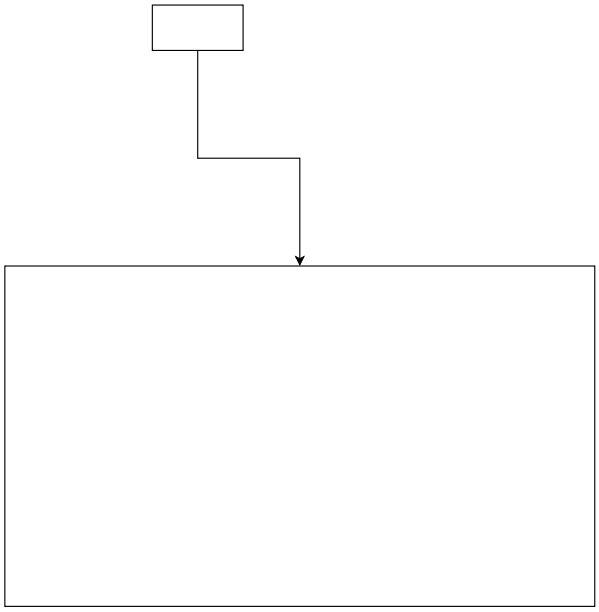
User logic is located between the basic tablet and the user, allowing you to process specific requests for this type of tablet, reliably saving changes to distributed storage. A running tablet typically uses a template that stores all data in memory, reads it only at the start, and synchronously changes the data in memory and in storage after a successful commit.

How does a tablet store data, and what are they like?

A basic tablet is an LSM tree that holds all of its table data. One level below the basic tablet is distributed storage, which, roughly speaking, is a KeyValue storage that stores binary large objects (blobs). A *BLOB* is a binary fragment from 1 byte to 10 MB in size, which has a fixed ID (usually called *BlobId* and of the `TLogoBlobID` type) and contains related data. The storage is immutable, meaning that only one value corresponds to each ID, and it cannot change over time. You can write and read a blob and then delete it when it is no longer needed.

To learn more about blobs and distributed storage, see YDB distributed storage.

For distributed storage, blobs are an opaque entity. A tablet can store several types of blobs. The most frequently written blob is a (recovery) log blob. A tablet's log is arranged as a list of blobs, each containing information about changes made to the tables. When run, the tablet finds the last blob in the log and then recursively reads all related blobs following the links. The log may also contain links to snapshot blobs, which contain data from multiple log blobs after a merge (the merge operation in the LSM tree).



The tablet writes blobs of different types to different *channels*. A channel specifies the branch of storage in which to store blobs and performs various functions, such as:

1. Selecting a storage type (different channels may be linked to different types of storage devices: SSD, HDD, or NVMe).
2. Load balancing, as each channel has a limit on IOPS, available space, and bandwidth.
3. Specifying the data type. When restoring the log, only the blobs from the null channel are read, allowing you to distinguish them from other blobs.

Tablet channel history

As mentioned previously, each group has a constant amount of data that fits into it and shares the bandwidth's throughput and the number of operations per second among all consumers. The load on tablets may vary. As a result, a group may become overloaded and it will be necessary to switch writes to another group. To address this, the concept of history is introduced, which allows you to determine the group that a blob is written to based on its channel and generation.

This mechanism works as follows:

TabletId

TabletId

125≤gen

Tablet

TabletViewer does not support full SVG 1.1

For each channel, the `TTabletStorageInfo` structure contains the `TTabletChannelInfo` substructure with generation ranges and the group number corresponding to each range. The ranges are strictly adjacent to each other, with the last range being open. Group numbers may overlap in different ranges and even across different channels, which is legal and quite common.

When writing a blob, a tablet selects the most recent range for the corresponding channel, as a write is always performed on behalf of a tablet's current generation. When reading a blob, the group number is fetched based on the `BlobId.Generation` of the blob being read.

YDB distributed storage

YDB distributed storage is a subsystem of YDB that ensures reliable data storage.

It allows you to store *blobs* (binary fragments ranging from 1 byte to 10 megabytes in size) with a unique identifier.

Description of the distributed storage Interface

Blob ID Format

Each blob has a 192-bit ID consisting of the following fields (in the order used for sorting):

1. **TabletId (64 bits):** ID of the blob owner tablet.
2. **Channel (8 bits):** Channel sequence number.
3. **Generation (32 bits):** Generation in which the tablet that captured this blob was run.
4. **Step (32 bits):** Blob group internal ID within the Generation.
5. **Cookie (24 bits):** ID used if the Step is insufficient.
6. **CrcMode (2 bits):** Selects a mode for redundant blob integrity verification at the distributed storage level.
7. **BlobSize (26 bits):** Blob data size.
8. **PartId (4 bits):** Fragment number when using blob erasure coding. At the "distributed storage <-> tablet" communication level, this parameter is always 0, referring to the entire blob.

Two blobs are considered different if at least one of the first five parameters (TabletId, Channel, Generation, Step, or Cookie) differs in their IDs. Therefore, it is impossible to write two blobs that differ only in BlobSize and/or CrcMode.

For debugging purposes, there is a string representation of the blob ID in the format `[TabletId:Generation:Step:Channel:Cookie:BlobSize:PartId]`, for example, `[12345:1:1:0:0:1000:0]`.

When writing a blob, the tablet selects the Channel, Step, and Cookie parameters. TabletId is fixed and must point to the tablet performing the write operation, while Generation must indicate the generation in which the tablet performing the operation is running.

When performing reads, the blob ID is specified, which can be arbitrary but is preferably preset.

Groups

Blobs are written to a logical entity called a *group*. A special actor called *DS proxy* is created on every node for each group that is written to. This actor is responsible for performing all operations related to the group. The actor is created automatically by the NodeWarden service, which will be described below.

Physically, a group is a set of multiple physical devices (OS block devices) located on different nodes, so that the failure of one device correlates as little as possible with the failure of another device. These devices are usually located in different racks or datacenters. On each of these devices, some space is allocated for the group, which is managed by a special service called *VDisk*. Each VDisk runs on top of a block storage device, from which it is separated by another service called *PDisk*. Blobs are broken into fragments based on erasure coding, with these fragments written to VDisks. Before splitting into fragments, optional encryption of the data in the group can be performed.

This scheme is shown in the figure below.

PDisk 1:1000

VDISK[GroupId:Generation:1...Viewer does not support full `VDISK[GroupId:Generation:1:2:0]` syntax

Each VDisk within a group has a sequence number, and disks are numbered 0 to N-1, where N is the number of disks in the group.

In addition, the group disks are grouped into fail domains, and fail domains are grouped into fail realms. Each fail domain usually has exactly one disk inside (although, in theory, it may have more, but this is not used in practice), while multiple fail realms are only used for groups whose data is stored in all three datacenters. Thus, in addition to a group sequence number, each VDisk is assigned an ID that consists of a fail realm index, the index that a fail domain has in a fail realm, and the index that a VDisk has in the fail domain. In string form, this ID is written as `VDISK[GroupId:GroupGeneration:FailRealm:FailDomain:VDisk]`.

All fail realms have the same number of fail domains, and all fail domains include the same number of disks. The number of fail realms, the number of fail domains inside each fail realm, and the number of disks inside each fail domain make up the geometry of the group. The geometry depends on the way the data is encoded in the group. For example, for block-4-2: `numFailRealms = 1`, `numFailDomainsInFailRealm >= 8` (only 8 fail domains are used in practice), `numVDisksInFailDomain >= 1` (strictly 1 fail domain is used in practice). For mirror-3-dc: `numFailRealms >= 3`, `numFailDomainsInFailRealm >= 3`, and `numVDisksInFailDomain >= 1` (3x3x1 are used).

Each PDisk has an ID that consists of the number of the node it is running on and the internal number of the PDisk inside this node. This ID is usually written as `NodeId:PDiskId`. For example, `1:1000`. If you know the PDisk ID, you can calculate the service ActorId of this disk and send it a message.

Each VDisk runs on top of a specific PDisk and has a *slot ID* comprising three fields (NodeID:PDiskId:VSlotId), as well as the above-mentioned VDisk ID. Strictly speaking, there are different concepts: a slot is a reserved location on a PDisk occupied by a VDisk, while a VDisk is an element of a group that occupies a certain slot and performs operations with the slot. Similar to PDisks, if you know the slot ID, you can calculate the service ActorId of the running VDisk and send it a message. To send messages from the DS proxy to the VDisk, an intermediate actor called *BS_QUEUE* is used.

The composition of each group is not constant and may change while the system is running. Hence the concept of group generation. Each "GroupId:GroupGeneration" pair corresponds to a fixed set of slots (a vector consisting of N slot IDs, where N is equal to group size) that stores the data of an entire group. *Group generation is not to be confused with tablet generation, as they are not related in any way*.

As a rule, groups of two adjacent generations differ by no more than one slot.

Subgroups

A special concept of a *subgroup* is introduced for each blob. It is an ordered subset of group disks with a strictly constant number of elements that will store the blob's data, depending on the encoding type (the number of elements in a group must be the same or greater). For single-datacenter groups with conventional encoding, this subset is selected as the first N elements of a cyclic disk permutation in the group, where the permutation depends on the BlobId hash.

Each disk in the subgroup corresponds to a disk in the group but is limited by the allowed number of stored blobs. For example, for block-4-2 encoding with four data parts and two parity parts, the functional purpose of the disks in a subgroup is as follows:

Number in the Subgroup	Possible PartIds
0	1
1	2
2	3
3	4
4	5
5	6
6	1,2,3,4,5,6
7	1,2,3,4,5,6

In this case, PartId=1..4 corresponds to data fragments (resulting from dividing the original blob into 4 equal parts), while PartId=5..6 represents parity fragments. Disks numbered 6 and 7 in the subgroup are called *handoff disks*. Any part, either one or more, can be written to them. The respective blob parts can only be written to disks 0..5.

In practice, when performing writes, the system tries to write 6 parts to the first 6 disks of the subgroup, and in the vast majority of cases, these attempts are successful. However, if any of the disks are unavailable, a write operation cannot succeed, which is when handoff disks come into play, receiving the parts belonging to the disks that did not respond in time. It may happen that several fragments of the same blob are sent to the same handoff disk as a result of complex failures and races. This is acceptable, although it makes no sense in terms of storage: each fragment should ideally be stored on a unique disk.

Redundancy recovery

If a disk fails, YDB can automatically reconfigure a storage group. Whether the disk failure is caused by the whole server failure or not is irrelevant in this context. Auto reconfiguration of storage groups reduces the risk of data loss in the event of a sequence of failures, provided these failures occur with sufficient time intervals to recover redundancy. By default, reconfiguration begins one hour after

YDB detects a failure.

Disk group reconfiguration replaces the VDisk located on the failed hardware with a new VDisk, and the system tries to place it on operational hardware. The same rules apply as when creating a storage group:

- The new VDisk is created in a fail domain that is different from any other VDisks in the group.
- In the `mirror-3-dc` mode, it is created within the same fail realm as the failed VDisk.

To ensure reconfiguration is possible, a cluster should have free slots available for creating VDisks in different fail domains. When determining the number of slots to keep free, consider the risk of hardware failure, the time required to replicate data, and the time needed to replace the failed hardware.

The disk group reconfiguration process increases the load on other VDisks in the group as well as on the network. The total data replication speed is limited on both the source and target VDisks to minimize the impact of redundancy recovery on system performance.

The time required to restore redundancy depends on the amount of data and hardware performance. For example, replication on fast NVMe SSDs may take an hour, while it could take more than 24 hours on large HDDs.

Disk group reconfiguration is limited or totally impossible when a cluster's hardware is distributed across the minimum required number of fail domains:

- If an entire fail domain is down, reconfiguration becomes impractical, as a new VDisk can only be placed in the fail domain that is down.
- Reconfiguration only happens when part of a fail domain is down. However, the load previously handled by the failed hardware will be redistributed across the surviving hardware, remaining in the same fail domain.

The load can be redistributed across all the hardware that is still running if the number of fail domains in a cluster exceeds the minimum amount required for creating storage groups by at least one. This means having 9 fail domains for `block-4-2` and 4 fail domains in each fail realm for `mirror-3-dc`, which is recommended.

Metadata distribution subsystems: StateStorage, Board, SchemeBoard

In a YDB cluster, three interconnected subsystems ensure metadata distribution between nodes: **StateStorage**, **Board**, and **SchemeBoard**. Each solves its own task, but all three are built on the same architectural principle — a distributed quorum service with deterministic replica addressing.

This article explains why these subsystems are needed, how they are structured, and how they work. An overview without core details for documentation users is in the Metadata distribution services section. Instructions for configuring and changing the configuration are described in the Configuring metadata distribution subsystems section.

Why metadata distribution subsystems are needed

A YDB cluster is a distributed system where millions of tablets can run simultaneously on thousands of nodes. For cluster components to interact with each other, they need to know:

- Where the leader of a specific tablet currently runs and how to reach it (**StateStorage**).
- Which nodes provide certain services, for example, connection points for clients (**Board**).
- what the current database schema is (**SchemeBoard**).

Distributing this data from a single cluster node is bad — it creates high load and problems when that node fails. Therefore, metadata is distributed across many cluster nodes using three specialized subsystems.

Subsystems

StateStorage — tablet state storage

StateStorage is a distributed service that stores the current state of tablets: where the leader runs, what its actor identifier, generation, and step are.

What StateStorage stores

For each tablet, StateStorage stores:

- **Current leader** — the actor identifier (ActorId) of the tablet leader.
- **Generation and step** (`generation:step`) — monotonically increasing counters used to resolve conflicts during leader election.
- **Follower list** — actor identifiers of the tablet replicas (if any).
- **Lock** — a flag indicating that the tablet is locked during the election of a new leader.

How StateStorage is used

StateStorage acts as a **tablet name resolution service**: any cluster node can use `TabletId` to find out `ActorId` of the current leader and directly contact it.

StateStorage also participates in the **tablet leader election process**. When a tablet starts or restarts, it registers itself in StateStorage and receives confirmation from the quorum of replicas.

> **Note**
>
> Data in StateStorage is **volatile**: it is stored only in the memory of replicas and is lost when processes restart. StateStorage is not a persistent store — it contains only information that can be easily restored both when tablets start and when the replicas themselves start.

Addressing in StateStorage

The set of replicas for a specific tablet is computed based on its `TabletId`. This means that replicas of different tablets can reside on different nodes, ensuring even load distribution.

Board — a service bulletin board

Board is a distributed service for publishing and searching metadata in the format “path → set of records”. It works on the publish-subscribe model: one or more actors publish information under a path, and other actors subscribe to that path and receive the current list of publications.

What Board stores

Board stores “path → payload” pairs. Multiple actors can publish data under the same path simultaneously — Board stores all publications and provides them to subscribers as a list.

How Board is used

The main use of Board is **storing information about endpoints** (connection points) of databases. When a database node starts, it publishes its address in Board under a path corresponding to the database name. Clients and other cluster components subscribe to that path and receive the current list of available endpoints.

How it works:

1. A publisher actor registers a record in Board under a given path.
2. A subscriber actor requests the list of records for a path and receives notifications about changes.

Unlike StateStorage, Board is not tied to specific tablets — it is intended for arbitrary services that need to make some data easily accessible in the cluster.

Addressing in Board

The selection of replicas for a specific path is computed from the hash of that path. This ensures deterministic routing: all publications and subscriptions for the same path land on the same replicas.

SchemeBoard — distribution of schema metadata

SchemeBoard is a distributed service for storing and distributing database schema metadata: tables, indexes, access rights, and other schema objects.

What SchemeBoard stores

SchemeBoard stores descriptions of schema objects: tables, directories, indexes, topics, and other schema objects. For each object, its full description is stored, including structure, settings, and access rights.

How SchemeBoard is used

SchemeBoard is a **cache of schema metadata** for all cluster components. When a database node receives a query, it needs to know the structure of the tables the query works with. Instead of accessing SchemeShard (a tablet that is the source of truth for the schema) every time, the node reads the schema from a local cache that is synchronized through SchemeBoard.

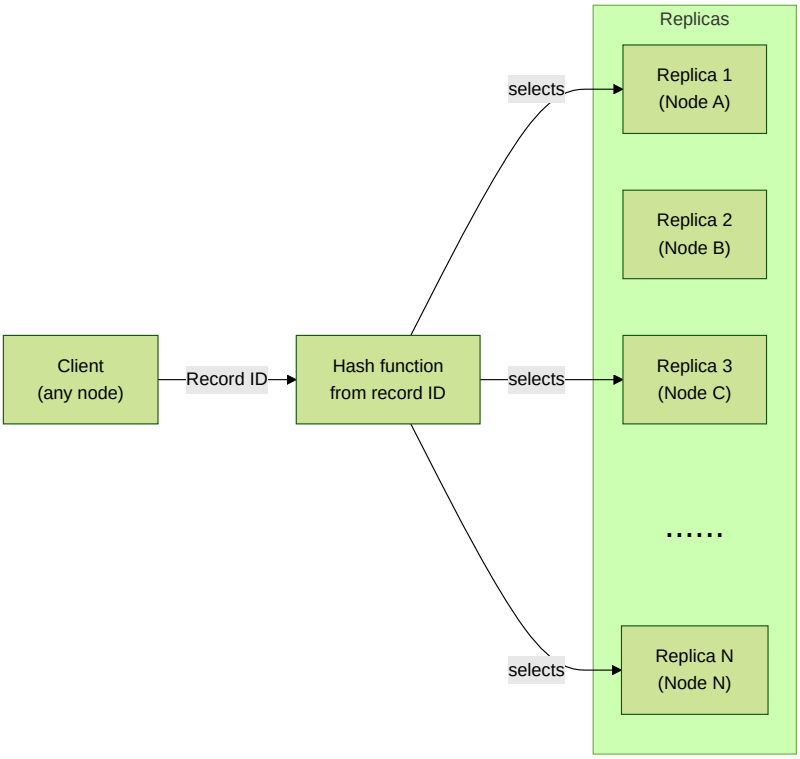
How it works:

1. When the schema changes, SchemeShard publishes an update to SchemeBoard.
2. Database nodes subscribe to changes in the schema objects they need and receive notifications about updates.

This allows database nodes to work with the current schema without constantly accessing SchemeShard, which significantly reduces its load and decreases query execution latency.

Addressing in SchemeBoard

The selection of replicas for a specific schema object is computed from the hash of the path to that object. This ensures deterministic routing of queries to schema metadata.



Comparison of subsystems

Characteristic	StateStorage	Board	SchemeBoard
Purpose	Storing tablet state	Publishing service metadata	Distributing schema metadata
Data type	Tablet leader state (ActorId, generation:step)	Arbitrary path → payload pairs	Schema object descriptions
Addressing key	TabletId	Path (string)	Path to the schema object
Main consumers	Tablet Pipe	gRPC proxy, clients (endpoint discovery)	Database nodes (schema cache)
Data source	The tablets themselves (on startup or leader election)	Publisher actors	SchemeShard

Deterministic replica selection

Each record in the subsystem is addressed by an identifier — for example, `TabletId` for StateStorage or a path to a schema object for SchemeBoard. Using this identifier, a hash function computes a fixed set of replicas on which the record is stored.

This is a key property: **any cluster node can independently compute on which replicas the record it needs is stored**. This makes the subsystems scalable and fault-tolerant.

Quorum

For each record, a certain number of replicas `nto_select` is selected. The system attempts to perform write operations with all `nto_select` replicas, but a failure of a minority of replicas is tolerated, and such a failure does not lead to temporary unavailability or suspension of work.
For a successful write operation, it is sufficient to get a response from the **majority** of the selected replicas — that is, from `nto_select / 2 + 1` replicas, where `nto_select` is the total number of replicas in the selection. This means that some replicas may be unavailable, and the subsystem will continue to work.

It is the quorum principle that allows safely taking nodes out for maintenance and performing rolling restarts of the cluster without losing availability.

Key concepts

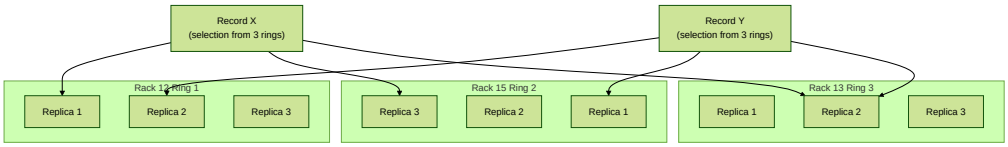
Replica

Replica is an actor running on a cluster node and storing a part of the subsystem's metadata. A replica accepts read and write requests and participates in forming a quorum.

Each replica is independent: it continues to serve requests even if other replicas are temporarily unavailable. Data that could not be written to an unavailable replica will be delivered to it later when it recovers — either explicitly through a retry or automatically through a state synchronization mechanism.

Ring

Motivation



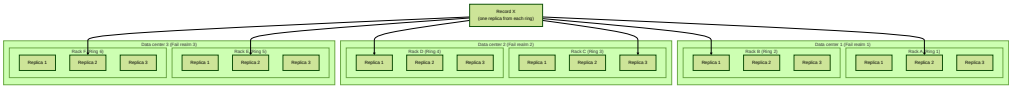
To distribute load evenly across cluster nodes, subsystems may need a large number of replicas: the more replicas there are, the fewer requests each replica handles. However, as the number of replicas grows, fault tolerance becomes a concern: if a failure domain (server rack) fails, several replicas may go down at once, affecting the quorum.

Definition and operating principle

A **ring** is a group of replicas from which **no more than one** replica is selected for each specific record. The replica selection within a ring is deterministic and based on a hash function of the record identifier. Thus, different records are served by different replicas within the same ring, ensuring even request distribution.

Rings and failure domains

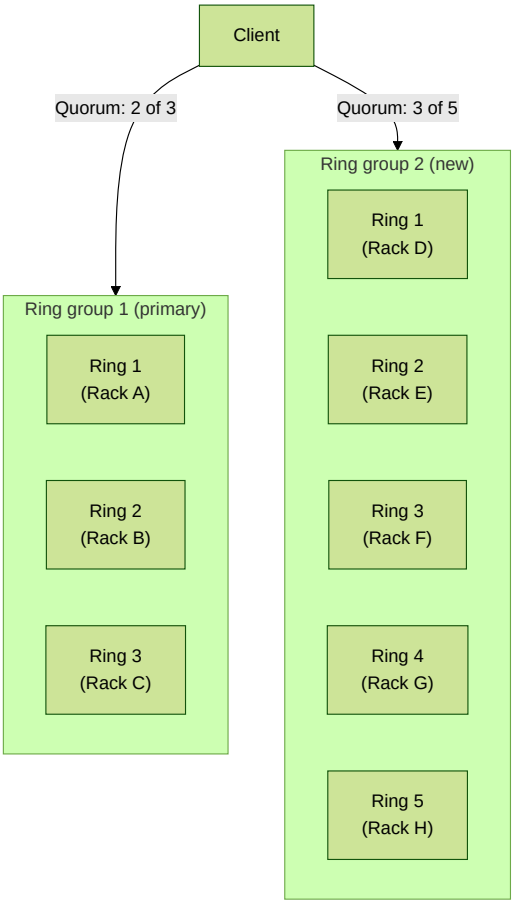
Replicas of each ring are placed within a single **failure domain** (fail domain) — one or several server racks. Replicas from different rings are placed in different racks. Replicas from different rings must not be placed in the same rack. This guarantees that if any rack fails, **no more than one replica** is lost from each selection — the one belonging to the ring whose replicas were in that rack.



Rings and failure realms

In clusters with multiple **failure realms** (fail realm) — for example, data centers — additional restrictions apply to the placement of replicas across rings:

- Replicas from different failure realms are not included in the same ring.
- The number of rings in each failure realm is limited.



These restrictions make it possible to control how many rings a failure of an entire data center will affect: if each failure realm contains no more than `k` rings, then when it fails, no more than `k` replicas from each selection will go down.

Ring group

A **ring group** is a set of rings for which a **separate quorum** is assembled. A subsystem can work with several ring groups simultaneously, assembling a quorum in each of them independently.

Ring groups are a mechanism for **seamless configuration changes**. They allow introducing new replica sets and retiring old ones without stopping the cluster. For more details, see the section Ring groups and configuration changes.

Ring groups and configuration changes

Seamless configuration changes

Changing subsystem configuration — for example, moving replicas to other nodes or changing the number of replicas — is done by adding and removing ring groups. This allows changing the configuration without stopping the cluster or losing availability.

The configuration change process consists of several steps:

1. A new ring group with the required configuration is added. At this stage, it is marked with the `write_only` flag — this means that the new group receives all records (synchronizes with the data) but **does not participate in the read quorum**. Read requests are still served by the old group.
2. After the new group has synchronized and become fully functional, the `write_only` flag is removed. Now both groups participate in the quorum.
3. The old group is marked with the `write_only` flag, and the new one becomes primary.
4. The old group is removed.

A pause (at least one minute) must be maintained between steps so that the configuration has time to propagate to all cluster nodes.

Detailed instructions for manual configuration changes are provided in the section Configuring metadata distribution subsystems.

Automatic reconfiguration (SelfHeal)

In clusters with V2 configuration, **Metadata Distribution SelfHeal** automatically manages the State Storage, Board, and SchemeBoard configurations. It monitors the state of cluster nodes and, when necessary:

- Moves replicas from failed nodes to healthy ones.
- Can add new replicas as the cluster expands, subject to the settings and available nodes.

SelfHeal works through the same ring group mechanism as manual reconfiguration, but performs all steps automatically. For more details, see Metadata Distribution SelfHeal.

Ring groups in a two-data-center configuration

In a configuration with two data centers (the bridge mode), each data center (pile) has its **own ring group**. This allows:

- Each data center operates autonomously, gathering a quorum within its own group.
- Quickly and seamlessly switch which data center is primary, without changing the replica configuration.

For more details about bridge mode, see the Bridge mode section.

Fault tolerance and failure model

Metadata distribution subsystems are designed with the YDB failure model in mind, based on the concepts of failure domains (usually server racks) and failure regions (usually data centers).

The replica placement rule (different rings in different racks; replicas of the same ring may be in one or several racks) provides the following guarantees:

- **Single node failure**: no more than one replica is lost from each sample. The quorum is preserved.
- **Failure of an entire rack**: since all replicas of one ring are in the same rack, exactly one replica is lost from each sample. With `nto_select = 5`, the quorum (3 of 5) is preserved even when an entire rack is lost.

- **Rolling restart**: sequential restart of nodes does not break the quorum, since only part of the replicas is unavailable at any given moment.

LocalDB: persistent uncommitted changes

Tablets may need to save a large number of changes over a long period and then commit or abort them entirely. To support this scenario, LocalDB allows marking uncommitted changes in tables with a unique 64-bit transaction identifier (`TxId`). This data is stored in the table alongside committed data but is not visible to other queries until commit. Committing or aborting a transaction is atomic and cheap, and over time this data is integrated into the table in the normal committed form. Thus, uncommitted data is not stored in memory for a long time and is not limited by its capacity.

This mechanism is used as the basis for the following functionality:

- Saving uncommitted changes in long YQL transactions and the ability to see these changes in the same transaction before they are committed.
- Saving effects in volatile distributed transactions with the ability to roll back.
- Cross-cluster consistent replication, where changes are streamed in small batches and periodically committed, making the next consistent snapshot of the source database visible.

Limitations

This mechanism has the following limitations:

1. For a single key, changes can be made in parallel within different `TxId`, but these transactions must be committed in the same order in which the changes were written. For example, if there is a change for key K from transaction tx1 and then from transaction tx2, you can commit transaction tx1 and then tx2, and both changes will be visible. However, if you commit tx2 first, then tx1 must be aborted.
2. The number of uncommitted transactions and the amount of data in them for a specific key must be limited by higher-level layers.
3. `TxId` must be globally unique and must not be reused after a transaction commit or abort, including across different shards.

Writing uncommitted changes

In the recovery log (see flat_redo_writer.h), there are the following events:

- EvUpdateTx saves changes to the table with the specified uncommitted `TxId`. This event is created by the TDatabase::UpdateTx method of the local database (LocalDB).
- EvRemoveTx is used to remove the specified `TxId` when a transaction is aborted. This event is created by the TDatabase::RemoveTx method of the local database.
- EvCommitTx is used to commit the specified `TxId` with the specified MVCC commit version. This event is created by the TDatabase::CommitTx method of the local database.

Storing uncommitted changes in MemTable

MemTable in LocalDB is a small key-sorted tree of recently made changes that is stored in memory. The key in this tree is the table key, and the value is a pointer to a chain of changes for the corresponding key. For each change, the MVCC version of that change is specified (a pair `Step` / `TxId` with the global commit time). The rows in the change chain are merged within a single MemTable. For example, suppose we had the following operations for key K:

Version	Operation
`v1000/10`	`UPDATE ... SET A = 1`
`v2000/11`	`UPDATE ... SET B = 2`
`v3000/12`	`UPDATE ... SET C = 3`

Then the chain of rows with changes for this key in a single MemTable would look as follows:

Version	Row
`v3000/12`	`SET A = 1, B = 2, C = 3`
`v2000/11`	`SET A = 1, B = 2`
`v1000/10`	`SET A = 1`

In some cases, a MemTable may split between operations, which happens, for example, at the start of compaction. Then the MemTable from the example above would look like this:

MemTable	Version	Row
Epoch 2	`v3000/12`	`SET B = 2, C = 3`
Epoch 2	`v2000/11`	`SET B = 2`
Epoch 1	`v1000/10`	`SET A = 1`

New changes are applied to the current MemTable, even if they have not yet been committed. When writing, uncommitted changes are marked with a special version, specifying the maximum value for `Step` (as if implying a distant future) and the `TxId` of the transaction as `TxId`. Merging of lower-level changes is not performed. For example, suppose we then performed the following uncommitted operations for key K:

TxId	Operation
15	`UPDATE ... SET C = 10`
13	`UPDATE ... SET B = 20`

The chain of changes in the MemTable will now look like this:

Version	Row

`v{max}/13`	`SET B = 20`
`v{max}/15`	`SET C = 10`
`v3000/12`	`SET A = 1, B = 2, C = 3`
`v2000/11`	`SET A = 1, B = 2`
`v1000/10`	`SET A = 1`

During reading, for changes with version `Step == max`, the iterator checks their `TxId` against the transaction table. For committed transactions, the MVCC commit version is indicated there. Then it applies all committed changes until it finds and applies the first merged record with version `Step != max`.

Suppose we committed a transaction with `TxId = 13` at point `v4000/20`. At that moment, a record `[13] => v4000/20` appears in the transaction table, and this transaction becomes committed. All subsequent reads will see changes with `TxId = 13`, skipping the transaction with `TxId = 15` because it was not committed before `TxId = 13`. The chain of changes for key K does not change.

Now suppose we performed `SET A = 30` in version `v5000/21`. The resulting chain of changes will look as follows:

Version	Row
`v5000/21`	`SET A = 30, B = 20, C = 3`
`v{max}/13`	`SET B = 20`
`v{max}/15`	`SET C = 10`
`v3000/12`	`SET A = 1, B = 2, C = 3`
`v2000/11`	`SET A = 1, B = 2`
`v1000/10`	`SET A = 1`

A new row was added in the merged state, including changes for `TxId = 13`. Since transaction `TxId = 15` is not committed, its changes were skipped, which is reflected in the merged state for `v5000/21`. It is important that the upstream code does not commit `TxId = 15` after this, because such a commit would lead to an anomaly: some versions during reading will see the transaction as committed, and some will not.

Compaction of uncommitted changes

Compaction takes a part of the table data, merges them in sorted order, and writes them as a new SST that replaces the compacted data. If a MemTable participates in compaction, this also implies compaction of a part of the change log. In the compacted log, there may be `EvRemoveTx` / `EvCommitTx` messages that modify the committed transaction table — they must also end up in persistent storage. This is implemented by writing `TxStatus` blobs (see flat_page_txstatus.h), which LocalDB saves along with writing the SST with data. These blobs store the current list of committed and deleted transactions, which replaces the entire previously written log in terms of `EvRemoveTx` / `EvCommitTx` events. The compaction receives a reference to the entire current table, but during writing, the table is filtered, preserving only those transactions that were mentioned in the compacting MemTable or previous `TxStatus` pages.

At the level of data pages (see flat_page_data.h), uncommitted changes from MemTable (or other SSTs) are aggregated by `TxId` while preserving their relative order and are added before the main record as uncommitted delta records. A record has MVCC flags (`HasHistory`, `IsVersioned`, `IsErased`) that indicate the presence of MVCC history for the key and the presence of fields with the MVCC version of the row. For delta records, a special IsDelta flag is used, which is a `HasHistory` flag without specifying other MVCC flags. For rows with the delta flag, after the fixed part, the TDelta structure is stored in the extension fields, which specifies the `TxId` of the transaction that was uncommitted at the time of compaction.

There can be multiple delta records for a single key, and optionally the most recent committed record. Since only one record per key can exist on a data page, the offset table points to the first delta record, and the remaining records are accessible through the alternative offsets table for that record:

Offset	Description
-X*8	Main offset
...	...
-16	Delta 2 offset
-8	Delta 1 offset
0	Delta 0 header
...	...
Delta 1 offset	Delta 1 header
...	...
Main offset	Main header

Having a pointer to the Delta 0 record, the remaining records for the key can be obtained via the `GetAltRecord(size_t index)` method, where `index` is the record number in the chain (1 for Delta 1). The chain ends either with a pointer to the main record (without the delta flag) or 0 if the main record is absent.

Continuing the example started above, suppose that after writing the transaction with `TxId = 13`, the current MemTable was fully compacted. The record for the 32-bit key K may look as follows (offsets are relative to the pointer in the record list on the page):

Offset	Value	Description
-16	58	Main offset

-8	29	Delta 1 offset
0	0x21	Delta 0: IsDelta + ERowOp::Upsert
1	0x00	.. key column non-NULL
2	K	.. key column (32-bit)
6	0x00	.. column A empty
7	0	.. column A (32-bit)
11	0x01	.. column B = ECellOp::Set
12	20	.. column B (32-bit)
16	0x00	.. column C empty
17	0	.. column C (32-bit)
21	13	.. TDelta::TxId
29	0x21	Delta 1: IsDelta + ERowOp::Upsert
30	0x00	.. key column non-NULL
31	K	.. key column (32-bit)
35	0x00	.. column A empty
36	0	.. column A (32-bit)
40	0x00	.. column B empty
41	0	.. column B (32-bit)
45	0x01	.. column C = ECellOp::Set
46	10	.. column C (32-bit)
50	15	.. TDelta::TxId
58	0x61	Main: HasHistory + IsVersioned + ERowOp::Upsert
59	0x00	.. key column non-NULL
60	K	.. key column (32-bit)
64	0x01	.. column A = ECellOp::Set
65	1	.. column A (32-bit)
69	0x01	.. column B = ECellOp::Set
70	2	.. column B (32-bit)
74	0x01	.. column C = ECellOp::Set
75	3	.. column C (32-bit)
79	3000	.. RowVersion.Step
87	12	.. RowVersion.TxId
95	-	End of record

The remaining two records will be in the historical data at keys `(RowId, 2000, 11)` and `(RowId, 1000, 10)`, respectively. Their presence is indicated by the `HasHistory` flag in the main record.

During compaction, the iterator operates in a special mode, iterating over all deltas and all versions for each key. The compaction scan implementation (see flat_ops_compact.h) first aggregates the deltas that were uncommitted at the start of compaction by `TxId`, preserving their relative order. If changes from different `TxId` overlap, their order may change arbitrarily. Such reordering is valid because such transactions overlap in write order and the upper level is not allowed to commit them simultaneously. Once all uncommitted deltas are aggregated, they are written in the correct order to the resulting SST (see flat_part_writer.h and flat_page_writer.h). After that, iteration over row versions for the key begins, which are written to the SST in decreasing version order.

When the iterator encounters the first committed delta, the commit version of that delta is taken as the row version. All committed deltas below, including the first committed row version from each LSM level participating in the compaction, are merged into the row state. To move to the next version, the iterator skips committed deltas with a version greater than or equal to the last version, and the process repeats.

If a large number of deltas are written and compacted for a single key, and then quickly committed with different versions, the formation of all row versions will grow quadratically with the number of deltas. This is one reason why upper levels must control the number of deltas per key and prevent their uncontrolled growth. Another current limitation is that all uncommitted deltas must be kept in memory, because they can be committed at any moment and we must check this during search. Additionally, all deltas for a key must reside on the same page.

Statistics on uncommitted transactions

Optimistically, most write transactions eventually commit successfully, but sometimes transactions have to be aborted, even after compaction. Since after their abort a large amount of data may actually be deleted, for garbage collection purposes an `TxIdStats` page is saved in SST (see flat_page_txidstat.h) with statistics on the number of rows and bytes occupied by each `TxId`. As

transactions are aborted, the compaction strategy aggregates the amount of freed bytes and may decide to run additional compactions for garbage collection.

`TxIdStats` pages are also used to gradually reduce the commit table. After a transaction is committed, a record of it is stored in an in-memory hash table as long as there is at least one reference to the corresponding `TxId`. As SST is compacted, uncommitted deltas are overwritten as committed records and references on `TxIdStats` pages disappear. If the corresponding `TxId` was committed or aborted, and there are no references to it in either MemTable or SST, then this record is removed from the commit table and frees memory.

The size of the in-memory commit table is limited at the datashard level by the number of open transactions at any given time. Open transactions are those that have not yet been committed or aborted. During compaction, only deltas for transactions that were open at the start of compaction can be written to SST, because committed deltas are rewritten as regular committed rows, and aborted transactions leave no traces. Accordingly, the size of the commit table is limited by the number of open transactions multiplied by the number of SSTs.

Borrowing SSTs with uncommitted changes

When copying tables, as well as during DataShard splits and merges, the mechanism of "borrowing" SSTs in LocalDB is used. In this case, SSTs from the source shard are merged into the corresponding table on the destination shard. With the addition of uncommitted changes, there may be both changes from still open transactions (relevant in case of replication) and committed but not yet compacted changes. To ensure that data on the destination shards is read in the same form as on the source shard, `TxStatus` blobs are also borrowed and merged. Information from them is added to the commit table.

Transaction information may differ on different shards. Consider a new example:

1. A transaction writes a change for key K with `TxId` to shard S, while the data is compacted and the changes end up in a large SST.
2. Shard S starts exceeding the size threshold and splits into two shards L and R.
3. SSTs that contain changes for key K end up on both shards with a filter applied.
4. Key K ends up in shard L, but the transaction also exists on shard R because there is a reference to it from a borrowed SST.
5. The transaction commits the change on shard L, but no commit occurs on shard R, since logically and from the writer's perspective there were no changes on shard R.
6. Since the transaction completes, `TxId` on shard R is rolled back after some time, because in reality nothing changes in the shard's data.
7. Suppose later shards L and R are merged again.
8. In such a situation, `TxStatus` from shard L will have a commit, and `TxStatus` from shard R will have an abort for the same `TxId`. Since transactions successfully commit all changes, and an abort may be due to a filter applied, in case of merging conflicting information for `TxId`, the commit "wins" over the abort.

In practice, DataShard is fully compacted before each split or merge, so conflicting commit status information should not arise. For example, this means that transactions cannot decide to commit only part of the changes; all changes for a specific `TxId` must be committed together. It also means that transaction IDs cannot be reused, including across different shards. Only globally unique identifiers can also be used as `TxId` for uncommitted changes.

Hive

Hive is a tablet responsible for managing other tablets, including selecting nodes for them to run on and deciding when to rebalance tablets.

The creation and deletion of tablets is initiated by the SchemeShard tablet. When a tablet is created, Hive assigns it a unique TabletId, fills in TabletStorageInfo, chooses the most suitable node, and sends a command to start the tablet on that node. In some abnormal situations, a tablet may interrupt its operation, in which case the node on which it was running sends a message to Hive. Hive also assumes that if the connection with a certain node is lost, the tablets running on it have stopped. In such cases, Hive restarts the tablets on other nodes, incrementing the generation.

A YDB cluster runs multiple Hives:

- A single *root Hive* responsible for the system tablets of all databases in the cluster. All nodes in the cluster are registered in the root Hive.
- A *database Hive* (one per database) is responsible for the tablets servicing the user load of a specific database. Only the compute nodes of the database are registered in that database's Hive.

When a node registers, it informs Hive of the types of tablets and the number of tablets that can be run on it.

Resource Usage Metrics

Hive evaluates resource usage to evenly distribute tablets across nodes. For each tablet, the usage of four types of resources is tracked:

1. *CPU* — processor consumption, calculated as the number of microseconds spent on tablet work in the last second. A value of one second corresponds to 100% load of a single core.
2. *Memory* — the amount of RAM consumed by the tablet.
3. *Network* — the amount of traffic generated by the tablet.
4. *Counter* — a fake resource for even distribution of tablets. If a tablet has a nonzero consumption of any other resource, its Counter value is 0; otherwise, it is 1. This way, Counter is used for any tablets for which there is no data on real consumption, as well as for tablets where real consumption tracking is disabled. By default, this applies only to column-oriented tables.

Counter

The **Counter** resource is described in item 4 above.

Node usage

Additionally, to determine overloaded nodes, YDB uses memory consumption and processor resources in the actor system thread pools on each node. These values are converted into relative values (a number from 0 to 1). The maximum of these relative values is used as the node's overall resource consumption value — *Node usage*. Hive also applies aggregation over a window to all metrics to account for load spikes.

Resource usage information is used for choosing a node for a tablet. For example, if Hive has information only on the CPU consumption of a tablet, it tries to find a node with the lowest CPU load. If information on multiple resources is available, the highest of the resource usage values is used.

Autobalancing

At certain moments, Hive may start an auto-balancing process that moves tablets between nodes to improve load distribution. The situations when autobalancing occurs are listed below. The auto-balancer works iteratively, making decisions about moving tablets one at a time. It selects the most loaded node, chooses a tablet that runs on this node using weighted randomness, and chooses a more suitable node for it. This process is repeated until balance is restored. The way node load is determined depends on the type of balancing. For example, in case of CPU consumption imbalance, CPU usage is used. For uneven distribution of column-oriented tables, the number of tablets is used instead.

Resource Usage Imbalance

To quantify the balance of resource usage, Hive uses the *Scatter* metric, which is calculated separately for each resource using the following formula:

and are, respectively, the maximum and minimum usage of a resource across all nodes. To normalize consumption on each node, the number of available resources on the node is used, which may vary between nodes. Under low loads, this metric may fluctuate significantly. To avoid this, when calculating , it is assumed that resource usage cannot be lower than 30%. The balancer is triggered if exceeds a threshold.

The maximum value of across different resources is available as the sensor `Hive/MAX(BalanceScatter)` in the `tablets` subgroup.

Node Overload

Overloaded nodes can negatively affect YDB performance. CPU overload raises latencies, and consuming all memory can cause the node to crash with an out-of-memory error. The balancer is triggered when the load of one node exceeds 90% while the load on another node falls below 70%.

The maximum resource usage on a node is reported by the `Hive/MAX(BalanceUsageMax)` sensor in the `tablets` subgroup.

Even Distribution for a Specific Object

For tablets that use the Counter resource, the evenness of tablet distribution for each object (each table) is tracked in the form of the `ObjectImbalance` metric, similar to the described above. Restarting nodes may break the balance in tablet distribution and trigger balancing.

The maximum value of `ObjectImbalance` across different objects is reported by the `Hive/MAX(BalanceObjectImbalance)` sensor in the `tablets` subgroup.

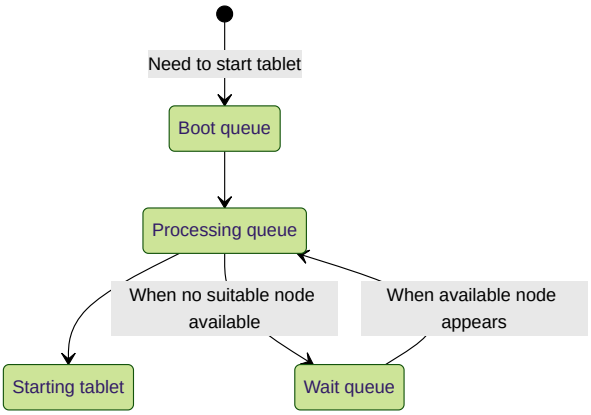
Tablet Boot Process

This article describes the process of launching tablets from the perspective of Hive. Hive makes decisions about launching tablets in various situations:

- A tablet has just been created.
- Connection is lost with the node where the tablet was running.
- The node where the tablet was running sends a message that it has stopped working (for example, due to loss of connection with the cluster disk subsystem).
- When moving a tablet as part of auto-balancing.

In any of these situations, the following occurs:

1. The tablet is added to the boot queue.
2. When processing the queue, a suitable node is selected for it.
3. A command to start the tablet is sent to the node.



Boot Queue

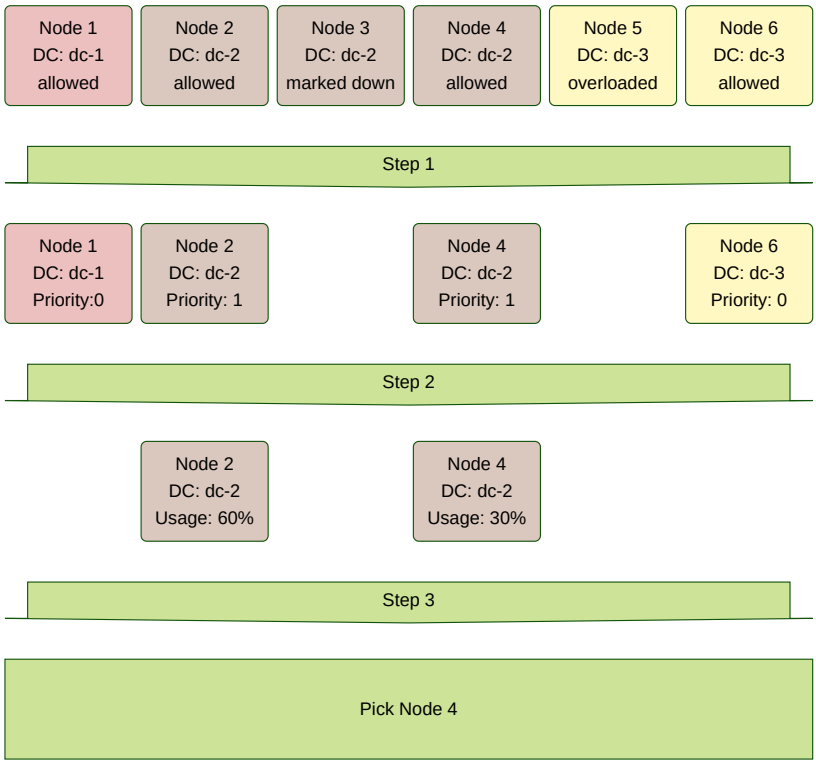
The boot queue, or *Boot queue*, is stored in Hive's memory and is prioritized. Tablet priority is determined by the following factors:

1. Tablet type — system tablets have higher priority than user tablets.
2. Resource consumption metrics — tablets with higher consumption have higher priority.
3. Tablets that restart frequently have lower priority.

When processing the queue, a limited number of tablets are processed at once (`max_boot_batch_size` in configuration). This is necessary so that when starting a large number of tablets, Hive does not stop responding to other requests for a long time.

If when processing a tablet it turns out that it cannot be started on any of the nodes, then this tablet is postponed to a separate *Wait queue*. When node availability changes (a new node connects, or a restriction is removed from a node in Hive UI), Hive returns to these tablets and when processing the boot queue alternates tablets from the Boot Queue and tablets from the Wait Queue.

Warning



Simultaneous startup of many tablets can create increased load on a node. Therefore, the maximum number of simultaneously starting tablets on one node is limited by the `max_tablets_scheduled` value from configuration. At the same time, if one of the nodes hits this limit, Hive stops starting new tablets on other nodes too, so that this does not affect the uniformity of distribution. This behavior can be controlled using the `boot_strategy` parameter.

Node Selection

There are strict restrictions on which nodes are allowed to start a tablet: not every node can start every type of tablet; tablets of a certain database can only be started on nodes of that database. Additionally, when **moving** tablets, overloaded nodes are not considered.

1. From all suitable nodes, nodes with maximum priority are selected. Priority is determined based on the data center where the node is located. You can explicitly specify data center priorities in the `default_tablet_preference` subsection in the configuration. For coordinators and mediators, priorities are determined dynamically to maintain them in the same data center when possible. Additionally, if a tablet terminates with an error on a certain node, the priority of that node is lowered for the next start of this tablet.
2. For nodes with maximum priority, a target metric is calculated, which almost matches the Node usage metric. It differs in that only those resources consumed by this particular tablet are considered, as well as the presence of a penalty for the number of tablets of the same schema object.
3. Finally, based on this metric, a node is selected. The selection algorithm at this stage is determined by the `node_select_strategy` parameter in the configuration. By default, a random node is selected from 7% of nodes with the minimum metric value.

Below is an illustration of the process.

Boot Process

Each node runs a Local service responsible for interacting with Hive. When starting a tablet, Hive sends a tablet start command to the Local service of the required node, containing all information necessary for startup: TabletID, generation, channel history, and startup mode (leader or follower). After the tablet starts, Local reports this to Hive. From this moment, the tablet is considered started from Hive's perspective and remains so until:

- Local reports that it has stopped working
- communication with Local is disrupted

In these situations, the startup process will begin again for the next generation of the tablet.

DataShard: locks and transaction change visibility

When a long-running YQL transaction writes data to tables, it may try to read the same table later. To support observing data consistent with transaction changes DataShard tablets support writing uncommitted changes as part of a transaction, include these changes in subsequent queries by the same transaction, and allow atomic commits of these changes as long as serializable isolation is not violated.

The underlying LocalDB support also allows very large transaction commits, not limited by the size of a single message between distributed actors.

High level overview

Complex YQL transactions (either interactive, i.e. when client begins a transaction and uses it to perform queries without committing in the same query, or that involve multiple sub-queries) are split into multiple "phases" by QP, where output of one phase potentially acts as input to the next phase. For example, when a YQL query contains a `JOIN`, the first phase may be reading the first table, and the second phase may use the output of the first table to perform lookup queries in the second table.

For read-only queries QP uses global MVCC snapshots to ensure consistency between sub-queries. But when transaction also writes, it needs to ensure serializable isolation is not violated at commit time. Currently, this is achieved using Optimistic concurrency control, where reads add optimistic "locks" to observed ranges, and writes by other transactions "break" those locks at their commit time. Transaction may successfully commit as long as none of those locks are broken at commit time, otherwise it fails with a "transaction locks invalidated" error.

There's another way to look at optimistic locks. A single transaction may read from multiple shards using read timestamps (this may be a single global MVCC snapshot timestamp, or multiple timestamps, different for each read), while other transactions concurrently write to the same tables or shards. When transaction commits, it is assigned a single commit timestamp in the global serializable order of execution. As long as all of those reads could be repeated at the commit timestamp, without any change to observed results, the transaction might as well have executed (in its entirety) at the commit timestamp. The optimistic lock, as long as it's not broken, tells the transaction that it is possible to move all reads to the commit timestamp.

Uncommitted changes are not too different from reads in that regard. As long as DataShard can store those changes and then "move" them to the final commit timestamp without conflicts, the transaction may commit, otherwise it must abort. The main difference is that unlike read locks (which are stored in-memory), uncommitted changes are persistent, must be tracked across reboots, and must be cleaned up correctly when no longer needed.

How locks are used for reads

Operations proposed to DataShards are assigned a globally unique 64-bit `TxId`, which are allocated in large batches from global TxAllocator tablets. When QP performs the first read in a multi-phase transaction, it also uses this `TxId` as a lock identifier (historically named `LockTxId`), which is then used in all subsequent queries in the same YQL transaction. DataShard will add new locks when operation has `LockTxId` specified (it is not zero):

- See LockTxId field in `TEvRead` read requests
- See LockTxId field in `TEvWrite` write requests
- See LockTxId field in `TDataTransaction` messages (used for encoding data transaction body)

You may also see the `LockNodeId` field, which specifies the originating node id of the lock, which is used by DataShard for subscribing to lock status, and cleaning up locks when they are no longer needed.

Note that `LockTxId` is just a unique number, that is used across multiple operations in the same YQL transaction, while `TxId` is unique for every operation for a single DataShard. The use of the first `TxId` as `LockTxId` is not required, but since QP already has a globally unique number, and `LockTxId` is unrelated to `TxId`, it elides an extra allocation.

Locks table (see datashard_locks.h and datashard_locks.cpp) indexes locks by their primary key ranges in a range tree, allowing finding and "breaking" them by point keys. In the simplest case when read operation reads a range it is added using a SetLock method, and when write operation writes a key it breaks other locks using a BreakLocks method.

When the lock is added for the first time, it is assigned a monotonically increasing `Counter` in the current tablet's `Generation` (see TLock message), and a row with these numbers is added to the virtual `/sys/locks` table (which is no longer used). These locks are then returned in result messages (e.g. see TEvReadResult).

In the successful scenario, the lock exists and is not broken, `Generation` and `Counter` fields do not change.

In the unsuccessful scenarios, previously acquired locks are broken. For example, when changing the `Generation` of the lock (disabling the lock on restart) or the `Counter` (on an explicit error status, or when disabling and recreating the lock in the same generation).

The first `Generation` and `Counter` for each shard are remembered by QP, and changes during transaction lifetime are indicative of possible inconsistencies and serializable isolation violations. Read-Write transactions, or transactions that did not use global MVCC snapshots for efficiency reasons, perform the final commit that validates `Generation` / `Counter` values and commit only succeeds when all of them match.

Reads using global MVCC snapshots are already consistent. Nevertheless, they still acquire locks in case transaction might perform a write later in the lifecycle.

When acquiring locks DataShard performs additional checks, on whether or not conflicting changes have been committed "above" the snapshot. When the conflict is detected, the read succeeds, however the lock will have `Counter` equal to ErrorAlreadyBroken, to signal that even though the read is consistent, writes will never succeed. Such transactions may stop trying to add new locks, and succeed when it turns out the full YQL transaction is read-only. When such transactions try to write, however, they are aborted early as it would be impossible to commit them anyway.

How locks are used for writes

When QP needs to make uncommitted changes in a YQL transaction, it uses DataShard write transactions with a non-zero `LockTxId`. DataShard will then use this `LockTxId` as `TxId` for persisting uncommitted changes, available as long as the lock is valid. Internally locks that have uncommitted writes are called write locks. Such locks also become persistent (see the Locks table and related tables below), surviving DataShard restarts.

There are some limitations to such uncommitted write transactions:

- Transaction must run in an immediate transaction mode (i.e. uncommitted writes cannot be distributed, uncommitted writes to different shards are performed independently instead)

- Transaction must have a valid `LockNodeId` specified, DataShard subscribes to lock status using this node and automatically rolls back uncommitted changes when the lock expires (e.g. when transaction aborts unexpectedly, node is restarted and transaction state is lost, etc.)
- Transaction must have a valid MVCC snapshot specified, which is used as the conflict detection baseline (and reads when needed), and expected to be used across all reads and writes in the same YQL transaction.
- The specified lock must be valid and non-broken, otherwise the specified `LockTxId` must not have any uncompacted data in LocalDB. This protects against edge cases where transaction rolls back due to lock status failure, and QP tries writing to the shard again.

When the YQL transaction later reads using the same `LockTxId`, reads will use a per-query transaction map with LocalDB, where the `LockTxId` appears as if it's already committed, allowing transaction to observe its own changes, but not other uncommitted changes. Since reads are performed using an MVCC snapshot, the transaction map will have a special entry `[LockTxId] => v{min}`, so the uncommitted change is visible in all snapshots.

Uncommitted writes need additional conflict detection (see CheckWriteConflicts in the MiniKQL engine host implementation). When multiple uncommitted transactions write to the same key, DataShard needs to ensure correctness by breaking conflicting transactions. Transaction observer objects (e.g. TLockedWriteTxObserver) are used to detect these conflicts, where LocalDB calls back various interface methods whenever a change is skipped or applied during reads, and a special read is used before each write to detect other uncommitted writes to the same key. Whenever a conflict is detected, it is added to conflict sets between locks, so each lock remembers which other locks must be broken when it commits, and which locks will break this lock when they commit.

Reads also need additional checks for conflicts when uncommitted writes are involved. Because reads need to not only be internally consistent, but also match the eventual state at the commit timestamp. Transaction observers are used to gather uncommitted writes from other transactions (reads need to be able to eventually move to the commit timestamp), which introduce conflict graph edges from write locks to read locks.

Even more complicated is the case where change visibility writes happen over committed changes after the transaction MVCC read snapshot, and transaction reads rows including those uncommitted changes. For example, let's consider this case:

1. Key K initially has `A = 1` at version `v4000/100` (the two numbers in version are `Step=4000` and `TxId=100` of the commit timestamp)
2. Tx1 is started with an MVCC snapshot `v5000/max`
3. Tx2 commits a blind `UPSERT` with `B = 2` at version `v6000/102`
4. Tx1 performs an uncommitted blind `UPSERT` with `C = 3` and `TxId` 101
5. At this point Tx1 may still commit successfully, because it didn't read key K and change with `C = 3` may still move to some future commit timestamp
6. Tx1 performs a read of key K, which happens at snapshot `v5000/max`:
    - This read will have `[101] => v{min}` in its custom transaction map
    - The iteration will be positioned at the first delta with `C = 3` (since `v{min} <= v5000/max`), which will be applied to the row state
    - All other committed deltas and rows will also be applied, i.e. the row state would include `B = 2` which is currently committed
    - However, there is a conflict: `B = 2` is committed above the MVCC read snapshot (`v6000/102 > v5000/max`)
    - This will be detected in OnApplyCommitted callback, which calls CheckReadConflict
    - Since this introduces a read inconsistency, the lock will be immediately broken, and an inconsistent read flag will be raised
7. Not only the above read would fail, Tx1 would not be able to commit since serializable isolation can no longer be provided
8. The application will get a "transaction locks invalidated" error and retry the transaction from the beginning

Interaction with change collectors

DataShards may have change collectors, which log table changes and stream them to other subsystems. This is used to support Change Data Capture and Asynchronous secondary indexes. Depending on the mode, change collector may need to know the previous row state, and may perform a row read before each write.

When transaction has uncommitted changes, change collectors need to process those as well, but those must not be streamed until they are committed, and moreover streamed changes must match the eventual commit order of those changes. Changes are first accumulated in a separate LockChangeRecords table, and when transaction eventually commits they are added to the output stream in bulk using a single record in a ChangeRecordCommits table. This way all change processing is done gradually, it matches the size of each individual write, and there is no expensive post-processing at commit time.

Interaction with distributed transactions

When distributed transaction starts execution, it first validates locks and sends its validation result to other participants. When all successful validation results are received, the transaction body may execute and apply its intended side-effects. In other words, when all reads from all involved shards may successfully move to the commit timestamp, the transaction may execute all buffered UPSERTs, otherwise transaction body is not executed at all participants, and all accumulated changes are rolled back. Normally, validation result is persisted, and correctness is preserved by runtime key conflicts between transactions. However, uncommitted writes add a serious complication, since when the write lock is committed DataShard doesn't even know which keys are involved (it would need to keep all keys in memory, which is prohibitively expensive). Left unchecked, DataShard might validate the write lock, send a successful result to other participants, while another conflicting transaction breaks this lock and rolls back all changes. It is preferred to optimize for the case where transactions don't conflict, and stopping the pipeline when uncommitted writes are involved would be prohibitively expensive.

Instead, when the write lock is validated, it becomes "frozen", and cannot be broken anymore. When a conflicting transaction tries to break a frozen lock, it is temporarily paused, and waits until the transaction with that frozen lock is first resolved. DataShard tracks which locks break which other locks on commit, and to avoid potential deadlocks it also tracks when commit of a transaction A may break validation results for transaction B and vice versa. When A must go before B in the global order from coordinators, DataShard won't start transaction B validation until A completes, but as long as transactions don't conflict they may be executed out-of-order.

Committing changes

When QP needs to commit previously uncommitted changes, it proposes a transaction that commits previously acquired locks. Specifically this transaction must not have a `LockTxId` specified (the commit is not setting any new locks), and must include a previously set lock in Locks transaction field, and with Op set to Commit. The commit transaction may either be immediate (when the YQL transaction involves a single shard, whether or not multiple phases have been used), or prepared as a distributed transaction with multiple participants.

To support distributed transactions all shards that validate locks must be included in SendingShards, and all shards that have side-effects must be included in ReceivingShards. During validation sending shards will generate persistent ReadSets and send them to all receiving shards, and receiving shards will wait for all expected ReadSets before executing the transaction. When transaction is executed with all successful validation results it will commit the lock by calling KqpCommitLocks. Otherwise, transaction body will not be executed, and lock is erased with all uncommitted changes rolled back by calling KqpEraseLocks, and it cannot be retried later on commit failure.

> **Note**
>
> Note that all uncommitted changes with the same `LockTxId` must be included in a commit transaction, and transaction must never try to partially commit. For example, when a transaction involves multiple writes, and one of those writes fails with an error, it would not be correct to skip the failed write and partially commit. Shards might merge later and non-matching transaction status would lead to consistency anomalies.

The commit transaction may also have additional side-effects, which are atomically executed after the lock is committed. QP will try to accumulate side-effects in memory until the same table is read in the same transaction, or until transaction commits, to reduce latency and fuse side-effects with commit as much as possible. When it is possible to accumulate all side-effects in memory, no uncommitted changes are persisted, and only read locks are optionally acquired.

When YQL transaction needs to rollback it runs an empty transactions with the Rollback lock op. Even if it didn't, when the TLockHandle is destroyed, subscribed DataShards will clean it up automatically in their TxRemoveLock internal transaction. The explicit removal is preferred, since uncommitted changes is a finite resource and asynchronous cleanup via `TLockHandle` would not ensure that resource is freed before new transactions try to write more uncommitted changes.

Limitations

Currently, uncommitted changes have a downside that all new writes have to search for conflicts. A single uncommitted write is enough to cause all new writes at a specific DataShard to switch to become non-blind, i.e. every write will have to perform a read first, which makes them more expensive, increases latency and decreases throughput. For maximum performance it is recommended to execute transactions where all reads are performed first, and a small amount of blind writes are performed last. This way uncommitted writes will not be used and DataShard performance will be optimal.

Due to LocalDB limitations DataShard also needs to ensure it doesn't accumulate too many open transactions, and the locks table is already limited to ~10k locks, which includes write locks. DataShard also has to count the number of uncommitted changes before each uncommitted write, which is implemented by counting skips in the transaction observer, and throwing TLockedWriteLimitException when the limit is exceeded.

Persistent locks survive DataShard reboots and restore the last state. Even though it is possible to persist specific ranges, this is not used in practice (DataShard would need to persist ranges during reads, which is expensive), and read locks are restored in the worst case "whole shard" as their range.

DataShard: distributed transactions

YDB implements distributed transactions, which are based on ideas from the Calvin: Fast Distributed Transactions for Partitioned Database Systems paper. These transactions consist of a set of operations performed by a group of participants, such as DataShards. Unlike Calvin, these operations are not required to be deterministic. To execute a distributed transaction, a proposer prepares the transaction at each participant, assigns a position (or a timestamp) to the transaction in the global transaction execution order using one of the coordinator tablets, and collects the transaction results. Each participant receives and processes a subset of transactions it is involved in, following a specific order. Participants may process their part of the larger transaction at different speeds rather than simultaneously. Distributed transactions share the same timestamp across all participating shards and must include all changes from transactions with preceding timestamps. When viewed as a logical sequence, timestamps act as a single logical timeline where any distributed transaction fully happens at a single point in time.

When the execution of a transaction depends on the state of other participants, the participants exchange data using so-called ReadSets. These are persistent messages exchanged between participants that are delivered at least once and contain read results with the state of the transaction. The use of ReadSets causes transactions to go through additional phases:

1. **Reading phase**: The participant reads, persists, and sends data that is needed by other participants. During this phase, QP transactions (type `TX_KIND_DATA`, which have a non-empty `TDataTransaction.KqpTransaction` field and subtype `KQP_TX_TYPE_DATA`) validate optimistic locks. Older MiniKQL transactions (type `TX_KIND_DATA`, which have a non-empty `TDataTransaction.MiniKQL` field) perform reads and send arbitrary table data during this phase. Another example of using the reading phase is the distributed TTL transaction for deleting expired rows. The primary shard generates a bitmask matching expired rows, ensuring that both the primary and index shards delete the same rows.
2. **Waiting phase**: The participant waits until it has received all the necessary data from the other participants.
3. **Execution phase**: The participant uses both local and remote data to determine whether to abort or complete the transaction. The participant generates and applies the effects specified in the transaction body if the transaction is completed successfully. The transaction body typically includes a program that uses the same input data and leads all participants to come to the same conclusion.

Participants are allowed to execute transactions in any order for efficiency. However, it's crucial that other transactions can't observe this order. Transaction ordering based on a coordinator's assigned timestamps ensures strict serializable isolation. In practice, single-shard transactions don't involve a coordinator, and shards use a locally consistent timestamp for such transactions. Variations in the arrival times of distributed transaction timestamps weaken the isolation level to serializable.

Additionally, YDB has support for "volatile" distributed transactions. These transactions allow participants, including coordinators, to store transaction data in volatile memory, which is lost when the shards are restarted until the transaction is completed and the effects are persisted. This also allows participants to abort the transaction until the very last moment, which will be guaranteed to abort for all other participants. Using volatile memory removes persistent storage from the critical path before the transaction execution, reducing latency.

When executing the user's YQL transactions, YDB currently uses distributed transactions only for the final commit of non-read-only transactions. Queries before the commit of a YQL transaction are executed as single-shard operations, using optimistic locks and global multi-version concurrency control (MVCC) snapshots to ensure data consistency.

Basic distributed transactions protocol

Operations that can be performed as distributed transactions in YDB include various types of participants. The basic protocol for distributed transactions is the same regardless of the type of transaction, with some notable differences in the schema changes, which have additional requirements to ensure these transactions are idempotent.

Distributed transactions are managed using proposer actors. Some examples of these are:

- TKqpDataExecutor executes DML queries, including distributed commits.
- SchemeShard executes distributed transactions for schema changes.
- TDistEraser executes a distributed transaction to consistently erase rows in tables with secondary indexes that match time-to-live (TTL) rules.

Distributed transactions in YDB are similar to two-phase commit protocols. The proposer actor goes through the following phases when executing a distributed transaction:

1. **Determining participants**: The proposer actor selects specific shards (`TabletId`) that are required for transaction execution. A table may consist of many shards (`DataShard` tablets with unique `TabletId` identifiers), but a particular transaction may only affect a smaller set of these shards based on the affected primary keys. This subset is fixed at the start of the transaction and cannot be changed later. Transactions that only affect a single shard are called "single-shard" transactions and are processed in what is known as the "immediate execution" mode.
2. **Prepare phase**: The proposer sends a special event, usually called `TEvProposeTransaction` (there is also the `TEvWrite` variant in DataShards), which specifies a `TxId`, a transaction identifier, unique within a particular cluster, and includes the transaction body (operations and parameters). Participants validate whether the specified transaction can be executed, select a range of allowed timestamps, `MinStep` and `MaxStep`, and reply with a `PREPARED` status on success.
   - For single-shard transactions, the proposer typically specifies an "immediate execution" mode (`Immediate`). The shard executes such transactions as soon as possible (at an unspecified timestamp consistent with other transactions) and replies with the result rather than `PREPARED`, which causes the planning phase to be skipped. Some special single-shard operations, such as `TEvUploadRowsRequest`, which implements `BulkUpsert`, don't even have a globally unique `TxId`.
   - The persistent transaction body is stored in the shard's local database, and the participant must ensure that it is executed when planned. In certain cases (for example, when performing a blind `UPSERT` into multiple shards), the participants must also ensure that the transaction is executed successfully, which may be in conflict with specific schema changes.
   - The volatile transaction body is stored in memory, and the participant responds with `PREPARED` as soon as possible. Future execution, whether successful or not, is not guaranteed in any way.
   - The proposer moves on to the next phase when they have received responses from all the participants.
   - It's not safe to re-send the propose event, except for schema operations, which, thanks to special idempotency fields, guarantee that a particular transaction will be executed exactly once.
3. **Planning phase**: When the proposer has received `PREPARED` replies from all participants, it calculates the aggregated `MinStep` and `MaxStep` values and selects a coordinator to assign the timestamp to the transaction. A `TEvTxProxy::TEvProposeTransaction` event is sent to the selected coordinator, which includes the `TxId` and a list of participants.
   - The transaction may only involve shards from the same database. Each shard attaches its ProcessingParams to the reply, which has the same list of coordinators when shards belong to the same database.
   - The coordinator is selected based on the received `ProcessingParams` because, historically, queries could be executed without specifying a database. The list of coordinators can only be determined from the participants.

    - When the `TEvTxProxy::TEvProposeTransaction` event is re-sent (currently only for schema transactions), it is possible that the transaction may have multiple timestamps associated with it. This is not typically a problem as the transaction will execute at the earliest possible timestamp, and any later timestamps will be ignored (the transaction will have been completed and removed by the time they occur).
4. **Execution phase**: The proposer waits for responses from the selected coordinator and participants, collecting the overall transaction outcome.
    - In some cases, such as a temporary network disconnection or a shard restart, the proposer may try to re-establish the connection and wait for the result. This process may continue until the transaction has been completed and the result is available.
    - When it is impossible to retrieve the result of a transaction from at least one of participant due to network issues, the transaction usually fails with an `UNDETERMINED` status, indicating that it is impossible to determine whether the transaction was successful.

Prepare phase in the DataShard tablet

Distributed transactions in the DataShard tablet begin with the `Prepare` phase, which can be proposed by one of the following events:

- TEvDataShard::TEvProposeTransaction provides an entry point for different types of transactions
- TDataEvents::TEvWrite provides a special entry point for transactions that write data and commit YQL transactions

Events that don't have an `Immediate` execution mode specified will begin the `Prepare` phase for the distributed transaction. The transaction body will be validated to determine whether it's even possible to execute it (for example, by using the CheckDataTxUnit unit for generic data transactions). A range of timestamps will then be selected:

- `MinStep` is selected based on the current mediator time or the wall clock.
- `MaxStep` is determined by a planning timeout, which at the moment is 30 seconds for data transactions.

Then, the transaction is written to disk (for persistent transactions) or kept in memory (for volatile transactions), the shard replies with a `PREPARED` status and starts waiting for a plan that specifies the `PlanStep` for the given `TxId`. The planning deadline is important because if the proposer fails unexpectedly, the shard cannot determine whether the proposer has successfully planned the transaction for a future timestamp, so the shard must ensure that the transaction will be executed when planned (unless it's volatile). Since transactions that are not yet planned block some concurrent operations (such as schema and partitioning changes), a deadline is used to make it impossible to plan a transaction after a certain time. When the mediator time exceeds `MaxStep` and there is no corresponding plan for the transaction, then the protocol guarantees that it will not be possible to plan the transaction anymore. The transaction that reaches the deadline can then be safely removed.

Transactions are stored on disk and in memory using the TTransQueue class. Basic information about persistent transactions is stored in the TxMain table, which is loaded into memory when DataShard starts. The potentially large transaction body is stored in the TxDetails table and is not kept in memory while waiting. The transaction body is loaded into memory just before conflict analysis with other transactions in the pipeline.

Volatile transactions are stored in memory and are currently lost when DataShard restarts (they may be migrated during graceful restarts in the future). The restart aborts the transaction for all participants, and any participant can initiate the abort before the transaction body is executed and its effects are persisted. Shards use this feature to make schema and partitioning changes faster by aborting all pending transactions without waiting for a planning deadline.

The distributed transaction body needs to have enough information about the other participants so that each shard can know when it needs to generate and send outgoing ReadSets and which shards should expect and wait for incoming ReadSets. QP transactions currently use ReadSets for validating and committing optimistic locks, which are described using TKqpLocks generated by the `TKqpDataExecutor` actor. This message describes the following shard sets:

- `SendingShards` are shards that send ReadSets to all shards in the `ReceivingShards` set.
- `ReceivingShards` are shards that expect ReadSets from all shards in the `SendingShards` set.

Volatile transactions expect all shards to be in the `SendingShards` set because any shard may abort the transaction and need to send its commit decision to other shards. They also expect all shards that apply changes to be in the `ReceivingShards` set. Whether or not changes are committed depends on the decisions of other shards. Exchanged ReadSet data is serialized into TReadSetData message with a single `Decision` field specified.

An example of a distributed transaction that doesn't use ReadSets is a persistent distributed transaction with blind writes. In this case, after successful planning, the transaction cannot be aborted, and the shards must ensure the future success of the transaction during the `Prepare` phase.

Planning phase

When all participants have provided their `PREPARED` responses, the proposer calculates the maximum `MinStep` and the minimum `MaxStep`, then selects a coordinator (which is currently implemented using a `TxId` hash) and sends a `TEvTxProxy::TEvProposeTransaction` event, which includes the `TxId` and a list of participants with the operation type (read or write) for each participant (even though this information is not currently used). The selected coordinator then selects the closest matching `PlanStep` and associates it with the specified `TxId` and the list of participants. Plan steps for persistent transactions are allocated every 10 milliseconds (this setting is called plan resolution), and the association is also stored on disk. Plan steps for volatile transactions are selected from those reserved for volatile planning and can be as frequent as every millisecond, and the association is only stored in memory.

Planning each plan step (which can contain zero or more transactions) involves distributing participants (and their transactions) to mediators. This is currently done by hashing the `TabletId` of each participant modulo the number of mediators. Each mediator receives a subset of the plan step in increasing the `PlanStep` order. The subset only includes matching participants and may be empty, even if the full plan step is not. If a mediator restarts or the network becomes temporarily disconnected, the coordinator reconnects and sends all unacknowledged plan steps again in order.

Plan steps with persistent transactions are only sent to mediators after being fully persisted to disk. They are only removed from the coordinator's local database when acknowledged by participants and are guaranteed to be delivered at least once. Plan steps with volatile transactions, on the other hand, are only stored in memory and may be lost if the coordinator restarts. When a plan step is resent, it may or may not include acknowledged transactions or previously sent volatile transactions that still need to be acknowledged. This includes empty plan steps. Only the latest empty plan step will be kept in memory for re-sending.

To reduce the number of errors during graceful restarts, the coordinator leaves its state actor in memory even after the tablet stops working. The address of this state actor is persisted after the instance has been fully initialized and before it is ready to accept new requests. New instances contact this state actor and transfer the last known in-memory state, including the list of planned volatile transactions. This state actor is also used to transfer any unused volatile planning reserves, allowing new instances to start faster without having to wait until those reserves expire.

Mediators receive a stream of `TEvTxCoordinator::TEvCoordinatorStep` events from each coordinator and merge them using the matching `PlanStep` field. Merged plan steps with steps less or equal to the minimum of the last step received from each coordinator are considered complete and are sent to participants using `TEvTxProcessing::TEvPlanStep` events. Each participant receives an event with the `PlanStep`, specifying the timestamp, and a list of `TxId` that must be executed at that timestamp. Transactions within each plan step are ordered based on their `TxId`. The `(Step, TxId)` pairs are then used as the global MVCC version in the database.

Participants acknowledge that they have received (and persisted in the case of a persistent transaction) each plan step by sending a `TEvTxProcessing::TEvPlanStepAccepted` event to the sender (which is a mediator tablet) and a `TEvTxProcessing::TEvPlanStepAck` event to the specified coordinator tablet actor (as specified in the `AckTo` field of each transaction). Plan steps and/or transactions will be considered delivered when these events have been processed and will not be resent.

Based on `TEvTxProcessing::TEvPlanStepAccepted` events, mediators also track which `PlanStep` has been delivered to all participants, inclusive. This maximum `PlanStep` is known as the current mediator time and is distributed to nodes with running DataShards through subscriptions to the `TimeCast` service. The current mediator time indicates that all possible `TEvTxProcessing::TEvPlanStep` events have been received and acknowledged by the shards up to and including the specified `PlanStep`. Therefore, shards should be aware of all transactions up to this timestamp. The current mediator time is helpful as it allows the shards to keep track of the time progressing even when they are not participating in distributed transactions. For efficiency, all shards are partitioned into several timecast buckets at each mediator. The current time in each bucket advances when all participants in transactions in that bucket acknowledge their `TEvTxProcessing::TEvPlanStep` events. The current mediator time is available to shards when they subscribe by sending TEvRegisterTablet event to the time cast service during shard startup and get the address of an atomic variable from the TEvRegisterTabletResult event. This atomic variable allows the system to avoid broadcasting many frequent events to idle shards.

DataShards handle `TEvTxProcessing::TEvPlanStep` events in the TTxPlanStep transaction. Transactions are found by their corresponding `TxId`, get their `Step` assigned, and then are added to the `Pipeline`. The `Pipeline` uses the `PlanQueue` to limit the number of concurrently running transactions and executes them in the `(Step, TxId)` order.

Execution phase in the DataShard tablet

The PlanQueue unit allows distributed transactions to start, subject to concurrency limits, in the increasing `(Step, TxId)` order. The transaction body is loaded from disk when needed (for evicted persistent transactions), QP transactions finalize execution plans and arrive at the BuildAndWaitDependencies unit. This unit analyzes transaction keys and ranges declared for reading and writing and may add dependencies on earlier conflicting transactions. For example, when transaction `A` writes to key `K` and a later transaction `B` reads from key `K`, then transaction `B` depends on transaction `A`, and transaction `B` cannot start until transaction `A` completes. Transactions leave `BuildAndWaitDependencies` when they no longer have direct dependencies on other transactions.

Next, persistent QP transactions execute the read phase (which includes validating optimistic locks) and generate outgoing OutReadSets in the BuildKqpDataTxOutRS unit. Then, the StoreAndSendOutRS persists outgoing ReadSets and access logs for optimistic locks. Optimistic locks that have attached uncommitted changes are marked with the `Frozen` flag, which prevents them from being aborted until the transaction completes. Otherwise, lock validity is ensured by assigning writes with a higher MVCC version and ensuring the correct execution order of conflicting transactions. Operations with access logs or outgoing ReadSets are added to the `Incomplete` set, which ensures that new writes can't change the validity of previous reads and generally need to use a higher MVCC version. However, new reads don't necessarily need to block on the outcome of the incomplete transaction and can use a lower MVCC version as long as it's consistent with other transactions.

Persistent QP transactions prepare data structures for incoming InReadSets in the PrepareKqpDataTxInRS unit and begin waiting for all necessary ReadSets from other participants in the LoadAndWaitInRS unit. In some cases, such as blind writes to multiple shards without lock validation, distributed transactions may not require the exchange of ReadSets, and the ReadSet-related units don't perform any actions in these scenarios.

Finally, the QP transaction operation reaches the ExecuteKqpDataTx unit. This unit validates local optimistic locks using previously persisted `AccessLog` data when available, validates ReadSets received from other participants, and, if everything checks out, executes the transaction body and returns a result. If lock validation fails locally or remotely, the transaction body is not executed, and the operation fails with an `ABORTED` status.

Volatile transactions

Volatile distributed transactions are stored only in memory and are lost when the shard is restarted. Nevertheless, they must guarantee that the distributed transaction either commits at all participants or is aborted promptly. The advantage of volatile transactions is that they don't require separate read, wait, and execution phases. Instead, they are executed atomically in a single phase with 1RTT storage latency from the start of the distributed commit to the successful reply. This means they usually don't slow down the pipeline and can increase transaction throughput. Since any shard can abort a volatile transaction without waiting for a planning deadline, it also limits the unavailability of the shard during partitioning and schema changes.

Volatile transactions are based on persistent uncommitted changes in the local database. During the execution phase, DataShard optimistically assumes that all remote locks will be validated, applies effects in the form of uncommitted changes (using the globally unique `TxId` of the distributed transaction), and adds the transaction record to the VolatileTxManager in a `Waiting` state for other participants to make decisions. A successful reply is only sent when all transaction effects are persistent, and a committed decision has been received from all other participants. Reads use the `TxMap` to observe all pending changes and check their status using the `TxObserver`. When a read result depends on the outcome of a volatile transaction, operations subscribe to its status and restart after it has been decided (either by reading committed changes or skipping them if the transaction aborts).

Having uncommitted and not yet aborted changes limits the shard's ability to perform blind writes. Because uncommitted changes must be committed in the same order in which they were applied to any given key, and shards don't keep these keys in memory after transactions have been executed, DataShard needs to read each key and detect conflicts before it can perform any write. These conflicting changes may be uncommitted changes associated with an optimistic lock (and these locks must be broken along with rolling back the changes) or uncommitted changes from waiting for volatile transactions. We don't want to block writes unnecessarily, so even non-volatile operations can switch to a volatile commit. Such operations allocate a `GlobalTxId` when necessary (this is a per-cluster unique `TxId` that is needed when the request doesn't provide one, such as in `BulkUpsert`) and write changes to conflicting keys as uncommitted. The transaction record is then added to the `VolatileTxManager` without specifying other participants and becomes initially committed. It also specifies a list of dependencies, which are transactions that must be completed before the transaction can be committed. These transactions don't block reads and are eventually committed in the local database after all their dependencies have been completed or aborted.

To reduce stalls in the pipeline, transactions use the conflict cache for keys that are declared for writes in distributed transactions. These keys are read while transactions are waiting in the queue, and conflicting transaction sets are cached by the RegisterDistributedWrites function call. All writes to cached keys update these conflict sets and keep them up-to-date. This allows distributed transactions with writes to execute faster by processing lists of conflicting transactions using a hash table lookup even when the table data is evicted from memory.

DataShard may have change collectors, such as async indexes and/or Change Data Capture (CDC). Collecting these changes for volatile transactions is similar to uncommitted changes in transactions, generating a stream of uncommitted change records using the `TxId` as its `LockId`. These records are then either added atomically to shard change records upon commit or deleted upon abort. Depending on the settings of the change collector, it may also need to read the current row state. Suppose this row state depends on other volatile transactions that are waiting. In that case, it is handled similarly to any other read by adding a dependency and restarting when these dependencies are resolved. This can cause the transaction pipeline to stall, but it's conceptually similar to persistent distributed transactions with ReadSets that read-write conflicts can also stall.

Volatile transactions also generate and write to disk OutReadSets for all other participants specified in the `ReceivingShards` sets in the same local database transaction, which writes uncommitted effects. When these uncommitted changes become persistent, these ReadSets are sent to other participants, notifying them that this shard is ready to commit the distributed transaction and will not change its decision until the transaction is aborted by another participant.

Shards forget about volatile transactions that do not persist in their transaction records when they are restarted and will not send outgoing ReadSets for transactions they no longer know anything about. Shards that successfully execute the transaction body send a special event called ReadSet Expectation to inform about them waiting for an incoming ReadSet. This is done even before the effects are persisted, so the shards have a chance to find out about aborted transactions as early as possible. Restarted shards will receive a request for a transaction they don't know about and respond with a special ReadSet without data. In this way, all participants will find out about the aborted transaction and abort it as well.

Volatile transaction guarantees

To reiterate, volatile transactions are stored in memory by coordinators and participants and may fail for various reasons. It's important to understand why a volatile transaction either commits or aborts for all participants and why it's not possible for a transaction to commit only for a subset of participants.

Some examples of potential sources of error for the transaction:

1. Any shard can unexpectedly restart, including when a new instance starts while the old one is still running and is unaware of the new one. Since transactions are only stored in memory, the new instance may not be aware of transactions that failed to save their effects to disk. A transaction may also have been successfully executed and committed without leaving any traces except for its committed effects.
2. The coordinator may unexpectedly restart without transferring its in-memory state, and the transaction may have been sent to some participants but not all of them.
3. Any shard might have decided to abort the transaction due to an error.

A vital guarantee is that if any shard successfully persists, uncommitted changes, and a transaction record, and if it receives a `DECISION_COMMIT` from all other participants, the transaction will be eventually committed at all participants and can't be rolled back. It's also important to note that if any shard aborts a transaction due to an error (such as forgetting about the transaction after restarting), the transaction will never be able to complete and will eventually roll back.

These guarantees are based on the following:

1. ReadSets with `DECISION_COMMIT` are sent to other participants only after all uncommitted changes, outgoing ReadSets, and a transaction record have been persisted to disk. Therefore, `DECISION_COMMIT` messages are persistent and will be delivered to other participants until acknowledged. Even if another shard aborts the transaction, these messages will continue to be delivered.
2. ReadSets are only acknowledged either when a shard successfully writes to disk or when a read-only lease is active and an unexpected ReadSet is received. Specifically, an older tablet instance will not acknowledge a ReadSet for a transaction already prepared and executed by a newer tablet. The local database ensures that a new tablet will not be activated until the read-only lease on older tablets has expired (provided that the monotonic clock frequency is not more than twice as fast). A successful write confirms that the tablet held the storage lock at the beginning of the commit, and no newer tablets were running simultaneously.
    - Volatile transactions use an optimization where received ReadSets are not written to disk. Acknowledgment is sent only after a commit or an abort (removal) of the transaction record has been fully persisted on disk.
    - When all participants have generated and persisted in their outgoing `DECISION_COMMIT` ReadSets, they will continue to receive the complete set of commit decisions until they have fully committed the transaction effects and sent their acknowledgments.
3. Any message related to an aborted transaction is only sent after the abort has been written to disk. This is necessary to handle situations where multiple generations of a particular shard are running at the same time. After a newer generation has successfully committed a transaction and acknowledged ReadSets, an older generation (which would fail when trying to access the disk or validate a read-only lease) may receive a `NO_DATA` reply to its ReadSet Expectation (which was acknowledged by the newer generation). However, the older generation will not be able to commit the removal of the transaction record and cannot reply with an error incorrectly. When the removal of the transaction record (and the transaction effects) have been fully committed, the current generation can be assured that newer generations won't start with the transaction again, and it won't commit.
4. After collecting all `DECISION_COMMIT` ReadSets, a successful reply does not need to wait for the final commit in the local database. Instead, it has to wait until the uncommitted effects and the transaction record have been persisted. This allows the successful reply to have a 1RTT storage latency on the critical path caused by writing uncommitted changes and the transaction record. This successful response is stable:
    - If a shard is restarted, its effects and transaction record will be persistent. In the worst case, it will be recovered in the `Waiting` state.
    - From the MVCC perspective, the transaction has already been completed, so any new reads will have an MVCC version that includes these changes. Any new read will begin waiting for the transaction to resolve, which is now guaranteed to succeed.
    - The restored `Waiting` transaction could not have its incoming ReadSets acknowledged, so they will be resent. Since we received `DECISION_COMMIT` earlier, they will be received again, and the transaction will quickly move to the `Committed` state.
5. As long as the transaction is in the queue, and especially while its `PlanStep` is not yet known, incoming ReadSets are stored in memory and will not be acknowledged. Acknowledgments are delayed until the transaction has been fully committed or is aborted prematurely (in which case, no changes have been made, and no transaction record has been committed, so newer generations cannot recover or commit the transaction).

Volatile distributed transactions also ensure that changes are visible and stable across multiple shards participating in the same distributed transaction. For instance, persistent distributed transactions allow the following anomaly:

1. Distributed transaction `Tx1` performs a blind write to keys `x` and `y` in two different shards.
2. Single-shard transaction `Tx2` reads key `x` and observes a value written by `Tx1`.
3. Single-shard transaction `Tx3` (which starts after `Tx2` has completed) reads key `y` and does not observe a value written by `Tx1`.

This anomaly can occur when a shard with key `x` quickly receives a transaction plan step with `Tx1` and performs a write. A subsequent read in `Tx2`, which arrives a bit later, will have its local MVCC version include changes to key `x` and observe the change. However, the shard with key `y` may be running on a slower node and may not be aware of the `Tx1` plan step when a subsequent read in `Tx3` arrives. Since the time cast bucket doesn't have `Tx1` acknowledged, its mediator time will remain in the past, and `Tx3` will have a local MVCC version that doesn't include changes to key `y`. From the user's perspective, `Tx2` must happen before `Tx3`, but the global serializable order turns out to be `Tx3`, `Tx1`, and `Tx2`.

Volatile transactions cannot observe this particular anomaly because a read that observes changes to key `x` must have received `DECISION_COMMIT` from the other shard with key `y`. This means that the transaction record has been persisted in both shards and, crucially, the shard with key `y` has marked it as completed. A read from key `y` will choose a local MVCC version that includes changes made by `Tx1` and will need to wait until `Tx1` is resolved.

In other words, if a client observes the result of a volatile transaction at a certain point in time, all subsequent reads will also observe the result of that volatile transaction, and changes stability is not violated.

Indirect planning of volatile transactions

The coordinator restart may cause the plan step to only reach a subset of the participants in a volatile distributed transaction. As a result, some shards may execute the transaction and begin waiting for ReadSets, while other shards continue waiting for the plan step to arrive. Due to the planning timeout of 30 seconds, some transactions could experience excessive delays before eventually aborting.

When any participant receives the first plan step of a volatile transaction, they will include the `PlanStep` in the ReadSets they send to other participants. The other participants then indirectly learn about the `PlanStep` assigned to the transaction and remember it as the `PredictedPlanStep`. Even if their own plan step is lost, DataShard will add the transaction to the `PlanQueue` when its mediator time (directly or indirectly) reaches the `PredictedPlanStep`, as if they had received a plan step with that predicted `PlanStep` and `TxId`. If the `PredictedPlanStep` is in the past, the transaction will be quickly aborted, as if it had reached the planning deadline.

Since the same transaction can be assigned to multiple plan steps, with some getting lost, different participants may have a distinct `PlanStep` assigned to the same transaction. The same transaction will then try to execute at different timestamps. DataShards verify that `DECISION_COMMIT` messages have their `PlanStep` matching their assigned `PlanStep` and only process them if the steps match. The transaction will be aborted if there is a mismatch in the plan steps.

Internals of the V2 configuration mechanism

The V2 configuration in YDB provides a unified approach to managing cluster settings. While the DevOps section describes how to use this mechanism, this article focuses on its technical design. It will be useful for YDB developers and contributors who want to make changes to this mechanism, as well as anyone who wants to gain a deeper understanding of what happens in a YDB cluster when the configuration changes.

The YDB cluster configuration is stored in several locations, and various cluster components coordinate synchronization between them:

- as a set of node configuration files in the file system of each YDB node (required to connect to the cluster when a node starts up).
- in a special metadata storage area on each PDisk (a quorum of PDisks is considered the single source of truth for the configuration).
- in the local database of the DS Controller tablet (required for the distributed storage).
- in the local database of the Console tablet.

Some parameters take effect on a node immediately after the modified configuration is delivered to its location, while others only take effect after the node is restarted.

Distributed configuration system (Distconf)

Distconf is a V2 configuration management system for a YDB cluster based on Node Warden, storage nodes, and their PDisks. All V2 configuration changes, including initial setup, pass through it.

The Leader's Role

The central element of the Distconf system is the **leader**: the only node in the cluster that currently has the authority to initiate and coordinate configuration changes. Having a single decision-making point eliminates races and conflicts, ensuring that changes are applied consistently. If the current leader fails, the cluster automatically starts the process of electing a new leader. Later in this section, we will look at how elections work and how the leader manages the cluster.

Quorum and Source of Truth

A key element of Distconf's reliability is storing the configuration directly on PDisks. Any change is considered successfully applied only when it is written to the metadata area on a **quorum** of disks. This means that even if some nodes or disks fail, the system can recover the current and consistent configuration by reading it from the remaining ones. It is the quorum storage on PDisks, not the state of any single node, that is the single source of truth about the cluster configuration. This mechanism is implemented in `distconf_persistent_storage.cpp`.

It is worth noting that writing to the PDisk metadata area for Distconf is a special low-level operation that occurs directly through `NodeWarden` and **does not use** the standard data path through `DSProxy`.

The quorum mechanism itself is hierarchical and implemented in `distconf_quorum.h`. The basic principle is "majority of majorities". To make a decision (for example, to apply a new configuration), the following is required:

1. A majority of responding disks within each data center. A data center that meets this condition is considered "operational".
2. A majority of "operational" data centers in the cluster.

For configurations affecting static storage groups, the requirement is even stricter: each static group must confirm its own internal quorum of VDisks in accordance with its fault tolerance scheme.

Binding Process and Leader Election

Leader election in Distconf is carried out through the `Binding` process, described in `distconf_binding.cpp`.

1. **Discovery**: Storage nodes get a full list of static cluster nodes through the standard `TEvInterconnect::TEvNodesInfo` mechanism.
2. **Building the binding tree**: Each node initiates a `bind` to a random node from the common list to which it is not yet subordinate. This process forms an acyclic graph, which in intermediate stages is a forest (a set of disconnected trees), and eventually a single tree spanning all nodes.
3. **Cycle prevention and topology exchange**: The cycle prevention mechanism is based on the constant exchange of information about the current topology. When node `A` tries to connect to node `B`, it sends its entire known subtree to `B`. Node `B` rejects the request if `A` is already its descendant. In case of a simultaneous attempt at a mutual connection, the conflict is resolved in favor of the node with the greater `NodeId` value.
4. **Leader determination**: In the process of merging trees, there inevitably remains one node that cannot connect to anyone other node because all other nodes are already in its subtree. This node becomes the root of the final tree and is declared the **leader**.

If the current leader fails, the `Binding` process is restarted, and the cluster elects a new leader.

Scatter/Gather — Command Propagation Mechanism

To manage the cluster, the leader uses the `Scatter/Gather` mechanism (`distconf_scatter_gather.cpp`), which operates on top of the tree built during the `Binding` process.

- **Scatter**
  When the leader needs to send a command to all nodes (for example, to propose a new configuration), it sends it to its direct children in the tree. Each node, upon receiving the command, retransmits it to its children. This is how the command is efficiently propagated throughout the tree to the leaves.
- **Gather**
  After executing the command, the nodes must report the result. The responses are collected in reverse order: the leaves send the results to their parents, who in turn aggregate them and send them up. As a result, the leader receives a generalized result from the entire cluster.

This mechanism is used for distributed operations, including a two-phase commit when changing the configuration. Scatter and gather tasks (`TScatterTasks`) are tracked by the leader to monitor the execution of operations.

Finite-State Machine (FSM) and Change Lifecycle

The entire configuration change process on the leader is managed by a finite-state machine (FSM), implemented in `distconf_fsm.cpp`. The FSM ensures that only one configuration change operation is performed at a time, preventing races and conflicts.

When a change request is received, the FSM transitions to the `IN_PROGRESS` state, blocking new requests.

The leader uses `Scatter/Gather` to perform a two-phase commit: first, it sends a Propose, and after receiving a quorum of confirmations, a Commit command.

After the successful completion or cancellation of the operation, the FSM returns to the `RELAX` state, allowing the processing of subsequent requests.

Configuration Management via InvokeOnRoot

`TEvNodeConfigInvokeOnRoot` requests are a unified mechanism for any cluster configuration changes. These commands can be initiated by both a **system administrator** (for example, via the CLI) and **other YDB components** in automatic mode (for example, by the `BlobStorageController` tablet during the `SelfHeal` process).

Regardless of the source, any such request is processed according to the same scenario:

1. The request is delivered to the Distconf leader node (if it was not sent to it, it is redirected automatically).
2. The leader starts the FSM and performs the Scatter/Gather process as described above.

This mechanism ensures that any configuration change, regardless of its nature, goes through a strict validation and quorum confirmation procedure.

The main commands supported by this mechanism:

- `UpdateConfig`: Make partial changes to the current configuration. The changes are transmitted as a `TStorageConfig` protobuf message.
- `QueryConfig`: Request the current and proposed configuration. The response contains `TStorageConfig` protobuf messages.
- `ReplaceStorageConfig`: Replace the current configuration with a new one, passed as YAML.
- `FetchStorageConfig`: Return the loaded YAML cluster configuration.
- `ReassignGroupDisk`: Replace a disk in a static storage group.
- `StaticVDiskSlain`: Handle a VDisk failure event in a static group.
- `DropDonor`: Remove donor disks after data migration is complete.
- `BootstrapCluster`: Initiate the initial creation of the cluster.

Integration and Additional Mechanisms

In addition to the main processes, Distconf works closely with other system components:

- **Distributed Storage Controller**

  The DS-controller receives configuration changes from Distconf and uses them for the operation of the distributed storage.
- **Database nodes**

  Database nodes subscribe to `TEvNodeWardenDynamicConfigPush` events to receive real-time configuration updates.
- **SelfHeal**

  When using Distconf for a static group, SelfHeal works similarly to dynamic groups.
- **Local YAML files on nodes**

  These are stored in the directory specified by the `ydbd --config-dir` server startup argument and are updated upon receiving information about each configuration change. These files are needed when a node starts to discover PDisks and other cluster nodes, as well as to establish initial network connections. The data in these files may be outdated, especially if the node has been shut down for a long time.

Basic Distconf workflow

1. When a node starts, Distconf tries to read the configuration from local PDisks.
2. It connects to a random storage node to check if the configuration is up-to-date.
3. If it fails to connect, but has a quorum of connected nodes, the node becomes the leader.
4. The leader tries to initiate the initial cluster setup, if allowed.
5. The leader sends the current configuration to all nodes via Scatter/Gather.
6. Nodes save the received configuration in the local PDisk metadata area and in the `--config-dir` directories.

Final configuration distribution

Storage location	Contains
`TPDiskMetadataRecord` on a quorum of PDisks	The true current configuration
Local `--config-dir` directory	Initial YAML for startup (may be outdated)
Console	Up-to-date copy (with minimal delay)
DS-controller	Subset of the configuration required for distributed storage

Bridge mode

> **Feature of Yandex Enterprise Database**
>
> This functionality is available only in the Yandex Enterprise Database. In the open-source version of YDB it is absent.

For a general description of the mode and use cases, see Bridge cluster operation mode. This article is intended for YDB developers and contributors and describes the technical implementation details of bridge mode.

YDB supports an arbitrary number of piles; for simplicity, the following discussion considers the case of two piles, referred to as pile A and pile B.

Configuration storage

Distconf stores the configuration of two static groups, two sets of state storage, as well as scheme board and board. It also stores the cluster operating mode.

The configuration of static groups, state storage, and boards uses a storage scheme with two quorum sets:

- Quorum A — includes only nodes from pile A. A write is considered successful if it has been applied on a majority of nodes in pile A and on the quorum of disks of the static group of pile A;
- Quorum B — includes only nodes from pile B. A write is considered successful if it has been applied on a majority of nodes in pile B and on the quorum of disks of the static group of pile B.

If one of the piles fails, writing to the corresponding quorum becomes impossible.

Distconf uses both quorums (A and B) to store configuration:

- Configuration with mode `PRIMARY/DISCONNECTED` is written only to quorum A;
- Configuration with mode `DISCONNECTED/PRIMARY` is written only to quorum B;
- All other modes are written to both quorums — A and B.

When performing failover, the administrator puts the cluster into mode `PRIMARY/DISCONNECTED` or `DISCONNECTED/PRIMARY`. In this mode, the configuration of shared components is stored only on the quorum of the `PRIMARY` pile.

To start recovery, the administrator puts the pair of the live pile and the failed pile into mode `PRIMARY/NOT_SYNCHRONIZED`. This configuration is stored on all quorums.

Writing configuration is forbidden if the new configuration is incompatible with the last one stored on the node. For example, a transition from `PRIMARY/DISCONNECTED` to `DISCONNECTED/PRIMARY` is not allowed. This prevents a situation where pile A and pile B simultaneously switch to modes that both claim the `PRIMARY` role.

To prevent pile A and pile B from interacting when configurations conflict, interconnect session establishment is blocked when such inconsistencies are detected on nodes.

When operating in bridge mode, Distconf creates a subtree in each pile, and the roots of these subtrees are attached to the Distconf leader. This minimizes the reconfiguration of Distconf node links when a pile is lost.

Starting static groups

The configuration of all static groups is stored in Distconf. The root of the Distconf subtree in each pile can obtain the configuration and decide which quorum is required to apply it based on that configuration. A `DISCONNECTED` pile does not participate in the quorum; therefore, applying configuration without a `DISCONNECTED` pile requires quorums A and B; applying configuration `PRIMARY/DISCONNECTED` requires only quorum A; applying configuration `DISCONNECTED/PRIMARY` requires only quorum B.

When the required quorum is formed, Distconf applies the configuration, and the Node Warden starts the VDisk and PDisk of the static groups.

Access to the static group is provided by the `dsproxy-proxy` service, which exposes the dsproxy interface to tablets and performs operations synchronously with both groups in the pair.

The dsproxy-proxy of a static group changes its operating mode according to the configuration received from Distconf. The dsproxy-proxy configuration is stored in the configuration of the shared components.

dsproxy-proxy behavior

In mode `PRIMARY/SYNCHRONIZED`, writes are performed synchronously to both groups; reads are performed from the `PRIMARY`, and each read issues a ping request to the second group to ensure timely detection of link failure or a change in that group's operating mode.

In mode `PRIMARY/DISCONNECTED`, reads and writes are performed only in the `PRIMARY` group.

In mode `PRIMARY/NOT_SYNCHRONIZED`, dsproxy-proxy supports several submodes that determine which kinds of writes are performed in the `NOT_SYNCHRONIZED` group:

- `WRITE_KEEP` — only `KEEP` flags are written;
- `WRITE_KEEP_BARRIER_DONOTKEEP` — barriers and `KEEP` and `DO_NOT_KEEP` flags are written;
- `WRITE_KEEP_BARRIER_DONOTKEEP_DATA` — data, barriers, and `KEEP` and `DO_NOT_KEEP` flags are written.

The dsproxy-proxy configuration includes:

- mode;
- submode;
- `PPGeneration` — the generation number of the dsproxy-proxy configuration;
- the generation number of the dsproxy group configuration from pile A;
- the generation number of the dsproxy group configuration from pile B.

When the dsproxy-proxy configuration changes, the configuration generation number and the group configuration generation are always updated for the `PRIMARY` group; for the others, they are updated except when in the `DISCONNECTED` state.

The group configuration includes:

- mode;
- submode;
- `PPGeneration` — the generation number of the controlling dsproxy-proxy configuration.

On each operation, the group checks the mode, submode, and `PPGeneration`. This ensures that operations from stale dsproxy-proxy instances that missed a mode or submode change are not executed, and avoids cross-interaction when two `PRIMARY` instances appear.

To transition from mode `PRIMARY/NOT_SYNCHRONIZED` to `PRIMARY/SYNCHRONIZED`, synchronization is performed. During synchronization, missing data is copied from the `PRIMARY` group to the `NOT_SYNCHRONIZED` group, and lock information is copied in both directions.

Bootstrap of BSController and other system tablets

The node list for starting a tablet need only specify one set of nodes that includes a sufficient number of nodes from each pile. The Bootstrapper must analyze the state storage proxy-proxy configuration and use it to determine whether the tablet can be started on a given node. If the tablet cannot be started on the node (because the node is not in the `PRIMARY` pile), the Bootstrapper must walk the tree of Bootstrappers connected to it and assign as the launcher a Bootstrapper from the `PRIMARY` pile. If no such Bootstrapper exists, the current Bootstrapper must not start the tablet.

Configuration and startup of other tablets

Dynamic storage groups are managed by the BS Controller. Instead of a single regular storage pool each time, three storage pools are created: in pool A — groups from pile A; in pool B — groups from pile B; in pool C — proxy-proxy groups formed from pairs of groups from pools A and B. Tablets managed by Hive use only the proxy-proxy groups from pool C.

Tablets are started only in the `PRIMARY` or `PROMOTED` pile. Moving tablets from `PRIMARY` to `PROMOTED` is done as smoothly as possible; moving tablets from `DISCONNECTED` to `PRIMARY` is done as quickly as possible.

Interconnect behavior

In the interconnect, metadata exchange is separated from session establishment. Metadata exchange occurs before session establishment and allows a pair of nodes to determine the set of interconnect features in use and to exchange configuration. The interconnect with nodes from the disconnected half of the cluster is torn down, and no connection attempts are made. Connection establishment is only possible after the pile is moved to state `PRIMARY/NOT_SYNCHRONIZED`.

Spilling Service

Overview

The **Spilling Service** is an actor service that provides temporary storage for data blobs in the YDB system. The service operates as a key-value store where clients can save data using a unique identifier and later retrieve it with that identifier.

Architecture

Main Components

- **Task queue**: The service maintains an internal queue of read and write operations. All spilling requests are placed in this queue and processed asynchronously.
- **Thread pool**: A pool of worker threads is used to perform I/O operations.
- **File management**: The service automatically creates, deletes, and manages files on disk.
- **Resource monitoring**: The service monitors disk space usage, the number of active operations, and other performance metrics.

Data Storage

Data is saved in files on the local file system. The Spilling Service ensures:

- distribution of records across files
- file deletion
- data lifecycle management

In case of an unexpected restart, obsolete files are automatically deleted.

Component Interaction

System components are integrated with the Spilling Service and interact with it through actor system events, explained below.

Memory State Monitoring

Compute nodes continuously monitor memory state through the allocator. The allocator informs nodes about decreasing free memory volume. However, the system does not wait for complete memory exhaustion because the spilling process also requires additional memory resources for serialization and buffering.

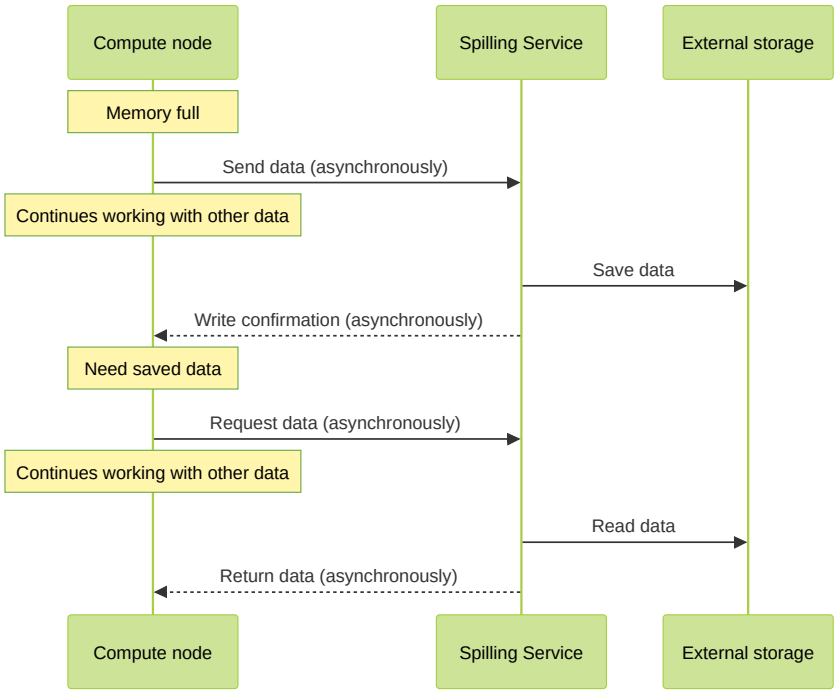
Event Dispatch

When spilling is required, the compute component (data transfer system or compute core) performs the following actions:

1. Serializes data into a blob.
2. Generates a unique identifier for the blob.
3. Creates a spilling request with the blob and the generated identifier.
4. Sends the request to the Spilling Service.
5. Releases resources and enters waiting mode, allowing other tasks to utilize computational resources.

Waiting for Results

After sending the request, the compute component releases resources for other tasks and enters waiting mode, allowing the system to optimally utilize cluster computing resources until the external storage write is complete.



Response Handling

The Spilling Service processes the request and returns a write confirmation for the specified identifier or an error message. The compute component can continue only after receiving confirmation.

Data Reading

When data recovery is needed, the component sends a read request with the blob identifier. The Spilling Service reads data from external storage and returns a response with the recovered data. During data loading, freed computational resources are utilized to process other tasks.

Spilling Workflow Diagram

Configuration

Detailed information about configuring the Spilling Service is available in the Spilling configuration section.

Overview of testing with load actors

Testing system performance is an important stage of adding changes to the YDB core. With load testing, you can:

- Determine the performance metrics and compare them to the values before the changes.
- Test how the system runs under high or peak loads.

The task to load a high-performance distributed system is non-trivial. A software developer often has to run multiple client instances to achieve the required server load. YDB implements a simple and convenient load generation mechanism: load actors. Actors are created and run directly on a cluster, which allows avoiding the use of additional resources for starting client instances. Load actors can be run on arbitrary cluster nodes: one, all, or only selected ones. You can create any number of actors on any node.

With load actors, you can test both the entire system and its individual components:

KeyValueLoad

KeyValueLoad

StorageLoad

StorageLoad

VDiskLoad

For example, you can generate a load on Distributed Storage without using tablet and Query Processor layers. This lets you test different system layers separately and find bottlenecks in an efficient way. By combining a variety of actor types, you can run different types of load.

> **Note**
>
> This feature is under development; the source code is available in the *main* branch of the YDB repository. To learn how to build YDB from the source code, see the instructions.

Actor types

Type	Description
KqpLoad	Generates a load on the Query Processor layer and loads all cluster components.
KeyValueLoad	Loads a key-value tablet.
StorageLoad	Loads Distributed Storage without using tablet and Query Processor layers.
VDiskLoad	Tests the performance of writes to the VDisk.
PDiskWriteLoad	Tests the performance of writes to the PDisk.
PDiskReadLoad	Tests the performance of reads from the PDisk.
PDiskLogLoad	Tests if cuts from the middle of the PDisk log are correct.
MemoryLoad	Allocates memory, useful when testing the logic.

Stop	Stops either all or only the specified actors.

Running a load

You can run load using the following tools:

- Cluster YDB UI: Allows you to create, based on a configuration, and start a load actor either on the current node or all tenant nodes at once.
- The `ydbd` utility: Allows you to send the actor configuration to any cluster node specifying the nodes to create and run the actor on.

The use case described below shows how to create and run the KqpLoad actor. The actor accesses the `/slice/db` database as a key-value store using 64 threads with a 30-second load. Before the test, the actor creates the necessary tables and deletes them once the test is completed. When being created, the actor is automatically assigned a tag. The same tag will be assigned to the test result.

YDB UI

1. Open the page for managing load actors on the desired node (for example, `http://<address>:8765/actors/load`, where `address` is the address of the cluster node to run the load on).
2. Paste the actor configuration into the input/output field:

```
KqpLoad: {
    DurationSeconds: 30
    WindowDuration: 1
    WorkingDir: "/slice/db"
    NumOfSessions: 64
    UniformPartitionsCount: 1000
    DeleteTableOnFinish: 1
    WorkloadType: 0
    Kv: {
        InitRowCount: 1000
        PartitionsByLoad: true
        MaxFirstKey: 18446744073709551615
        StringLen: 8
        ColumnsCnt: 2
        RowsCnt: 1
    }
}
```

3. To create and run the actor, click:

- **Start new load on current node**: Runs the load on the current node.
- **Start new load on all tenant nodes**: Runs the load on all the tenant nodes at once.

You'll see the following message in the input/output field:

```
{"status":"OK","tag":1}
```

- `status`: Load run status.
- `tag`: Tag assigned to the load.

CLI

1. Create an actor configuration file:

```
KqpLoad: {
    DurationSeconds: 30
    WindowDuration: 1
    WorkingDir: "/slice/db"
    NumOfSessions: 64
    UniformPartitionsCount: 1000
    DeleteTableOnFinish: 1
    WorkloadType: 0
    Kv: {
        InitRowCount: 1000
        PartitionsByLoad: true
        MaxFirstKey: 18446744073709551615
        StringLen: 8
        ColumnsCnt: 2
        RowsCnt: 1
    }
}
```

2. Start the actor:

```
curl <endpoint>/actors/load -H "Content-Type: application/x-protobuf-text" --data mode=start --data all_nodes
=<start_on_all_nodes> --data config="$(cat proto_file)"
```

- `endpoint`: Node HTTP endpoint (for example, `http://<address>:<port>`, where `address` is the node address and `port` is the node HTTP port).
- `proto_file`: Path to the actor configuration file.
- `start_on_all_nodes`: `true` to start load on all nodes of a tenant, `false` to start load only on node with given `endpoint`.

Viewing test results

You can view the test results using the YDB UI. For a description of output parameters, see the documentation of the respective actor.

YDB UI

1. Open the page for managing load actors on the desired node (for example, `http://<address>:<port>/actors/load`, where `address` is the node address and `port` is the HTTP port used for monitoring the node under load).
2. Click **Results**.

This shows the results of completed tests. Find the results with the appropriate tag.

Query Processor Load

Runs general performance testing for the YDB cluster by loading all components via the Query Processor layer. The load is similar to that from the workload YDB CLI subcommand, but it is generated from within the cluster.

You can run two types of load:

- **Stock**: Simulates a warehouse of an online store: creates multi-product orders, gets a list of orders per customer.
- **Key-value**: Uses the DB as a key-value store.

Before this test, the necessary tables are created. After it's completed, they are deleted.

Actor parameters

The basic actor parameters are described below. For the full list of parameters, see the load_test.proto file in the YDB Git repository.

Parameter	Description
`DurationSeconds`	Load duration in seconds.
`WindowDuration`	Statistics aggregation window duration.
`WorkingDir`	Path to the directory to create test tables in.
`NumOfSessions`	The number of parallel threads creating the load. Each thread writes data to its own session.
`DeleteTableOnFinish`	Set it to `False` if you do not want the created tables deleted after the load stops. This might be helpful when a large table is created upon the actor's first run, and then queries are made to that table.
`UniformPartitionsCount`	The number of partitions created in test tables.
`WorkloadType`	Type of load. For Stock: • `0`: InsertRandomOrder. • `1`: SubmitRandomOrder. • `2`: SubmitSameOrder. • `3`: GetRandomCustomerHistory. • `4`: GetCustomerHistory. For Key-Value: • `0`: UpsertRandom. • `1`: InsertRandom. • `2`: SelectRandom.
`Workload`	Kind of load. `Stock`: • `ProductCount`: Number of products. • `Quantity`: Quantity of each product in stock. • `OrderCount`: Initial number of orders in the database. • `Limit`: Minimum number of shards for tables. `Kv`: • `InitRowCount`: Before load is generated, the load actor writes the specified number of rows to the table. • `StringLen`: Length of the `value` string. • `ColumnsCnt`: Number of columns to use in the table. • `RowsCnt`: Number of rows to insert or read per SQL query.

Examples

The following actor runs a stock load on the `/slice/db` database by making simple UPSERT queries of `64` threads during `30` seconds.

```
KqpLoad: {
    DurationSeconds: 30
    WindowDuration: 1
    WorkingDir: "/slice/db"
    NumOfSessions: 64
    UniformPartitionsCount: 1000
    DeleteTableOnFinish: 1
    WorkloadType: 0
    Stock: {
        ProductCount: 100
        Quantity: 1000
        OrderCount: 100
        Limit: 10
    }
}
```

As a result of the test, the number of successful transactions per second, the number of transaction execution retries, and the number of errors are output.

KeyValueLoad

Loads a key-value tablet.

Actor configuration

```
message TKeyValueLoad {
    message TWorkerConfig {
        optional string KeyPrefix = 1;
        optional uint32 MaxInFlight = 2;
        optional uint32 Size = 11; // data size, bytes
        optional bool IsInline = 9 [default = false];
        optional uint32 LoopAtKeyCount = 10 [default = 0]; // 0 means "do not loop"
    }
    optional uint64 Tag = 1;
    optional uint64 TargetTabletId = 2;
    optional uint32 DurationSeconds = 5;
    repeated TWorkerConfig Workers = 7;
}
```

StorageLoad

Tests the read/write performance to and from Distributed Storage. The load is generated on Distributed Storage directly without using any tablet and Query Processor layers. When testing write performance, the actor writes data to the specified storage group. To test read performance, the actor first writes data to the specified storage group and then reads the data. After the load is removed, all the data written by the actor is deleted.

You can generate three types of load:

- **Continuous:** The actor ensures that the specified number of requests are running concurrently. To generate a continuous load, set a zero interval between requests (e.g., `WriteIntervals: { Weight: 1.0 Uniform: { MinUs: 0 MaxUs: 0 } }`), while keeping the `MaxInFlightWriteRequests` parameter value different from zero and omit the `WriteHardRateDispatcher` parameter.
- **Interval:** The actor runs requests at specific intervals. To generate an interval load, set a non-zero interval between requests, e.g., `WriteIntervals: { Weight: 1.0 Uniform: { MinUs: 50000 MaxUs: 50000 } }` and don't set the `WriteHardRateDispatcher` parameter. The maximum number of in-flight requests is set by the `InFlightWrites` parameter (0 means unlimited).
- **Hard rate:** The actor runs requests at certain intervals, but the interval length is adjusted to maintain a configured request rate per second. If the duration of the load is limited by `LoadDuration` than the request rate may differ between start and finish of the workload and will adjust gradually throughout all the main load cycle. To generate a load of this type, set the parameters of hard rate load (parameter `WriteHardRateDispatcher`). Note that if this parameter is set, the hard rate type of load will be launched, regardless the value of the `WriteIntervals` parameter. The maximum number of in-flight requests is set by the `InFlightWrites` parameter (0 means unlimited).

Actor parameters

The basic actor parameters are described below. For the full list of parameters, see the load_test.proto file in the YDB Git repository.

Parameter	Description
`DurationSeconds`	Load duration. The timer starts upon completion of the initial data allocation.
`Tablets`	The load is generated on behalf of a tablet with the following parameters: • `TabletId`: Tablet ID. It must be unique for each load actor across all the cluster nodes. This parameter and `TabletName` are mutually exclusive. • `TabletName`: Tablet name. If the parameter is set, tablets' IDs will be assigned automatically, tablets launched on the same node with the same name will be given the same ID, tablets launched on different nodes will be given different IDs. • `Channel`: Tablet channel. • `GroupId`: ID of the storage group to get loaded. • `Generation`: Tablet generation.
`WriteSizes`	Size of the data to write. It is selected randomly for each request from the `Min` - `Max` range. You can set multiple `WriteSizes` ranges, in which case a value from a specific range will be selected based on its `Weight`.
`WriteHardRateDispatcher`	Setting up the parameters of load with hard rate for write requests. If this parameter is set than the value of `WriteIntervals` is ignored.
`WriteIntervals`	Setting up the parameters for probabilistic distribution of intervals between the records loaded at intervals (in milliseconds). You can set multiple `WriteIntervals` ranges, in which case a value from a specific range will be selected based on its `Weight`.
`MaxInFlightWriteRequests`	The maximum number of write requests being processed simultaneously.
`ReadSizes`	Size of the data to read. It is selected randomly for each request from the `Min` - `Max` range. You can set multiple `ReadSizes` ranges, in which case a value from a specific range will be selected based on its `Weight`.
`WriteHardRateDispatcher`	Setting up the parameters of load with hard rate for read requests. If this parameter is set than the value of `ReadIntervals` is ignored.
`ReadIntervals`	Setting up the parameters for probabilistic distribution of intervals between the queries loaded by intervals (in milliseconds). You can set multiple `ReadIntervals` ranges, in which case a value from a specific range will be selected based on its `Weight`.
`MaxInFlightReadRequests`	The maximum number of read requests being processed simultaneously.
`FlushIntervals`	Setting up the parameters for probabilistic distribution of intervals (in microseconds) between the queries used to delete data written by the write requests in the main load cycle of the StorageLoad actor. You can set multiple `FlushIntervals` ranges, in which case a value from a specific range will be selected based on its `Weight`. Only one flush request will be processed concurrently.
`PutHandleClass`	Class of data writes to the disk subsystem. If the `TabletLog` value is set, the write operation has the highest priority.
`GetHandleClass`	Class of data reads from the disk subsystem. If the `FastRead` is set, the read operation is performed with the highest speed possible.
`Initial allocation`	Setting up the parameters for initial data allocation. It defines the amount of data to be written before the start of the main load cycle. This data can be read by read requests along with the data written in the main load cycle.

Write requests class

Class	Description
`TabletLog`	The highest priority of write operation.

`AsyncBlob`	Used for writing SSTables and their parts.
`UserData`	Used for writing user data as separate blobs.

Read requests class

Class	Description
`AsyncRead`	Used for reading compacted tablets' data.
`FastRead`	Used for fast reads initiated by user.
`Discover`	Reads from Discover query.
`LowRead`	Low priority reads executed on the background.

Parameters of probabilistic distribution

An interval written as a repeated `TIntervalInfo` field is calculated by the following algorithm:

- An element from the `TIntervalInfo` array is selected at random with the probability proportionate to its weight.
- For an element of the `TIntervalUniform` type, the value is chosen with equal probability in the range Min-Max. `Min-Max` (if `MinMs/MaxMs` is used, the value is in milliseconds; if `MinUs/MaxUs` is used, the value is in microseconds).
- For an element of the `TIntervalPoisson` type, the interval is selected using the formula `Min(log(-x / Frequency), MaxIntervalMs)`, where `x` is a random value in the interval `[0, 1]`. As a result, the intervals follow the Poisson distribution with the given `Frequency`, but with the interval within `MaxIntervalMs`.

A similar approach is used for the probabilistic distribution of the size of the written data. However, in this case, only the data size follows a uniform probability distribution, within the interval `[Min, Max]`.

Parameters of load with hard rate

Parameter	Description
`RequestRateAtStart`	Requests per second at the moment of load start. If load duration limit is not set then the request rate will remain the same and equal to the value of this parameter.
`RequestRateOnFinish`	Requests per second at the moment of load finish.

Parameters of initial data allocation

Parameter	Description
`TotalSize`	Total size of allocated data. This parameter and `BlobsNumber` are mutually exclusive.
`BlobsNumber`	Total number of allocated blobs.
`BlobSizes`	Size of the blobs to write. It is selected randomly for each request from the `Min` - `Max` range. You can set multiple `WriteSizes` ranges, in which case a value from a specific range will be selected based on its `Weight`.
`MaxWritesInFlight`	Maximum number of simultaneously processed write requests. If this parameter is not set then the number of simultaneously processed requests is not limited.
`MaxWriteBytesInFlight`	Maximum number of total amount of simultaneously processed write requests' data. If this parameter is not set then the total amount of data being written concurrently is unlimited.
`PutHandleClass`	Class of data writes to the disk subsystem.
`DelayAfterCompletionSec`	The amount of time in seconds the actor will wait upon completing the initial data allocation before starting the main load cycle. If its value is `0` or not set the load will start immediately after the completion of the data allocaion.

An interval written as a repeated `TIntervalInfo` field is calculated by the following algorithm:

- An element from the `TIntervalInfo` array is selected at random with the probability proportionate to its weight.
- For an element of the `TIntervalUniform` type, the value is chosen with equal probability in the range Min-Max. `Min-Max` (if `MinMs/MaxMs` is used, the value is in milliseconds; if `MinUs/MaxUs` is used, the value is in microseconds).
- For an element of the `TIntervalPoisson` type, the interval is selected using the formula `Min(log(-x / Frequency), MaxIntervalMs)`, where `x` is a random value in the interval `[0, 1]`. As a result, the intervals follow the Poisson distribution with the given `Frequency`, but with the interval within `MaxIntervalMs`.

A similar approach is used for the probabilistic distribution of the size of the written data. However, in this case, only the data size follows a uniform probability distribution, within the interval `[Min, Max]`.

Examples

Write load

The following actor writes data to the group with the ID `2181038080` during `60` seconds. The size per write is `4096` bytes, the number of in-flight requests is no more than `256` (continuous load):

```
StorageLoad: {
    DurationSeconds: 60
    Tablets: {
        Tablets: { TabletId: 1000 Channel: 0 GroupId: 2181038080 Generation: 1 }
        WriteSizes: { Weight: 1.0 Min: 4096 Max: 4096 }
        WriteIntervals: { Weight: 1.0 Uniform: { MinUs: 0 MaxUs: 0 } }
        MaxInFlightWriteRequests: 256
        FlushIntervals: { Weight: 1.0 Uniform: { MinUs: 10000000 MaxUs: 10000000 } }
        PutHandleClass: TabletLog
    }
}
```

When viewing test results, the following values should be of most interest to you:

- `Writes per second`: Number of writes per second, e.g., `28690.29`.
- `Speed@ 100%`: 100 percentile of write speed in MB/s, e.g., `108.84`.

Read load

To generate a read load, you need to write data first. Data is written by requests of `4096` bytes every `50` ms with no more than `1` in-flight request (interval load). If a request fails to complete within `50` ms, the actor will wait until it is complete and run another request in `50` ms. Data older than `10` s is deleted. Data reads are performed by requests of `4096` bytes with `16` in-flight requests allowed (continuous load):

```
StorageLoad: {
    DurationSeconds: 60
    Tablets: {
        Tablets: { TabletId: 5000 Channel: 0 GroupId: 2181038080 Generation: 1 }
        WriteSizes: { Weight: 1.0 Min: 4096 Max: 4096}
        WriteIntervals: { Weight: 1.0 Uniform: { MinUs: 50000 MaxUs: 50000 } }
        MaxInFlightWriteRequests: 1

        ReadSizes: { Weight: 1.0 Min: 4096 Max: 4096 }
        ReadIntervals: { Weight: 1.0 Uniform: { MinUs: 0 MaxUs: 0 } }
        MaxInFlightReadRequests: 16
        FlushIntervals: { Weight: 1.0 Uniform: { MinUs: 10000000 MaxUs: 10000000 } }
        PutHandleClass: TabletLog
        GetHandleClass: FastRead
    }
}
```

When viewing test results, the following value should be of most interest to you:

- `ReadSpeed@ 100%`: 100 percentile of read speed in MB/s, e.g., `60.86`.

Read only

Before the start of the main load cycle the `1 GB` data block of blobs with sizes between `1 MB` and `5 MB` is allocated. To avoid overloading the system with write requests the number of simultaneously processed requests is limited by the value of `5`. After completing the initial data allocation the main cycle is launched. It consists of read requests sent with increasing rate: from `10` to `50` requests per second, the rate will increase gradually for `300` seconds.

```
StorageLoad: {
    DurationSeconds: 300
    Tablets: {
        Tablets: { TabletId: 5000 Channel: 0 GroupId: 2181038080 Generation: 1 }

        MaxInFlightReadRequests: 10
        GetHandleClass: FastRead
        ReadHardRateDispatcher {
                RequestsPerSecondAtStart: 10
                RequestsPerSecondOnFinish: 50
        }

        InitialAllocation {
                TotalSize: 1000000000
                BlobSizes: { Weight: 1.0 Min: 1000000 Max: 5000000 }
                MaxWritesInFlight: 5
        }
    }
}
```

Calculated percentiles will only represent the requests of the main load cycle and won't include write requests sent during the initial data allocation. The graphs in Monitoring should be of interest, for example, they allow to trace the request latency degradation caused by the increasing load.

VDiskLoad

Generates a write-only load on the VDisk. Simulates a Distributed Storage Proxy. The test outputs the VDisk write performance in operations per second.

Actor parameters

The basic actor parameters are described below. For the full list of parameters, see the load_test.proto file in the YDB Git repository.

Parameter	Description
`VDiskId`	Parameters of the VDisk used to generate load. • `GroupID`: Group ID. • `GroupGeneration`: Group generation. • `Ring`: Group ring ID. • `Domain`: Ring fail domain ID. • `VDisk`: Index of the VDisk in the fail domain.
`GroupInfo`	Description of the group hosting the loaded VDisk (of the appropriate generation).
`TabletId`	ID of the tablet that generates the load. It must be unique for each load actor.
`Channel`	ID of the channel inside the tablet that will be specified in the BLOB write and garbage collection commands.
`DurationSeconds`	The total test time in seconds; when it expires, the load stops automatically.
`WriteIntervals`	Setting up the parameters for probabilistic distribution of intervals between the records.
`WriteSizes`	Size of the data to write. It is selected randomly for each request from the `Min`-`Max` range. You can set multiple `WriteSizes` ranges, in which case a value from a specific range will be selected based on its `Weight`.
`InFlightPutsMax`	Maximum number of concurrent BLOB write queries against the VDisk (TEvVPut queries); if omitted, the number of queries is unlimited.
`InFlightPutBytesMax`	Maximum number of bytes in the concurrent BLOB write queries against the VDisk (TEvVPut-requests).
`PutHandleClass`	Class of data writes to the disk subsystem. If the `TabletLog` value is set, the write operation has the highest priority.
`BarrierAdvanceIntervals`	Setting up the parameters for probabilistic distribution of intervals between the advance of the garbage collection barrier and the write step.
`StepDistance`	Distance between the currently written step `Gen:Step` of the BLOB and its currently collected step. The higher is the value, the more data is stored. Data is written from `Step = X` and deleted from all the BLOBs where `Step = X - StepDistance`. The `Step` is periodically incremented by one (with the `BarrierAdvanceIntervals` period).

Parameters of probabilistic distribution

An interval written as a repeated `TIntervalInfo` field is calculated by the following algorithm:

- An element from the `TIntervalInfo` array is selected at random with the probability proportionate to its weight.
- For an element of the `TIntervalUniform` type, the value is chosen with equal probability in the range Min-Max. `Min-Max` (if `MinMs/MaxMs` is used, the value is in milliseconds; if `MinUs/MaxUs` is used, the value is in microseconds).
- For an element of the `TIntervalPoisson` type, the interval is selected using the formula `Min(log(-x / Frequency), MaxIntervalMs)`, where `x` is a random value in the interval `[0, 1]`. As a result, the intervals follow the Poisson distribution with the given `Frequency`, but with the interval within `MaxIntervalMs`.

A similar approach is used for the probabilistic distribution of the size of the written data. However, in this case, only the data size follows a uniform probability distribution, within the interval `[Min, Max]`.

PDiskWriteLoad

Tests the performance of writes to the PDisk. The load is generated on behalf of a VDisk. The actor creates chunks on the specified PDisk and writes random data to them. After the load stops, the data written by the actor is deleted.

You can generate two types of load:

- **Continuous:** The actor ensures the specified number of requests are run concurrently. To generate a continuous load, set a zero interval between requests, e.g., `IntervalMsMin: 0` and `IntervalMsMax: 0`, while keeping the `InFlightWrites` parameter different from zero.
- **Interval:** The actor runs requests at preset intervals. To generate interval load, set a non-zero interval between requests, e.g., `IntervalMsMin: 10` and `IntervalMsMax: 100`. You can set the maximum number of in-flight requests using the `InFlightWrites` parameter. If its value is `0`, their number is unlimited.

Actor parameters

The basic actor parameters are described below. For the full list of parameters, see the load_test.proto file in the YDB Git repository.

Parameter	Description
`PDiskId`	ID of the Pdisk being loaded on the node.
`PDiskGuid`	Globally unique ID of the PDisk being loaded.
`VDiskId`	The load is generated on behalf of a VDisk with the following parameters: • `GroupID`: Group ID. • `GroupGeneration`: Group generation. • `Ring`: Group ring ID. • `Domain`: Ring fail domain ID. • `VDisk`: Index of the VDisk in the fail domain.
`Chunks`	Chunk parameters. `Slots`: Number of slots per chunk, determines the write size. You can specify multiple `Chunks`, in which case a specific chunk to write data to is selected based on its `Weight`.
`DurationSeconds`	Load duration in seconds.
`IntervalMsMin`, `IntervalMsMax`	Minimum and maximum intervals between requests under interval load, in milliseconds. The interval value is selected randomly from the specified range.
`InFlightWrites`	Number of simultaneously processed write requests.
`LogMode`	Logging mode. In `LOG_SEQUENTIAL` mode, data is first written to a chunk and then, once the write is committed, to a log.
`Sequential`	Type of writes. • `True`: Sequential. • `False`: Random.
`IsWardenlessTest`	Set it to `False` in case the PDiskReadLoad actor is run on the cluster; otherwise, e.g. when it is run during unit tests, set it to `True`.

Examples

The following actor writes data blocks of `32` MB during `120` seconds with `64` in-flight requests (continuous load):

```
PDiskWriteLoad: {
    PDiskId: 1000
    PDiskGuid: 2258451612736857634
    VDiskId: {
        GroupID: 11234
        GroupGeneration: 5
        Ring: 1
        Domain: 1
        VDisk: 3
    }
    Chunks: { Slots: 4096 Weight: 1 }
    Chunks: { Slots: 4096 Weight: 1 }
    Chunks: { Slots: 4096 Weight: 1 }
    Chunks: { Slots: 4096 Weight: 1 }
    Chunks: { Slots: 4096 Weight: 1 }
    Chunks: { Slots: 4096 Weight: 1 }
    Chunks: { Slots: 4096 Weight: 1 }
    Chunks: { Slots: 4096 Weight: 1 }
    DurationSeconds: 120
    IntervalMsMin: 0
    IntervalMsMax: 0
    InFlightWrites: 64
    LogMode: LOG_SEQUENTIAL
    Sequential: false
    IsWardenlessTest: false
}
```

When viewing test results, the following value should be of most interest to you:

- `Average speed since start`: Average write speed since start, in MB/s, e.g., `615.484013`.

PDiskReadLoad

Tests the performance of reads from the PDisk. The load is generated on behalf of a VDisk. The actor creates chunks on the specified PDisk, writes random data to them, and reads the data from them using the specified parameters. After the load stops, the data written by the actor is deleted.

You can generate two types of load:

- **Continuous:** The actor ensures the specified number of requests are run concurrently. To generate continuous load, set a zero interval between requests (e.g., `IntervalMsMin: 0` and `IntervalMsMax: 0`), while keeping the `InFlightReads` parameter different from zero.
- **Interval:** The actor runs requests at preset intervals. To generate interval load, set a non-zero interval between requests, e.g., `IntervalMsMin: 10` and `IntervalMsMax: 100`. You can set the maximum number of in-flight requests using the `InFlightReads` parameter. If its value is `0`, their number is unlimited.

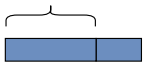
Actor parameters

The basic actor parameters are described below. For the full list of parameters, see the load_test.proto file in the YDB Git repository.

Parameter	Description
`PDiskId`	ID of the Pdisk being loaded on the node.
`PDiskGuid`	Globally unique ID of the PDisk being loaded.
`VDiskId`	The load is generated on behalf of a VDisk with the following parameters: • `GroupID`: Group ID. • `GroupGeneration`: Group generation. • `Ring`: Group ring ID. • `Domain`: Ring fail domain ID. • `VDisk`: Index of the VDisk in the fail domain.
`Chunks`	Chunk parameters. `Slots`: Number of slots per chunk, determines the write size. You can specify multiple `Chunks`, in which case a specific chunk to read data from is selected based on its `Weight`.
`DurationSeconds`	Load duration in seconds.
`IntervalMsMin`, `IntervalMsMax`	Minimum and maximum intervals between requests under interval load, in milliseconds. The interval value is selected randomly from the specified range.
`InFlightReads`	Number of simultaneously processed read requests.
`Sequential`	Type of reads. • `True`: Sequential. • `False`: Random.
`IsWardenlessTest`	Set it to `False` in case the PDiskReadLoad actor is run on the cluster; otherwise, e.g. when it is run during unit tests, set it to `True`.

Examples

The following actor reads data blocks of 32 MB during 120 seconds with 64 in-flight requests (continuous load):



```
PDiskReadLoad: {
    PDiskId: 1000
    PDiskGuid: 2258451612736857634
    VDiskId: {
        GroupID: 11234
        GroupGeneration: 5
        Ring: 1
        Domain: 1
        VDisk: 3
    }
    Chunks: { Slots: 4096 Weight: 1 }
    Chunks: { Slots: 4096 Weight: 1 }
    Chunks: { Slots: 4096 Weight: 1 }
    Chunks: { Slots: 4096 Weight: 1 }
    Chunks: { Slots: 4096 Weight: 1 }
    Chunks: { Slots: 4096 Weight: 1 }
    Chunks: { Slots: 4096 Weight: 1 }
    Chunks: { Slots: 4096 Weight: 1 }
    DurationSeconds: 120
    IntervalMsMin: 0
    IntervalMsMax: 0
    InFlightReads: 64
    Sequential: false
    IsWardenlessTest: false
}
```

When viewing test results, the following value should be of most interest to you:

- `Average speed since start`: Average read speed since start, in MB/s, e.g., `1257.148154`.

PDiskLogLoad

All VDisks hosted on a certain PDisk log data about their own performance to the common PDisk log. VDisks gradually delete their obsolete data at the beginning of the log to free up disk space. Sometimes, after one VDisk completes logging data and before another one starts logging it, a section with useless obsolete data may appear. In this case, such data is deleted automatically, and the PDiskLogLoad actor will perform a test to check whether such an operation is running correctly.

> This ad-hoc actor is used for testing specific functionality. This is not a load actor. It is designed to check whether something works properly.

Actor parameters

The basic actor parameters are described below. For the full list of parameters, see the load_test.proto file in the YDB Git repository.

Parameter	Description
`PDiskId`	ID of the Pdisk being loaded on the node.
`PDiskGuid`	Globally unique ID of the PDisk being loaded.
`VDiskId`	Parameters of the VDisk used to generate load. • `GroupID`: Group ID. • `GroupGeneration`: Group generation. • `Ring`: Group ring ID. • `Domain`: Ring fail domain ID. • `VDisk`: Index of the VDisk in the fail domain.
`MaxInFlight`	Number of simultaneously processed requests.
`SizeIntervalMin`	Minimum size of log record in bytes.
`SizeIntervalMax`	Maximum size of log record in bytes.
`BurstInterval`	Interval between logging sessions in bytes.
`BurstSize`	Total amount of data to log per session, in bytes.
`StorageDuration`	Virtual time in bytes. Indicates how long the VDisk should store its data in the log.
`IsWardenlessTest`	Set it to `False` in case the PDiskReadLoad actor is run on the cluster; otherwise, e.g. when it is run during unit tests, set it to `True`.

Examples

The following actor simulates the performance of two VDisks. The first VDisk logs a message of `65536` bytes every `65536` bytes and deletes data that exceeds `1048576` bytes. The second one writes `1024` bytes as messages of `128` bytes every `2147483647` bytes and deletes data that exceeds `2147483647` bytes.

```
PDiskLogLoad: {
    Tag: 1
    PDiskId: 1
    PDiskGuid: 12345
    DurationSeconds: 60
    Workers: {
        VDiskId: {GroupID: 1 GroupGeneration: 5 Ring: 1 Domain: 1 VDisk: 1}
        MaxInFlight: 1
        SizeIntervalMin: 65536
        SizeIntervalMax: 65536
        BurstInterval: 65536
        BurstSize: 65536
        StorageDuration: 1048576
    }
    Workers: {
        VDiskId: {GroupID: 2 GroupGeneration: 5 Ring: 1 Domain: 1 VDisk: 1}
        MaxInFlight: 1
        SizeIntervalMin: 128
        SizeIntervalMax: 128
        BurstInterval: 2147483647
        BurstSize: 1024
        StorageDuration: 2147483647
    }
    IsWardenlessTest: false
}
```

The test passes if none of the cluster nodes got overloaded and the status of the PDisk in question is `Normal`. You can check this using the cluster YDB UI.

MemoryLoad

Allocates memory blocks of the specified size at certain intervals. After the load is removed, the allocated memory is released. Using this actor, you can test the logic, e.g., whether a certain trigger is fired when the RSS limit is reached.

> **Note**
>
> This ad-hoc actor is used for testing specific functionality. This is not a load actor. It is designed to check whether something works properly.

Actor parameters

Parameter	Description
`DurationSeconds`	Load duration in seconds.
`BlockSize`	Allocated block size in bytes.
`IntervalUs`	Interval between block allocations in microseconds.

Examples

The following actor allocates blocks of `1048576` bytes every `9000000` microseconds during `3600` seconds and takes up 32 GB while running:

```
MemoryLoad: {
    DurationSeconds: 3600
    BlockSize: 1048576
    IntervalUs: 9000000
}
```

Stop

Using this command, you can stop either entire load or only the specified part of it.

Actor parameters

Parameter	Description
`Tag`	Tag of the load actor to stop. You can view the tag in the cluster YDB UI.
`RemoveAllTags`	If this parameter value is set to `True`, all the load actors are stopped.

Examples

The command below stops the load tagged `123`:

```
Stop: {
    Tag: 123
}
```

To stop the entire load, run this command:

```
Stop: {
    RemoveAllTags: true
}
```

Chaos Testing

Chaos testing is a methodology for verifying the resilience of YDB by deliberately injecting failures into a running cluster. The goal is to ensure that YDB correctly survives real-world failures: node losses, network partitions, disk problems, and other abnormal situations. The **Nemesis** tool is responsible for injecting this chaos.

What Is Tested

Chaos testing verifies cluster behavior under the following types of failures:

Network Failures

- Node network isolation (blocking incoming and outgoing traffic)
- System time skew on nodes

Node Failures

- Forceful termination of cluster node processes
- Stopping and restarting nodes
- Suspending node processes

Tablet Failures

Tablets are the primary computational units of YDB. Resilience is verified by forcefully terminating various tablet types:

- **Coordinator** — distributed transaction coordinator
- **Hive** — tablet placement manager
- **BSController** — distributed storage controller
- **SchemeShard** — schema manager
- **DataShard** — data storage tablets
- **Mediator** — transaction mediator
- **PersQueue** — message queue tablets
- Other system tablets

Tablet rebalancing between nodes via Hive is also tested.

Disk Failures

- Safely taking a disk out of service on a node
- Cleaning up disks on nodes

Multi-Datacenter Cluster Scenarios

- Stopping all nodes in a single datacenter
- Network isolation of a datacenter

Bridge Mode Cluster Scenarios

- Stopping all nodes in a single pile
- Network isolation of a pile

Integration with Stress Testing

Chaos testing is typically run in conjunction with stress testing workloads from the ydb/tests/stress directory. This combination ensures that the cluster is tested under load conditions while experiencing various failure scenarios.

How Verification Works

While failures are being injected, the system checks two properties on demand:

- **Liveness** — the cluster remains available and continues to process requests
- **Safety** — no signs of data correctness violations or internal system invariant breaches appear in cluster logs and metrics

Failures are injected automatically on a schedule, and check results are aggregated and available for analysis.

The Nemesis Tool

YDB uses the **Nemesis** tool for chaos testing — a fault injection application located in the YDB repository on GitHub. It is deployed directly on the nodes of the cluster under test and manages fault injection according to a configured schedule.

> **Warning**
>
> Nemesis only works with YDB clusters that were deployed using the `ydbd_slice` utility.

Installation

Deploy Nemesis to your cluster:

```
# Single-file config (cluster.yaml contains both hosts and database template)
nemesis install --yaml-config-location /path/to/cluster.yaml

# Two-file config (separate cluster.yaml and databases.yaml)
nemesis install \
    --yaml-config-location /path/to/cluster.yaml \
    --database-config-location /path/to/databases.yaml
```

The first host in the cluster configuration becomes the orchestrator; all other hosts become agents. Services are deployed as systemd units and started automatically.

The primary way to observe a Nemesis run and inspect its results is the web UI served by the orchestrator. Open the URL printed at the end of `nemesis install` in a browser; by default it is available at:

```
http://<orchestrator_host>:31434/static/index.html
```

The UI displays:

- **Active faults** — currently injected faults and their execution logs, grouped by category (network, node, tablet, disk, datacenter, pile)
- **Schedules** — fault types registered for automatic injection, their configured intervals, and the next scheduled run
- **Manual controls** — buttons to inject individual faults on demand
- **Execution history** — past fault injections with timestamps and target hosts
- **Liveness checks** — cluster-wide health checks run by the orchestrator
- **Safety checks** — violation detectors over the local logs for the last 24 hours

The same data is available via the HTTP API on the orchestrator if you need to scrape it programmatically.

Interpreting Results

A Nemesis run is judged against two properties: **liveness** and **safety**. The pass/fail criteria are:

- **Pass** — throughout the run, all liveness checks report the cluster as healthy and all safety wardens return empty violation lists
- **Fail** — at least one liveness check reported the cluster as unavailable (cluster did not recover after a fault within the expected window), **or** at least one safety warden returned a non-empty list of violations (for example, errors or assertions in cluster logs, schemeshard inconsistencies, datashard invariant breaches)

In the UI, healthy checks appear in the violations list; failed checks display the violation messages produced by the corresponding warden.

To investigate a problem, open the failing check in the UI and read the listed violation messages.

For the meaning of individual checks and the exact patterns each warden looks for, see the Nemesis README.

Stopping Services

Stop all Nemesis services on the cluster:

```
nemesis stop --yaml-config-location /path/to/cluster.yaml
```

Extending Nemesis

To add a new chaos type (fault) or a new safety/liveness check, see the README. It describes how to implement and register new fault runners, planners, and warden classes.

YDB reference

This documentation section contains reference information about various aspects of YDB, including:

- YQL - Overview
- Using YDB UI
- Integrations YDB
- YDB CLI
- Reference for YDB SDK
- Languages and APIs
- Kafka API
- YDB Cluster Configuration
- Reference on YDB observability
- YDB DSTool overview
- ydbops utility overview
- YDB Docker container reference

YQL - Overview

YQL (YDB Query Language) is a universal declarative query language for YDB, a dialect of SQL. YQL has been natively designed for large distributed databases, and therefore has a number of differences from the SQL standard.

YDB tools support interfaces for sending YQL queries and receiving their execution results:

- YDB CLI
- YDB SDK

This documentation section contains the YQL reference that includes the sections:

- Data types with a description of data types used in YQL
- Syntax with a full list of YQL commands
- Built-in functions with a description of the available built-in functions

You can also take a tutorial to get familiar with the basic YQL commands, in the YQL tutorial section.

YQL - Overview

YQL (YDB Query Language) is a universal declarative query language for YDB, a dialect of SQL. YQL has been natively designed for large distributed databases, and therefore has a number of differences from the SQL standard.

YDB tools support interfaces for sending YQL queries and receiving their execution results:

- YDB CLI
- YDB SDK

This documentation section contains the YQL reference that includes the sections:

- Data types with a description of data types used in YQL
- Syntax with a full list of YQL commands
- Built-in functions with a description of the available built-in functions

You can also take a tutorial to get familiar with the basic YQL commands, in the YQL tutorial section.

YQL data types

This section contains articles on YQL data types:

- Simple/Primitive types
- Serial types
- Optional types
- Containers
- Special types
- Type casting
- Text representation of data types
- Data representation in JSON format

Primitive data types

The terms "simple", "primitive", and "elementary" data types are used as synonyms.

Numeric types

Type	Description	Notes
`Bool`	Boolean value.	
`Int8`	Signed integer. Valid values: from -2^7 to 2^7-1.	
`Int16`	Signed integer. Valid values: from -2^{15} to $2^{15}-1$.	
`Int32`	Signed integer. Valid values: from -2^{31} to $2^{31}-1$.	
`Int64`	Signed integer. Valid values: from -2^{63} to $2^{63}-1$.	
`Uint8`	Unsigned integer. Valid values: from 0 to 2^8-1.	
`Uint16`	Unsigned integer. Valid values: from 0 to $2^{16}-1$.	
`Uint32`	Unsigned integer. Valid values: from 0 to $2^{32}-1$.	
`Uint64`	Unsigned integer. Valid values: from 0 to $2^{64}-1$.	
`Float`	Floating-point number with variable precision, 4 bytes in size.	Cannot be used in the primary key and in the columns that form the secondary index key
`Double`	Floating-point number with variable precision, 8 bytes in size.	Cannot be used in the primary key and in the columns that form the secondary index key
`Decimal(precision, scale)`	Floating-point number with fixed precision, 16 bytes in size. Precision is the maximum total number of stored decimal digits, takes values from 1 to 35. Scale is the maximum number of stored decimal digits to the right of the decimal point, takes values from 0 to the value of precision.	
`DyNumber`	Binary representation of a floating-point number with up to 38 digits of precision. Valid values: positive from 1×10^{-130} to $1\times10^{126}-1$, negative from $-1\times10^{126}-1$ to -1×10^{-130} and 0. Compatible with the `Number` type of AWS DynamoDB. Not recommended for use in ydb-native applications.	Not supported in columnar tables

Examples

```
SELECT
  Bool("true"),
  Uint8("0"),
  Int32("-1"),
  Uint32("2"),
  Int64("-3"),
  Uint64("4"),
  Float("-5"),
  Double("6"),
  Decimal("1.23", 5, 2), -- up to 5 decimal places, of which 2 are after the decimal point
  DyNumber("1"),
  String("foo"),
  Utf8("hello"),
  Yson("<a=1>[3;%false]"),
  Json(@@{"a":1,"b":null}@@),
  Date("2017-11-27"),
  Datetime("2017-11-27T13:24:00Z"),
  Timestamp("2017-11-27T13:24:00.123456Z"),
  Interval("P1W2DT2H3M4.567890S"),
  TzDate("2017-11-27,Europe/Moscow"),
  TzDatetime("2017-11-27T13:24:00,America/Los_Angeles"),
  TzTimestamp("2017-11-27T13:24:00.123456,GMT"),
  Uuid("f9d5cc3f-f1dc-4d9c-b97e-766e57ca4ccb");
```

String types

Type	Description	Notes
`String`	String, can contain arbitrary binary data	

`Bytes` (alias for `String`)	String, can contain arbitrary binary data	
`Utf8`	Text in UTF-8 encoding	
`Text` (alias for `Utf8`)	Text in UTF-8 encoding	
`Json`	JSON in text representation	Does not support comparison, cannot be used in the primary key and in the columns that form the secondary index key
`JsonDocument`	JSON in binary indexed representation	Does not support comparison, cannot be used in the primary key and in the columns that form the secondary index key
`Yson`	YSON in text or binary representation	Does not support comparison, cannot be used in the primary key and in the columns that form the secondary index key
`Uuid`	Universal identifier UUID	Not supported in columnar tables

The maximum size of a value in a cell of a non-key column with any string data type is 8 MB.

{% endnote %}

In contrast to the `Json` data type, which stores the original text representation provided by the user, `JsonDocument` uses a binary indexed representation. An important semantic difference is that `JsonDocument` does not preserve formatting, the order of keys in objects, or their duplicates.

Thanks to the indexed representation, `JsonDocument` allows you to traverse the document model using `JsonPath` without the need to parse the entire content. This enables efficient execution of operations from the JSON API, reducing latency and the cost of user queries. Query execution on `JsonDocument` can be several times more efficient, depending on the type of load.

Due to the added redundancy, `JsonDocument` is less efficient in terms of storage. The additional storage overhead depends on the specific content and averages 20–30% of the original volume. Storing data in `JsonDocument` format requires additional conversion from the text representation, which makes writing less efficient. However, for most read-intensive scenarios involving JSON data processing, this data type is preferable and is recommended for use.

The Double type is used to store numbers (JSON Number) in JsonDocument and for arithmetic operations on them in the JSON API. Loss of precision is possible when using non-standard number representations in the original JSON document.

Date and time

Basic range

Types `Date`, `Datetime`, `Timestamp`, `Interval`, and related timezone-aware variants.

Extended range

Types `Date32`, `Datetime64`, `Timestamp64`, `Interval64`, and related timezone-aware variants.

Type	Description	Possible values	Size (bytes)	Notes
`Date`	UTC midnight, accuracy to the day	from 00:00 January 1, 1970 to 00:00 January 1, 2106	2	—
`Date32`	UTC midnight, accuracy to the day	from 00:00 January 1, 144169 BC to 00:00 January 1, 148107 AD	4	—
`Datetime`	UTC time, accuracy to the second	from 00:00 January 1, 1970 to 00:00 January 1, 2106	4	—
`Datetime64`	UTC time, accuracy to the second	from 00:00 January 1, 144169 BC to 00:00 January 1, 148107 AD	8	—
`Timestamp`	UTC time, accuracy to the microsecond	from 00:00 January 1, 1970 to 00:00 January 1, 2106	8	—
`Timestamp64`	UTC time, accuracy to the microsecond	from 00:00 January 1, 144169 BC to 00:00 January 1, 148107 AD	8	—
`Interval`	Time interval, accuracy to the microsecond	from -136 years to +136 years	8	Not supported in columnar tables
`Interval64`	Time interval, accuracy to the microsecond	from -292277 years to +292277 years	8	Not supported in columnar tables
`TzDate`	UTC time corresponding to midnight in a given timezone	from 00:00 January 1, 1970 to 00:00 January 1, 2106		Not supported in table columns
`TzDate32`	UTC time corresponding to midnight in a given timezone	from 00:00 January 1, 144169 BC to 00:00 January 1, 148107 AD	4 and timezone mark	—
`TzDateTime`	UTC time with timezone mark and accuracy to the second	from 00:00 January 1, 1970 to 00:00 January 1, 2106		Not supported in table columns
`TzDateTime64`	UTC time with timezone mark and accuracy to the second	from 00:00 January 1, 144169 BC to 00:00 January 1, 148107 AD	8 and timezone mark	—

`TzTimestamp`	UTC time with timezone mark and accuracy to the microsecond	from 00:00 January 1, 1970 to 00:00 January 1, 2106		Not supported in table columns
`TzTimestamp64`	UTC time with timezone mark and accuracy to the microsecond	from 00:00 January 1, 144169 BC to 00:00 January 1, 148107 AD	8 and timezone mark	—

[1] Midnight is understood as the moment when all *time* components are equal to zero.

Interval type behavior and limitations

The `Interval` type uses syntax based on the ISO 8601 standard, with several specifics:

- only intervals that can be represented as an integer number of microseconds are supported (intervals in years `Y` and months `M` are not supported due to their variable duration);
- intervals with start/end points or repetitions are not supported;
- the use of a negative sign to indicate a shift into the past is supported;
- combining the week literal `W` with other literals is supported;
- microseconds can be specified as a fractional part of a second.

Interval data examples

```
SELECT
    Interval("P1W2DT2H3M4.567890S"), -- interval 1 week 2 days 2 hours 3 minutes 4.567890 seconds
    Interval("P1W"),                 -- interval 1 week (7 days)
    Interval("-P1D");                -- interval in the past 1 day (24 hours)
```

Time zone label support features

The time zone label for the `TzDate`, `TzDatetime`, `TzTimestamp` types is an attribute that is used:

- When converting (using CAST, DateTime::Parse, DateTime::Format) to and from a string.
- In DateTime::Split — the time zone component appears in `Resource<TM>`.

The actual time position value for these types is stored in UTC, and the time zone label does not participate in other calculations. For example:

```
SELECT -- these expressions are always true for any time zones: the time zone does not affect the point in ti
me.
    AddTimezone(CurrentUtcDate(), "Europe/Moscow") ==
        AddTimezone(CurrentUtcDate(), "America/New_York"),
    AddTimezone(CurrentUtcDatetime(), "Europe/Moscow") ==
        AddTimezone(CurrentUtcDatetime(), "America/New_York");
```

It is important to understand that when converting between `TzDate` and `TzDatetime` or `TzTimestamp`, the date corresponds not to midnight local time in the timezone, but to midnight UTC for the date in UTC.

Casting of primitive data types

Explicit casting

Explicit casting using CAST:

Casting to numeric types

Type	Bool	Int8	Int16	Int32	Int64	Uint8	Uint16	Uint32	Uint64	Float	Double	Decimal
Bool	—	Yes[1]	Yes[1]	Yes[1]	Yes[1]	Yes[1]	Yes[1]	Yes[1]	Yes[1]	Yes[1]	Yes[1]	No

[1] Using the built-in function Yson::ConvertTo.

Examples

```
SELECT
    CAST("12345" AS Double),               -- 12345.0
    CAST(1.2345 AS Uint8),                 -- 1
    CAST(12345 AS String),                 -- "12345"
    CAST("1.2345" AS Decimal(5, 2)),       -- 1.23
    CAST("xyz" AS Uint64) IS NULL,         -- true, since it failed
    CAST(-1 AS Uint16) IS NULL,            -- true, negative to unsigned
    CAST([-1, 0, 1] AS List<Uint8?>),            -- [null, 0, 1]
-- The element type is optional: the failed element is null.
    CAST(["3.14", "bad", "42"] AS List<Float>),   -- [3.14, 42]
-- The element type is not optional: the failed element is removed.
    CAST(255 AS Uint8),                    -- 255
    CAST(256 AS Uint8) IS NULL;            -- true, out of range
```

Implicit casting

Implicit type casting that occurs in basic operations (`+`, `-`, `*`, `/`, `%`) between different data types. The table cells indicate the result type of the operation if it is possible:

Numeric types

If the numeric types do not match, a BITCAST of both arguments to the result type is performed first, and then the operation.

Type	Int8	Int16	Int32	Int64	Uint8	Uint16	Uint32	Uint64	Float	Double
Int8	—	`Int16`	`Int32`	`Int64`	`Int8`	`Uint16`	`Uint32`	`Uint64`	`Float`	`Double`
Int16	`Int16`	—	`Int32`	`Int64`	`Int16`	`Int16`	`Uint32`	`Uint64`	`Float`	`Double`
Int32	`Int32`	`Int32`	—	`Int64`	`Int32`	`Int32`	`Int32`	`Uint64`	`Float`	`Double`
Int64	`Int64`	`Int64`	`Int64`	—	`Int64`	`Int64`	`Int64`	`Int64`	`Float`	`Double`
Uint8	`Int8`	`Int16`	`Int32`	`Int64`	—	`Uint16`	`Uint32`	`Uint64`	`Float`	`Double`
Uint16	`Uint16`	`Int16`	`Int32`	`Int64`	`Uint16`	—	`Uint32`	`Uint64`	`Float`	`Double`
Uint32	`Uint32`	`Uint32`	`Int32`	`Int64`	`Uint32`	`Uint32`	—	`Uint64`	`Float`	`Double`
Uint64	`Uint64`	`Uint64`	`Uint64`	`Int64`	`Uint64`	`Uint64`	`Uint64`	—	`Float`	`Double`
Float	`Float`	`Float`	`Float`	`Float`	`Float`	`Float`	`Float`	`Float`	—	`Double`
Double	`Double`	`Double`	`Double`	`Double`	`Double`	`Double`	`Double`	`Double`	`Double`	—

Date and time types

Type	Date	Datetime	Timestamp	Interval	TzDate	TzDatetime	TzTimestamp	Date32	Datetime64	Timestamp64

TzTimestamp64	—	—	—	—	—	—	—	—	—	—

Serial data types

Serial data types are integers with an additional value-generation mechanism. They are used for auto-increment columns: each new row inserted into the table automatically gets a unique value in such a column (similar to the SERIAL type in PostgreSQL or AUTO_INCREMENT in MySQL).

> **Note**
>
> Using serial types as a primary key is not recommended: monotonically increasing values lead to uneven data distribution and hot partitions. For details, see Selecting a primary key for maximum performance.

Usage example

```
CREATE TABLE users (
    user_id Serial,
    name Utf8,
    email Utf8,
    PRIMARY KEY (user_id)
);
```

```
UPSERT INTO users (name, email) VALUES ('Alice', 'alice@example.com');
INSERT INTO users (name, email) VALUES ('Bob', 'bob@example.com');
REPLACE INTO users (name, email) VALUES ('John', 'john@example.com');
```

```
SELECT * FROM users;
```

email	name	user_id
`alice@example.com`	Alice	1
`bob@example.com`	Bob	2
`john@example.com`	John	3

You can supply a value for a `Serial` column explicitly on insert; the row is then handled like a plain integer column, and the `Sequence` is not affected:

```
UPSERT INTO users (user_id, name, email) VALUES (4, 'Peter', 'peter@example.com');
```

Description

Only columns that participate in a table's primary key may use the `Serial` type.

Defining this type on a column creates a separate schema object, `Sequence`, bound to that column and used as a generator of sequence values. This object is private and hidden from the user. The `Sequence` is destroyed together with the table.

Sequence values start at 1, increment by 1, and are bounded according to the type used.

Type	Maximum value	Value type
`SmallSerial`		`Int16`
`Serial2`		`Int16`
`Serial`		`Int32`
`Serial4`		`Int32`
`Serial8`		`Int64`
`BigSerial`		`Int64`

If the sequence overflows on insert, an error is returned:

```
Error: Failed to get next val for sequence: /dev/test/users/_serial_column_user_id, status: SCHEME_ERROR
    <main>: Error: sequence [OwnerId: <some>, LocalPathId: <some>] doesn't have any more values available, co
de: 200503
```

The next value is allocated by the generator before the row is actually inserted and is considered consumed even if the row is not successfully written (for example, when the transaction rolls back). Therefore the set of values in such a column may have gaps and consist of several disjoint ranges.

For tables with auto-increment columns, the copy, dump, restore, and import/export operations are supported.

Data types accepting NULL

Any typed data in YQL, including table columns, can be either non-nullable (guaranteed value) or nullable (empty value denoted as `NULL`). Data types that can include `NULL` values are called *optional* or, in SQL terms, *nullable*.

Optional data types in the text format use the question mark at the end (for example, `String?`) or the notation `Optional<...>`. The following operations are most often performed on optional data types:

- IS NULL: Matching an empty value
- COALESCE: Leave the filled values unchanged and replace `NULL` with the default value that follows
- UNWRAP: Extract the value of the original type from the optional data type, `T?`. is converted to `T`
- JUST: Add optionality to the current type, `T` is converted to `T?`.
- NOTHING: Create an empty value with the specified type.

`Optional` (nullable) isn't a property of a data type or column, but a container type where containers can be arbitrarily nested into each other. For example, a column with the type `Optional<Optional<Boolean>>` can accept 4 values: `NULL` of the whole container, `NULL` of the inner container, `TRUE`, and `FALSE`. The above-declared type differs from `List<List<Boolean>>`, because it uses `NULL` as an empty list, and you can't put more than one non-null element in it. In addition, `Optional<Optional<T>>` type values are returned as results when searching by the key in the `Dict(k,v)` dictionary with `Optional<T>` type values. Using this type of result data, you can distinguish between a `NULL` value in the dictionary and a situation when the key is missing.

Note

Container types (including `Optional<T>` containers and more complex types derived from them) can't currently be used as column data types when creating YDB tables.
YQL queries can return values of container types and accept them as input parameters.

Example

```
$dict = {"a":1, "b":null};
$found = $dict["b"];
select if($found is not null, unwrap($found), -1);
```

Result:

```
# column0
null
```

Logical and arithmetic operations with NULL

The `NULL` literal has a separate singular `Null` type and can be implicitly converted to any optional type (for example, the nested type `Optional<Optional<...Optional<T>...>>`). In ANSI SQL, `NULL` means "an unknown value", that's why logical and arithmetic operations involving `NULL` or empty `Optional` have certain specifics.

Examples

```
SELECT
    True OR NULL,        -- Just(True) (works the same way as True OR <unknown value of type Bool>)
    False AND NULL,      -- Just(False)
    True AND NULL,       -- NULL   (more precise than Nothing<Bool?> – <unknown value of type Bool>)
    NULL OR NOT NULL,    -- NULL   (all NULLs are "different")
    1 + NULL,            -- NULL   (Nothing<Int32?>) - the result of adding 1 together with
                         --         unknown value of type Int)
    1 == NULL,           -- NULL   (the result of adding 1 together with unknown value of type Int)
    (1, NULL) == (1, 2), -- NULL   (composite elements are compared by component
                         --         through `AND`)
    (2, NULL) == (1, 3), -- Just(False) (expression is equivalent to 2 == 1 AND NULL == 3)
```

Data types that do not allow NULL values

Primitive types in YQL cannot hold a `NULL` value: the container described above, `Optional`, is intended for storing `NULL`. In SQL terms, primitive types in YQL are *non-nullable* types.

In YQL, there is no implicit type conversion from Optional to T, so the enforceability of the NOT NULL constraint on a table column is ensured at the query compilation stage in YDB.

You can create a non-nullable column in a YDB table using the CREATE TABLE operation with the keyword `NOT NULL`:

```
CREATE TABLE t (
    Key Uint64 NOT NULL,
    Value String NOT NULL,
    PRIMARY KEY (Key))
```

After that, write operations to table `t` will only be executed if the values to be inserted into the `key` and `value` columns do not contain `NULL` values.

Example of the interaction between the NOT NULL constraint and YQL functions

Many of the YQL functions have optional types as return values. Since YQL is a strongly-typed language, a query like

```
CREATE TABLE t (
    c Utf8 NOT NULL,
    PRIMARY KEY (c)
);
INSERT INTO t(c)
SELECT CAST('q' AS Utf8);
```

cannot be executed. The reason for this is the type mismatch between the column `c`, which has the type `Utf8`, and the result of the `CAST` function, which has the type `Optional<Utf8>`. To make the query work correctly in such scenarios, it is necessary to use the COALESCE function, whose argument can specify a fallback value to insert into the table in case the function (in the example, CAST) returns an empty `Optional`. If, in the case of an empty `Optional`, the insertion should not be performed and an error should be returned, the UNWRAP function can be used to unpack the contents of the optional type.

Containers

YQL supports container types to define complex data structures organized in various ways.
Values of container types can be passed to YQL queries as input parameters or returned from YQL queries as columns of the set of results.
Container types can't be used as column data types for YDB tables.

Type	Declaration, example	Description
List	`List<Type>`, `List<Int32>`	A variable-length sequence consisting of same-type elements.
Dictionary	`Dict<KeyType, ValueType>`, `Dict<String,Int32>`	Set of key-value pairs with a fixed type of keys and values.
Set	`Set<KeyType>`, `Set<String>`	A set of elements with a fixed type is a special case of a dictionary with the `Void` value type.
Tuple	`Tuple<Type1, ..., TypeN>`, `Tuple<Int32,Double>`	Set of unnamed fixed-length elements with types specified for all elements.
Structure	`Struct<Name1:Type1, ..., NameN:TypeN>`, `Struct<Name:String,Age:Int32>`	A set of named fields with specified value types, fixed at query start (must be data-independent).
Stream	`Stream<Type>`, `Stream<Int32>`	Single-pass iterator by same-type values, not serializable
Variant on tuple	`Variant<Type1, Type2>`, `Variant<Int32,String>`	A tuple known to have exactly one element filled
Variant on structure	`Variant<Name1:Type1, Name2:Type2>`, `Variant<value:Int32,error:String>`	A structure known to have exactly one element filled
Enumeration	`Enum<Name1, Name2>`, `Enum<value,error>`	A container with exactly one enumeration element selected and defined only by its name.

If necessary, you can nest containers in any combination, for example, `List<Tuple<Int32,Int32>>`.

In certain contexts, optional values can also be considered a container type (`Optional<Type>`) that behaves like a list of length 0 or 1.

To create literals of list containers, dictionary containers, set containers, tuple containers, or structure containers, you can use the operator notation.
To create a variant literal over a tuple or structure, use the function Variant.
To create an enumeration literal, use the function Enum.

To access the container elements, use a dot or square brackets, depending on the container type.

Special data types

Type	Description
`Callable`	A callable value that can be executed by passing arguments in parentheses in YQL SQL syntax.
`Resource`	Resource is an opaque pointer to a resource you can pass between the user defined functions (UDF). The type of the returned and accepted resource is declared inside a function using a string label. When passing a resource, YQL checks for label matching to prevent passing of resources between incompatible functions. If the labels mismatch, a type error occurs.
`Tagged`	Tagged is the option to assign an application name to any other type.
`Generic`	The data type used for data types.
`Unit`	Unit is the data type used for non-enumerable entities (data sources and data sinks, atoms, etc.).
`Null`	Void is a singular data type with the only possible null value. It's the type of the `NULL` literal and can be converted to any `Optional` type.
`Void`	Void is a singular data type with the only possible `"null"` value.
`EmptyList`	A singular data type with the only possible [] value. It's the type of the `[]` literal and can be converted to any `List` type.
`EmptyDict`	A singular data type with the only possible {} value. It's a type of the `{}` literal and can be converted to any `Dict` or `Set` type.

Rules for type casting using the operator CAST

Rules for casting primitive data types

- When casting primitive data types, some of the source information may be discarded unless contained in the target type. For example:
  - The `Float` / `Double` fractional part, when casting to integer types.
  - The `Datetime` / `Timestamp` time, when casting to `Date`.
  - The timezone, when casting from timezone types to date/time types without a timezone.
- If, in a certain combination of the source and target type, casting can't be performed for all possible values of the source type, then, if the casting fails, `CAST` returns `NULL`. In such cases, one `Optional` level is added to the return value type, unless already present. For example, the constructs: `CAST("3.14" AS Float?)` and `CAST("3.14" AS Float)` are fully equivalent and return `Float?`.
- If casting is possible for all values of the source type, then adding '?' works the same way as `Just` on top: `CAST(3.14 AS Utf8?)` is same as `Just(CAST(3.14 AS Utf8))`.

All combinations of primitive data types for which `CAST` can be used are described here.

Casting rules for containers

Rules for Optional

- If a higher `Optional` level is set for the target type than for the source type, it's same as adding `Just` on top of `CAST` with a lower `Optional` level.
- If the source type has a higher level of `Optional` for the source type, then `NULL` at any level higher than the target level results in `NULL`.
- At equal levels of `Optional`, the `NULL` value preserves the same level.

```
SELECT
    CAST(1 AS Int32?),                  -- is equivalent to Just(1)
    CAST(Just(2/1) AS Float??),         -- [2]
    CAST(Just(3/0) AS Float??) IS NULL; -- false: the result is Just(NULL)
```

Rules for List/Dict

- To create a list, `CAST` is applied to each item in the source list to cast it to the target type.
- If the target item type is non-optional and `CAST` on the item might fail, then such casting is discarded. In this case, the resulting list might be shorter or even empty if every casting failed.
- For dictionaries, the casting is totally similar to lists, with `CAST` being applied to keys and values.

```
SELECT
    CAST([-1, 0, 1] AS List<Uint8?>),             -- [null, 0, 1]
    CAST(["3.14", "bad", "42"] AS List<Float>),   -- [3.14, 42]

    CAST({-1:3.14, 7:1.6} AS Dict<Uint8, Utf8>),  -- {7: "1.6"}
    CAST({-1:3.14, 7:1.6} AS Dict<Uint8?, Utf8>); -- {7: "1.6", null:"3.14"}
```

Rules for Struct/Tuple

- A structure or tuple is created by applying `CAST` to each item of the source type to cast it to an item with the same name or target type index.
- If some field is missing in the target type, it's simply discarded.
- If some field is missing in the source value type, then it can be added only if it's optional and accepts the `NULL` value.
- If some field is non-optional in the target type, but its casting might fail, then `CAST` adds Optional to the structure or tuple level and might return `NULL` for the entire result.

```
SELECT
    CAST((-1, 0, 1) AS Tuple<Uint16?, Uint16?, Utf8>), -- (null, 0, "1")
    CAST((-2, 0) AS Tuple<Uint16, Utf8>),              -- null
    CAST((3, 4) AS Tuple<Uint16, String>),             -- (3, "4"): the type is Tuple<Uint16, String>?
    CAST(("4",) AS Tuple<Uint16, String?>),            -- (4, null)
    CAST((5, 6, null) AS Tuple<Uint8?>);               -- (5,): the items were removed.

SELECT -- One field was removed and one field was added: ("three":null, "two": "42")
    CAST(<|one:"8912", two:42|> AS Struct<two:Utf8, three:Date?>);
```

Rules for Variant

- A variant with a specific name or index is cast to a variant with the same name or index.
- If casting of a variant might fail and the type of this variant is non-optional, then `CAST` adds Optional to the top level and can return `NULL`.
- If some variant is missing in the target type, then `CAST` adds Optional to the top level and returns `NULL` for such a value.

Nested containers

- All of the above rules are applied recursively for nested containers.

Text representation of data types

Introduction

Since YQL is a strongly typed language, the data type is important for many of its aspects. To make data type management easy, YQL has a data type definition convention in text format. It's mentioned in many places in the documentation. There's also a library that provides functions for building a data type based on a text description (for example, when manually defining the signature for the called value) or for serializing the data type into a string for debugging purposes.

Functions for data types are described in the article. Below is the format of text representation of data types.

General conventions

- Primitive data types are represented in text format simply by referencing their name.
- A complex data type is composed of other data types. If you depict this structure as a tree, it has primitive data types as leaves and containers as other nodes. You may treat special data types as exceptions, because they can function as both.
- The text representation repeats the structure of this tree from the root to the leaves: each node of the tree specifies the name of the current data type, and proceeding to a deeper level is denoted by different types of brackets.
- Feel free to use spaces and line breaks if they improve readability.
- If the ID contains something else except the Latin letters and numbers, put it in single quotes and use C-escaping.

Containers

- Use angle brackets to specify the types of container elements.

  Example: `List<Int32>`.
- If a container can hold multiple heterogeneous elements, they are listed inside angle brackets with a comma.

  Example: `Tuple<Int32, String>`.
- If a container can hold named elements, use comma-separated name-type pairs with a colon in-between instead of comma-separated data types.

  Example: `Struct<a:Int32, b:String>`.
- The underlying `Variant` container type is chosen based on the presence of names in arguments.

  Example: `Variant<Int32, String>` is a variant on tuple, `Variant<a:Int32, b:String>` is a variant on structure.

Types that allow NULL

- They are called `Optional` in YQL terms, or nullable in the classic SQL terms.
- Formally, this type is a container. So, you may declare it as `Optional<...>`, but the shortcut notation of a question mark suffix is usually used instead.

  Example: `String?`.

Called values

- The basic form of the called values looks as follows: `(arg1, arg2, ...) -> result`.

  An example of declaring a function signature that accepts two strings and returns a number: `(String, String) -> Int64`.
- The called values can return the called values: in this case, they make up a chain of the required length.

  Example: `(String, String) -> (String, String) -> Int64`.
- Optional arguments must have the `Optional` type at the top level and be enclosed in square brackets.

  Example: `(String, [String?, Double?]) -> Int64`.
- The arguments of the called values can contain flags.

  Currently, the only possible flag is `AutoMap`. It means that if NULL is passed to this argument, the result must also be set to NULL without running the function.

  Example: `(String{Flags: AutoMap}) -> Int64`.
- Use this particular format if you need `Optional<Callable...>`, because the trailing question mark refers to the result of the called value.

Resources

- Unlike containers, a resource isn't parameterized by the element type (it's a pointer in memory and YQL knows nothing about its contents). Instead, a resource is parameterized by a string label that can safeguard against passing resources between incompatible functions.

  Example: `Resource<Foo>`.

Data representation in JSON format

Bool

Boolean value.

- Type in JSON: `bool`.
- Sample YDB value: `true`.
- Sample JSON value: `true`.

Int8, Int16, Int32, Int64

Signed integer types.

- Type in JSON: `number`.
- Sample YDB value: `123456`, `-123456`.
- Sample JSON value: `123456`, `-123456`.

Uint8, Uint16, Uint32, Uint64

Unsigned integer types.

- Type in JSON: `number`.
- Sample YDB value: `123456`.
- Sample JSON value: `123456`.

Float

Real 4-byte number.

- Type in JSON: `number`.
- Sample YDB value: `0.12345679`.
- Sample JSON value: `0.12345679`.

Double

Real 8-byte number.

- Type in JSON: `number`.
- Sample YDB value: `0.12345678901234568`.
- Sample JSON value: `0.12345678901234568`.

Decimal

Fixed-precision number.

- Type in JSON: `string`.
- Sample YDB value: `-320.789`.
- Sample JSON value: `"-320.789"`.

String, Yson

Binary strings. Encoding algorithm depending on the byte value:

- [0-31] — `\u00XX` (6 characters denoting the Unicode character code).
- [32-126] — as is. These are readable single-byte characters that don't need to be escaped.
- [127-255] — `\u00XX`.

Decoding is a reverse process. Character codes in `\u00XX`, maximum 255.

- Type in JSON: `string`.
- Sample YDB value: A sequence of 4 bytes:
  - 5 `0x05`: A control character.
  - 10 `0x0a`: The `\n` newline character.
  - 107 `0x6b`: The `k` character.
  - 255 `0xff`: The `ÿ` character in Unicode.
- Sample JSON value: `"\u0005\nk\u00FF"`.

Utf8, Json, Uuid

String types in UTF-8. Such strings are represented in JSON as strings with JSON characters escaped: `\\`, `\"`, `\n`, `\r`, `\t`, `\f`.

- Type in JSON: `string`.
- Sample YDB value: C++ code:

```
"Escaped characters: "
"\\ \" \f \b \t \r\n"
"Non-escaped characters: "
"/ ' < > & []() ".
```

- Sample JSON value: `"Escaped characters: \\ \" \f \b \t \r\nNon-escaped characters: / ' < > & []() "`.

Date

Date. Uint64, unix time days.

- Type in JSON: `string`.
- Sample YDB value: `18367`.
- Sample JSON value: `"2020-04-15"`.

Datetime

Date and time. Uint64, unix time seconds.

- Type in JSON: `string`.
- Sample YDB value: `1586966302`.
- Sample JSON value: `"2020-04-15T15:58:22Z"`.

Timestamp

Date and time. Uint64, unix time microseconds.

- Type in JSON: `string`.
- Sample YDB value: `1586966302504185`.
- Sample JSON value: `"2020-04-15T15:58:22.504185Z"`.

Interval

Time interval. Int64, precision to the microsecond, the interval values must not exceed 24 hours.

- Type in JSON: `number`.
- Sample YDB value: `123456`, `-123456`.
- Sample JSON value: `123456`, `-123456`.

Optional

Means that the value can be `null`. If the value is `null`, then in JSON it's also `null`. If the value is not `null`, then the JSON value is expressed as if the type isn't `Optional`.

- Type in JSON is missing.
- Sample YDB value: `null`.
- Sample JSON value: `null`.

List

List. An ordered set of values of a given type.

- Type in JSON: `array`.
- Sample YDB value:
  - Type: `List<Int32>`.
  - Value: `1, 10, 100`.
- Sample JSON value: `[1,10,100]`.

Stream

Stream. Single-pass iterator by same-type values,

- Type in JSON: `array`.
- Sample YDB value:
  - Type: `Stream<Int32>`.
  - Value: `1, 10, 100`.
- Sample JSON value: `[1,10,100]`.

Struct

Structure. An unordered set of values with the specified names and type.

- Type in JSON: `object`.
- Sample YDB value:
  - Type: `Struct<'Id':Uint32,'Name':String,'Value':Int32,'Description':Utf8?>`;
  - Value: `"Id":1,"Name":"Anna","Value":-100,"Description":null`.
- Sample JSON value: `{"Id":1,"Name":"Anna","Value":-100,"Description":null}`.

Tuple

Tuple. An ordered set of values of the set types.

- Type in JSON: `array`.
- Sample YDB value:
  - Type: `Tuple<Int32??,Int64???,String??,Utf8???>`;
  - Value: `10,-1,null,"Some string"`.
- Sample JSON value: `[10,-1,null,"Some string"]`.

Dict

Dictionary. An unordered set of key-value pairs. The type is set both for the key and the value. It's written in JSON to an array of arrays including two items.

- Type in JSON: `array`.
- Sample YDB value:
  - Type: `Dict<Int64,String>`.
  - Value: `1:"Value1",2:"Value2"`.

- Sample JSON value: `[[1,"Value1"],[2,"Value2"]]`.

Lexical structure

The query in the YQL language is a valid UTF-8 text consisting of **statements** separated by semicolons (`;`).
The last semicolon can be omitted.
Each command is a sequence of **tokens** that are valid for this command.
Tokens can be **keywords**, **identifiers**, **literals**, and so on.
Tokens are separated by whitespace characters (space, tab, line feed) or **comments**. The comment is not a part of the command and is syntactically equivalent to a space character.

Syntax compatibility modes

Two syntax compatibility modes are supported:

- Advanced C++ (default)
- ANSI SQL

ANSI SQL mode is enabled with a special comment `--!ansi_lexer`, which must be in the beginning of the query.

Specifics of interpretation of lexical elements in different compatibility modes are described below.

Comments

The following types of comments are supported:

- Single-line comment: starts with `--` (two minus characters following one another) and continues to the end of the line
- Multiline comment: starts with `/*` and ends with `*/`

```
SELECT 1; -- A single-line comment
/*
   Some multi-line comment
*/
```

In C++ syntax compatibility mode (default), a multiline comment ends with the **nearest** `*/`.
The ANSI SQL syntax compatibility mode accounts for nesting of multiline comments:

```
--!ansi_lexer
SELECT * FROM T; /* this is a comment /* this is a nested comment, without ansi_lexer it raises an error  */
*/
```

Keywords and identifiers

Keywords are tokens that have a fixed value in the YQL language. Examples of keywords: `SELECT`, `INSERT`, `FROM`, `ACTION`, and so on. Keywords are case-insensitive, that is, `SELECT` and `SeLEcT` are equivalent to each other.
The list of keywords is not fixed and is going to expand as the language develops. A keyword can't contain numbers and begin or end with an underscore.

Identifiers are tokens that identify the names of tables, columns, and other objects in YQL. Identifiers in YQL are always case-sensitive.
An identifier can be written in the body of the program without any special formatting, if the identifier:

- Is not a keyword
- Begins with a Latin letter or underscore
- Is followed by a Latin letter, an underscore, or a number

```
SELECT my_column FROM my_table; -- my_column and my_table are identifiers
```

To include an arbitrary ID in the body of a query, the ID is enclosed in backticks:

```
SELECT `column with space` from T;
SELECT * FROM `my_dir/my_table`
```

IDs in backticks are never interpreted as keywords:

```
SELECT `select` FROM T; -- select - Column name in the T table
```

When using backticks, you can use the standard C escaping:

```
SELECT 1 as `column with\n newline, \x0a newline and \` backtick `;
```

In ANSI SQL syntax compatibility mode, arbitrary IDs can also be enclosed in double quotes. To include a double quote in a quoted ID, use two double quotes:

```
--!ansi_lexer
SELECT 1 as "column with "" double quote"; -- column name will be: column with " double quote
```

Query parameterization

Query parameters are named expressions whose values are passed separately from the query text (see DECLARE). Such parameters can only be substituted in the parts of a query that are not required for its compilation. For example, a parameter can be used in a filter:

```
DECLARE $my_param AS String;
SELECT Data FROM my_table WHERE Data LIKE $my_param
```

Or in data:

```
DECLARE $my_param AS String;
SELECT Data || $my_param FROM my_table
```

At the same time, parameters cannot be used in the parts required for query compilation, for example:

- In table names;
- In any parameters of the WITH block;
- In any expressions inside EvaluateExpr.

For such parts, you can only use string constants inside the query, for example:

```
$table = "my_table";
SELECT * FROM $table
```

SQL hints

SQL hints are special settings with which a user can modify a query execution plan
(for example, enable/disable specific optimizations or force the JOIN execution strategy).
Unlike PRAGMA, SQL hints act locally – they are linked to a specific point in the YQL query (normally, after the keyword)
and affect only the corresponding statement or even a part of it.
SQL hints are a set of settings "name-value list" and defined inside special comments —
comments with SQL hints must have `+` as the first character:

```
--+ Name1(Value1 Value2 Value3) Name2(Value4) ...
```

An SQL hint name must be comprised of ASCII alphanumeric characters and start with a letter. Hint names are case insensitive.
A hint name must be followed by a custom number of space-separated values. A value can be a custom set of characters.
If there's a space or parenthesis in a set of characters, single quotation marks must be used:

```
--+ foo('value with space and paren)')
```

```
--+ foo('value1' value2)
-- equivalent to
--+ foo(value1 value2)
```

To escape a single quotation within a value, double it:

```
--+ foo('value with single quote '' inside')
```

If there're two or more hints with the same name in the list, the latter is used:

```
--+ foo(v1 v2) bar(v3) foo()
-- equivalent to
--+ bar(v3) foo()
```

Unknown SQL hint names (or syntactically incorrect hints) never result in errors, they're simply ignored:

```
--+ foo(value1) bar(value2  baz(value3)
-- due to a missing closing parenthesis in bar, is equivalent to
--+ foo(value1)
```

Thanks to this behavior, previous valid YQL queries with comments that look like hints remain intact.
Syntactically correct SQL hints in a place unexpected for YQL result in a warning:

```
-- presently, hints after SELECT are not supported
SELECT /*+ foo(123) */ 1; -- warning 'Hint foo will not be used'
```

What's important is that SQL hints are hints for an optimizer, so:

- Hints never affect search results.
- As YQL optimizers improve, a situation is possible when a hint becomes outdated and is ignored (for example, the algorithm based on a given hint completely changes or the optimizer becomes so sophisticated that it can be expected to choose the best solution, so some manual settings are likely to interfere).

String literals

A string literal (constant) is expressed as a sequence of characters enclosed in single quotes. Inside a string literal, you can use the C-style escaping rules:

```
SELECT 'string with\n newline, \x0a newline and \' backtick ';
```

In the C++ syntax compatibility mode (default), you can use double quotes instead of single quotes:

```
SELECT "string with\n newline, \x0a newline and \" backtick ";
```

In ASNI SQL compatibility mode, double quotes are used for IDs, and the only escaping that can be used for string literals is a pair of single quotes:

```
--!ansi_lexer
SELECT 'string with '' quote'; -- result: string with ' quote
```

Based on string literals, simple literals can be obtained.

Multi-line string literals

A multiline string literal is expressed as an arbitrary set of characters enclosed in double at signs `@@`:

```
$text = @@some
multiline
text@@;
SELECT LENGTH($text);
```

If you need to use double at signs in your text, duplicate them:

```
$text = @@some
multiline with double at: @@@@
text@@;
SELECT $text;
```

Typed string literals

- For string literals, including multi-string ones, the `String` type is used by default (see also PRAGMA UnicodeLiterals).
- You can use the following suffixes to explicitly control the literal type:
  - `s` — `String`
  - `u` — `Utf8`
  - `y` — `Yson`
  - `j` — `Json`

Example

```
SELECT "foo"u, '[1;2]'y, @@{"a":null}@@j;
```

Numeric literals

- Integer literals have the default type `Int32`, if they fit within the Int32 range. Otherwise, they automatically expand to `Int64`.
- You can use the following suffixes to explicitly control the literal type:
  - `l`: `Int64`
  - `s`: `Int16`
  - `t`: `Int8`
- Add the suffix `u` to convert a type to its corresponding unsigned type:
  - `ul`: `Uint64`
  - `u`: `Uint32`
  - `us`: `Uint16`
  - `ut`: `Uint8`
- You can also use hexadecimal, octal, and binary format for integer literals using the prefixes `0x`, `0o` and `0b`, respectively. You can arbitrarily combine them with the above-mentioned suffixes.
- Floating point literals have the `Double` type by default, but you can use the suffix `f` to narrow it down to `Float`.

```
SELECT
  123l AS `Int64`,
  0b01u AS `Uint32`,
  0xfful AS `Uint64`,
  0o7ut AS `Uint8`,
  456s AS `Int16`,
  1.2345f AS `Float`;
```

Expressions

String concatenation

Executed using the binary operator `||`.

As with other binary operators, if the data on either side is `NULL`, the result is also `NULL`.

Don't confuse this operator with a logical "or": in SQL, it's denoted by the `OR` keyword. It's also not worth doing concatenation using `+`.

Examples

```
SELECT "fo" || "o";
```

Matching a string by pattern

`REGEXP` and `RLIKE` are aliases used to call Re2::Grep. `MATCH`: Same for Re2::Match.

`LIKE` works as follows:

- Patterns can include two special characters:
  - `%`: Zero or more of any characters.
  - `_`: Exactly one of any character.

All other characters are literals that represent themselves.

- As opposed to `REGEXP`, `LIKE` must be matched exactly. For example, to search a substring, add `%` at the beginning and end of the pattern.
- `ILIKE` is a case-insensitive version of `LIKE`.
- If `LIKE` is applied to the key column of the sorted table and the pattern doesn't start with a special character, filtering by prefix drills down directly to the cluster level, which in some cases lets you avoid the full table scan. This optimization is disabled for `ILIKE`.
- To escape special characters, specify the escaped character after the pattern using the `ESCAPE '?'` keyword. Instead of `?` you can use any character except `%`, `_` and `\`. For example, if you use a question mark as an escape character, the expressions `?%`, `?_` and `??` will match their second character in the template: percent, underscore, and question mark, respectively. The escape character is undefined by default.

The most popular way to use the `LIKE` and `REGEXP` keywords is to filter a table using the statements with the `WHERE` clause. However, there are no restrictions on using templates in this context: you can use them in most of contexts involving strings, for example, with concatenation by using `||`.

LIKE / ILIKE with a fulltext index

For fulltext indexes with n-grams (`use_filter_ngram` / `use_filter_edge_ngram`), `LIKE` / `ILIKE` over the indexed text column is supported.

```
SELECT id, title
FROM articles VIEW ft_idx
WHERE body ILIKE "%learn%ing%"
LIMIT 20;
```

Examples

```
SELECT * FROM my_table
WHERE string_column REGEXP '\\d+';
-- the second slash is required because
-- all the standard string literals in SQL
-- can accept C-escaped strings
```

```
SELECT
    string_column LIKE '___!_!_!_!!!!!!' ESCAPE '!'
    -- searches for a string of exactly 9 characters:
    --   3 arbitrary characters
    --   followed by 3 underscores
    --  and 3 exclamation marks
FROM my_table;
```

```
SELECT * FROM my_table
WHERE key LIKE 'foo%bar';
-- if the table is sorted by key, it will only scan the keys,
-- starting with "foo", and then, among them,
-- will leave only those that end in "bar"
```

Operators

Arithmetic operators

The operators `+`, `-`, `*`, `/`, `%` are defined for primitive data types that are variations of numbers.

For the Decimal data type, bankers rounding is used (to the nearest even integer).

Examples

```
SELECT 2 + 2;
```

```
SELECT 0.0 / 0.0;
```

Comparison operators

The operators `=`, `==`, `!=`, `<>`, `>`, `<`, `>=`, `<=` are defined for:

- Primitive data types except Yson and Json.
- Tuples and structures with the same set of fields. No order is defined for structures, but you can check for (non-)equality. Tuples are compared element-by-element left to right.

Examples

```
SELECT 2 > 1;
```

Logical operators

Use the operators `AND`, `OR`, `XOR` for logical operations on Boolean values (`Bool`).

Examples*

```
SELECT 3 > 0 AND false;
```

Bitwise operators

Bitwise operations on numbers:

- `&`, `|`, `^`: AND, OR, and XOR, respectively. Don't confuse bitwise operations with the related keywords. The keywords `AND`, `OR`, and `XOR` are used *for Boolean values only*, but not for numbers.
- `~`: A negation.
- `<`, `>`: Left or right shifts.
- `|<`, `>|`: Circular left or right shifts.

Examples

```
SELECT
    key << 10 AS key,
    ~value AS value
FROM my_table;
```

Precedence and associativity of operators

Operator precedence determines the order of evaluation of an expression that contains different operators.
For example, the expression `1 + 2 * 3` is evaluated as `1 + (2 * 3)` because the multiplication operator has a higher precedence than the addition operator.

Associativity determines the order of evaluating expressions containing operators of the same type.
For example, the expression `1 + 2 + 3` is evaluated as `(1 + 2) + 3` because the addition operator is left-associative.
On the other hand, the expression `a ?? b ?? c` is evaluated as `a ?? (b ?? c)` because the `??` operator is right-associative

The table below shows precedence and associativity of YQL operators.
The operators in the table are listed in descending order of precedence.

Priority	Operator	Description	Associativity
1	`a[], a.foo, a()`	Accessing a container item, calling a function	Left
2	`+a, -a, ~a, NOT a`	Unary operators: plus, minus, bitwise and logical negation	Right
3	`a||b`	String concatenation	Left
4	`a*b, a/b, a%b`	Multiplication, division, remainder of division	Left
5	`a+b, a-b`	Addition/Subtraction	Left
6	`a ?? b`	Operator notation for NVL/COALESCE	Right
7	`a<b, a>b, a|<b, a>|b, a|b, a^b, a&b`	Shift operators and logical bit operators	Left
8	`a<b, a=b, a=b, a>b`	Comparison	Left
9	`a IN b`	Occurrence of an element in a set	Left
9	`a==b, a=b, a!=b, a<>b,` `a is (not) distinct from b`	Comparison for (non-)equality	Left
10	`a XOR b`	Logical XOR	Left
11	`a AND b`	Logical AND	Left
12	`a OR b`	Logical OR	Left

IS [NOT] NULL

Matching an empty value (`NULL`). Since `NULL` is a special value equal to nothing, the ordinary comparison operators can't be used to match it.

Examples

```
SELECT key FROM my_table
WHERE value IS NOT NULL;
```

IS [NOT] DISTINCT FROM

Comparing of two values. Unlike the regular comparison operators, NULLs are treated as equal to each other.
More precisely, the comparison is carried out according to the following rules:

1. The operators `IS DISTINCT FROM` / `IS NOT DISTINCT FROM` are defined for those and only for those arguments for which the operators `!=` and `=` are defined.
2. The result of `IS NOT DISTINCT FROM` is equal to the logical negation of the `IS DISTINCT FROM` result for these arguments.
3. If the result of the `==` operator is not equal to zero for some arguments, then it is equal to the result of the `IS NOT DISTINCT FROM` operator for the same arguments.
4. If both arguments are empty `Optional` or `NULL`s, then the value of `IS NOT DISTINCT FROM` is `True`.
5. The result of `IS NOT DISTINCT FROM` for an empty `Optional` or `NULL` and filled-in `Optional` or non-`Optional` value is `False`.

For values of composite types, these rules are used recursively.

BETWEEN

Checking whether a value is in a range. It's equivalent to two conditions with `>=` and `<=` (range boundaries are included). Can be used with the `NOT` prefix to support inversion.

Examples

```
SELECT * FROM my_table
WHERE key BETWEEN 10 AND 20;
```

IN

Checking whether a value is inside of a set of values. It's logically equivalent to a chain of equality comparisons using `OR` but implemented more efficiently.

> **Warning**
>
> Unlike a similar keyword in Python, in YQL `IN` **DOES NOT** search for a substring inside a string. To search for a substring, use the function String::Contains or LIKE/REGEXP mentioned above.

Immediately after `IN`, you can specify the `COMPACT` modifier.
If `COMPACT` is not specified, then `IN` with a subquery is executed as a relevant `JOIN` (`LEFT SEMI` for `IN` and `LEFT ONLY` for `NOT IN`), if possible.
Using the `COMPACT` modifier forces the in-memory execution strategy: a hash table is immediately built from the contents of the right `IN` part in-memory, and then the left part is filtered.

The `COMPACT` modifier must be used with care. Since the hash table is built in-memory, the query may fail if the right part of `IN` contains many large or different elements.

Examples

```
SELECT column IN (1, 2, 3)
FROM my_table;
```

```
SELECT * FROM my_table
WHERE string_column IN ("a", "b", "c");
```

```
$foo = AsList(1, 2, 3);
SELECT 1 IN $foo;
```

```
$values = (SELECT column + 1 FROM table);
SELECT * FROM my_table WHERE
    -- filtering by an in-memory hash table for one_table
    column1 IN COMPACT $values AND
    -- followed by LEFT ONLY JOIN with other_table
    column2 NOT IN (SELECT other_column FROM other_table);
```

AS

Can be used in the following scenarios:

- Adding a short name (alias) for columns or tables within the query.
- Using named arguments in function calls.
- To specify the target type in the case of explicit type casting, see CAST.

Examples

```
SELECT key AS k FROM my_table;
```

```
SELECT t.key FROM my_table AS t;
```

```
SELECT
    MyFunction(key, 123 AS my_optional_arg)
FROM my_table;
```

CAST

Tries to cast the value to the specified type. The attempt may fail and return `NULL`. When used with numbers, it may lose precision or most significant bits.

For the Decimal parametric data type, two additional arguments are specified:

- Total number of decimal places (up to 35, inclusive).
- Number of places after the decimal point (out of the total number, meaning it can't be larger than the previous argument).

Examples

```
SELECT
    CAST("12345" AS Double),               -- 12345.0
    CAST(1.2345 AS Uint8),                 -- 1
    CAST(12345 AS String),                 -- "12345"
    CAST("1.2345" AS Decimal(5, 2)),       -- 1.23
    CAST("xyz" AS Uint64) IS NULL,         -- true, since it failed
    CAST(-1 AS Uint16) IS NULL,            -- true, negative to unsigned
    CAST([-1, 0, 1] AS List<Uint8?>),            -- [null, 0, 1]
-- The element type is optional: the failed element is null.
    CAST(["3.14", "bad", "42"] AS List<Float>),   -- [3.14, 42]
-- The element type is not optional: the failed element is removed.
    CAST(255 AS Uint8),                    -- 255
    CAST(256 AS Uint8) IS NULL;            -- true, out of range
```

BITCAST

Performs a bitwise conversion of an integer value to the specified integer type. The conversion is always successful, but may lose precision or high-order bits.

Examples

```
SELECT
    BITCAST(100000ul AS Uint32),     -- 100000
    BITCAST(100000ul AS Int16),      -- -31072
    BITCAST(100000ul AS Uint16),     -- 34464
    BITCAST(-1 AS Int16),            -- -1
    BITCAST(-1 AS Uint16);           -- 65535
```

CASE

Conditional expressions and branching. It's similar to `if`, `switch` and ternary operators in the imperative programming languages. If the result of the `WHEN` expression is `true`, the value of the `CASE` expression becomes the result following the condition, and the rest of the `CASE` expression isn't calculated. If the condition is not met, all the `WHEN` clauses that follow are checked. If none of the `WHEN` clauses are met, the `CASE` value is assigned the result from the `ELSE` clause.
The `ELSE` branch is mandatory in the `CASE` expression. Expressions in `WHEN` are checked sequentially, from top to bottom.

Since its syntax is quite sophisticated, it's often more convenient to use the built-in function IF.

Examples

```
SELECT
  CASE
    WHEN value > 0
    THEN "positive"
    ELSE "negative"
  END
FROM my_table;
```

```
SELECT
  CASE value
    WHEN 0 THEN "zero"
    WHEN 1 THEN "one"
    ELSE "not zero or one"
  END
FROM my_table;
```

Named expressions

Complex queries may be sophisticated, containing lots of nested levels and/or repeating parts. In YQL, you can use named expressions to assign a name to an arbitrary expression or subquery. Named expressions can be referenced in other expressions or subqueries. In this case, the original expression/subquery is actually substituted at point of use.

A named expression is defined as follows:

```
<named-expr> = <expression> | <subquery>;
```

Here `<named-expr>` consists of a $ character and an arbitrary non-empty identifier (for example, `$foo`).

If the expression on the right is a tuple, you can automatically unpack it by specifying several named expressions separated by commas on the left:

```
<named-expr1>, <named-expr2>, <named-expr3> ... = <expression-returning-tuple>;
```

In this case, the number of expressions must match the tuple size.

Each named expression has a scope. It starts immediately after the definition of a named expression and ends at the end of the nearest enclosed namescope (for example, at the end of the query or at the end of the body of the lambda function, ACTION). Redefining a named expression with the same name hides the previous expression from the current scope.

If the named expression has never been used, a warning is issued. To avoid such a warning, use the underscore as the first character in the ID (for example, `$_foo`).
The named expression `$_` is called an anonymous named expression and is processed in a special way: it works as if `$_` would be automatically replaced by `$_<some_uniq_name>`.
Anonymous named expressions are convenient when you don't need the expression value. For example, to fetch the second element from a tuple of three elements, you can write:

```
$_, $second, $_ = AsTuple(1, 2, 3);
select $second;
```

An attempt to reference an anonymous named expression results in an error:

```
$_ = 1;
select $_; --- error: Unable to reference anonymous name $_
```

Anonymous argument names are also supported for lambda functions, ACTION.

Note

If named expression substitution results in completely identical subgraphs in the query execution graph, the graphs are combined to execute a subgraph only once.

Examples

```
$multiplier = 712;
SELECT
  a * $multiplier, -- $multiplier is 712
  b * $multiplier,
  (a + b) * $multiplier
FROM abc_table;
$multiplier = c;
SELECT
  a * $multiplier -- $multiplier is column c
FROM abc_table;
```

```
$intermediate = (
  SELECT
    value * value AS square,
    value
  FROM my_table
);
SELECT a.square * b.value
FROM $intermediate AS a
INNER JOIN $intermediate AS b
ON a.value == b.square;
```

```
$a, $_, $c = AsTuple(1, 5u, "test"); -- unpack a tuple
SELECT $a, $c;
```

```
$x, $y = AsTuple($y, $x); -- swap expression values
```

Table expressions

A table expression is an expression that returns a table. Table expressions in YQL are as follows:

- Subqueries: `(SELECT key, subkey FROM T)`
- Named subqueries: `$foo = SELECT * FROM T;` (in this case, `$foo` is also a table expression)

Semantics of a table expression depends on the context where it is used. In YQL, table expressions can be used in the following contexts:

- Table context: after FROM. In this case, table expressions work as expected: for example, `$input = SELECT a, b, c FROM T; SELECT * FROM $input` returns a table with three columns. The table context also occurs after UNION ALL, JOIN;

- Vector context: after IN. In this context, the table expression must contain exactly one column (the name of this column doesn't affect the expression result in any way). A table expression in a vector context is typed as a list (the type of the list element is the same as the column type in this case). Example: `SELECT * FROM T WHERE key IN (SELECT k FROM T1)`;
- A scalar context arises *in all the other cases*. As in a vector context, a table expression must contain exactly one column, but the value of the table expression is a scalar, that is, an arbitrarily selected value of this column (if no rows are returned, the result is `NULL`). Example: `$count = SELECT COUNT(*) FROM T; SELECT * FROM T ORDER BY key LIMIT $count / 2`;

The order of rows in a table context, the order of elements in a vector context, and the rule for selecting a value from a scalar context (if multiple values are returned), aren't defined. This order also cannot be affected by `ORDER BY`: `ORDER BY` without `LIMIT` is ignored in table expressions with a warning, and `ORDER BY` with `LIMIT` defines a set of elements rather than the order within that set.

Lambda functions

Let you combine multiple expressions into a single callable value.

List arguments in round brackets, following them by the arrow and lambda function body. The lambda function body includes either an expression in round brackets or curly brackets around an optional chain of named expressions assignments and the call result after the `RETURN` keyword in the last expression.

The scope for the lambda body: first the local named expressions, then arguments, then named expressions defined above by the lambda function at the top level of the query.

Only use pure expressions inside the lambda body (those might also be other lambdas, possibly passed through arguments). However, you can't use SELECT, INSERT INTO, or other top-level expressions.

One or more of the last lambda parameters can be marked with a question mark as optional: if they haven't been specified when calling lambda, they are assigned the `NULL` value.

Examples

```
$f = ($y) -> {
    $prefix = "x";
    RETURN $prefix || $y;
};

$g = ($y) -> ("x" || $y);

$h = ($x, $y?) -> ($x + ($y ?? 0));

SELECT $f("y"), $g("z"), $h(1), $h(2, 3); -- "xy", "xz", 1, 5
```

```
-- if the lambda result is calculated by a single expression, then you can use a more compact syntax:
$f = ($x, $_) -> ($x || "suffix"); -- the second argument is not used
SELECT $f("prefix_", "whatever");
```

Accessing containers

For accessing the values inside containers:

- `Struct<>`, `Tuple<>` and `Variant<>`, use a **dot**. The set of keys (for the tuple and the corresponding variant — indexes) is known at the query compilation time. The key is **validated** before beginning the query execution.
- `List<>` and `Dict<>`, use **square brackets**. The set of keys (set of indexes for keys) is known only at the query execution time. The key is **not validated** before beginning the query execution. If no value is found, an empty value (NULL) is returned.

Description and list of available containers.

When using this syntax to access containers within table columns, be sure to specify the full column name, including the table name or table alias separated by a dot (see the first example below).

Examples

```
SELECT
  t.struct.member,
  t.tuple.7,
  t.dict["key"],
  t.list[7]
FROM my_table AS t;
```

```
SELECT
  Sample::ReturnsStruct().member;
```

Unsupported classic SQL constructs

Correlated EXISTS and NOT EXISTS

`EXISTS` and `NOT EXISTS` can be used with uncorrelated subqueries. Correlated subqueries are not supported. To select rows based on the presence or absence of matching rows, use `LEFT SEMI JOIN` or `LEFT ONLY JOIN`. For details, see Correlated subqueries, EXISTS, and NOT EXISTS.

INTERSECT and EXCEPT

YQL does not support `INTERSECT` or `EXCEPT`.

NATURAL JOIN

An alternative is to explicitly list the matching columns on both sides.

NOW() / CURRENT_TIME()

An alternative is to use the functions CurrentUtcDate, CurrentUtcDatetime and CurrentUtcTimestamp.

Correlated subqueries, EXISTS, and NOT EXISTS

A correlated subquery refers to a column or table alias from an outer query. Each subquery in YQL has its own scope and cannot refer to columns or table aliases from an outer query. Therefore, YQL does not support correlated subqueries. Support for correlated subqueries is planned for future releases.

Support matrix

SQL pattern	YQL support	Use instead
An uncorrelated subquery in `FROM` or `IN`	Supported	Use the subquery directly
An uncorrelated `EXISTS (SELECT ...)`	Supported; returns `true` if the subquery contains at least one row	Use directly when the condition does not depend on an outer row
An uncorrelated `NOT EXISTS (SELECT ...)`	Supported; returns `true` if the subquery is empty	Use directly when the condition does not depend on an outer row
`EXISTS` referring to an outer column	Not supported	`LEFT SEMI JOIN`, or `INNER JOIN` with unique right-side keys
`NOT EXISTS` referring to an outer column	Not supported	`LEFT ONLY JOIN`
A correlated scalar or aggregate subquery	Not supported	Precompute the result and use `JOIN`

EXISTS

An uncorrelated `EXISTS` checks whether its subquery contains at least one row. Its result does not depend on a row from an outer query. For example, the following query returns every client if the `orders` table is non-empty and no clients otherwise:

```
SELECT client_id, name
FROM clients
WHERE EXISTS (
    SELECT 1
    FROM orders
);
```

The following common SQL query is not supported because the inner query refers to the outer alias `c`:

```
-- Not supported in YQL.
SELECT c.client_id, c.name
FROM clients AS c
WHERE EXISTS (
    SELECT 1
    FROM orders AS o
    WHERE o.client_id = c.client_id
);
```

Use `LEFT SEMI JOIN` to return a client only when at least one matching order exists:

```
SELECT c.client_id, c.name
FROM clients AS c
LEFT SEMI JOIN orders AS o
ON o.client_id = c.client_id;
```

`LEFT SEMI JOIN` returns columns from the left side only. Several matching rows on the right side do not duplicate a row from the left side, so this rewrite preserves the existence-check semantics.

Alternatively, use `INNER JOIN` after deduplicating the matching keys on the right side:

```
$order_clients = (
    SELECT client_id
    FROM orders
    GROUP BY client_id
);

SELECT c.client_id, c.name
FROM clients AS c
INNER JOIN $order_clients AS o
ON o.client_id = c.client_id;
```

The right side contains at most one row for each key, so the join does not duplicate rows from the left side. Applying `DISTINCT` to the left-side columns is unnecessary and can collapse equal rows from the outer input.

For a single non-optional key, `IN` is another possible rewrite:

```
SELECT c.client_id, c.name
FROM clients AS c
WHERE c.client_id IN (
    SELECT o.client_id
    FROM orders AS o
);
```

NOT EXISTS

An uncorrelated `NOT EXISTS` returns the inverse of `EXISTS`: `true` when its subquery is empty and `false` when the subquery contains at least one row. Its result also does not depend on a row from an outer query.

Use `LEFT ONLY JOIN` to return a client only when no matching order exists:

```
SELECT c.client_id, c.name
FROM clients AS c
LEFT ONLY JOIN orders AS o
ON o.client_id = c.client_id;
```

Correlated aggregate subqueries

Precompute the aggregate and join it to the outer table:

```
$last_order = (
    SELECT client_id, MAX(created_at) AS last_order_at
    FROM orders
    GROUP BY client_id
);

SELECT c.client_id, o.last_order_at
FROM clients AS c
LEFT JOIN $last_order AS o
ON o.client_id = c.client_id;
```

- Known limitations

ACTION

DEFINE ACTION

Specifies a named action that is a parameterizable block of multiple top-level expressions.

Syntax

1. `DEFINE ACTION`: action definition.
2. Action name that will be used to access the defined action further in the query.
3. The values of parameter names are listed in parentheses.
4. `AS` keyword.
5. List of top-level expressions.
6. `END DEFINE`: The marker of the last expression inside the action.

One or more of the last parameters can be marked with a question mark `?` as optional. If they are omitted during the call, they will be assigned the `NULL` value.

DO

Executes an `ACTION` with the specified parameters.

Syntax

1. `DO`: Executing an action.
2. The named expression for which the action is defined.
3. The values to be used as parameters are listed in parentheses.

`EMPTY_ACTION`: An action that does nothing.

Example

```
DEFINE ACTION $hello_world($name, $suffix?) AS
    $name = $name ?? ($suffix ?? "world");
    SELECT "Hello, " || $name || "!";
END DEFINE;

DO EMPTY_ACTION();
DO $hello_world(NULL);
DO $hello_world("John");
DO $hello_world(NULL, "Earth");
```

BEGIN .. END DO

Performing an action without declaring it (anonymous action).

Syntax

1. `BEGIN`.
2. List of top-level expressions.
3. `END DO`.

An anonymous action can't include any parameters.

Example

```
DO BEGIN
    SELECT 1;
    SELECT 2 -- here and in the previous example, you might omit ';' before END
END DO
```

ALTER ASYNC REPLICATION

The `ALTER ASYNC REPLICATION` statement modifies the status and parameters of an asynchronous replication instance.

Syntax

```
ALTER ASYNC REPLICATION <name> SET (option = value [, ...])
```

Parameters

- `name` — a name of the asynchronous replication instance.
- `SET (option = value [, ...])` — asynchronous replication parameters:
  - `STATE` : the state of asynchronous replication. Valid values are:
    - `PAUSED` : pause the application of changes. Changefeeds in the source continue accumulating records according to the availability policy set by `AVAILABILITY_PERIOD` . Replica objects already attached remain read-only.
    - `STANDBY` : start or resume change data replication. For replication created with `INITIAL_SCAN = FALSE` , attaches previously restored target tables. Before starting replication, finish importing all tables as described in the initial synchronization guide.
    - `DONE` : complete the asynchronous replication process. For forced completion, also specify `FAILOVER_MODE = 'FORCE'` .
  - `FAILOVER_MODE` : the replication completion mode. Applies only with `STATE = 'DONE'` . This parameter is not required for `PAUSED` or `STANDBY` . Valid values are:
    - `FORCE` — forced failover.
- Authentication settings for the source database (one of the following):
  - Using a token:
    - `TOKEN_SECRET_PATH` — the secret that contains the token.
  - Using a username and password:
    - `USER` — the username.
    - `PASSWORD_SECRET_PATH` — the secret that contains the password.
  - Using a service agent:
    - `SERVICE_ACCOUNT_ID` — the identificator of the service account.
    - `INITIAL_TOKEN_SECRET_PATH` — the secret that contains the account's token. It is used for initial authentication.

Examples

The following statement starts replication after importing the initial data:

```
ALTER ASYNC REPLICATION my_replication SET (STATE = 'STANDBY');
```

The following statement pauses the application of changes:

```
ALTER ASYNC REPLICATION my_replication SET (STATE = 'PAUSED');
```

To resume replication, use `STATE = 'STANDBY'` . With a finite `AVAILABILITY_PERIOD` , account for the age of messages already accumulated, the pause, and subsequent processing time: pausing does not suspend the availability period. With `'UNLIMITED'` , unacknowledged changes are retained until processed; monitor free space in the source.

The following statement forces the asynchronous replication process to complete:

```
ALTER ASYNC REPLICATION my_replication SET (STATE = "DONE", FAILOVER_MODE = "FORCE");
```

The following query changes the secret:

```
ALTER ASYNC REPLICATION my_replication SET (TOKEN_SECRET_PATH = "my_token");
```

- CREATE ASYNC REPLICATION
- DROP ASYNC REPLICATION

ALTER DATABASE

Changes database settings.

Syntax

```
ALTER DATABASE path action;
```

Parameters

- `path` — path to the database;
- `action` — any of the database modification actions described below:
  - Change database owner.
  - Change database settings.

Change database owner

Changes the database owner. Only a database administrator can perform this operation.

Syntax

```
ALTER DATABASE path OWNER TO user_name;
```

Parameters

- `path` — path to the database;
- `user_name` — name of the user who will become the database owner.

Examples

Make user `user1` the owner of database `/Root/test`:

```
ALTER DATABASE `/Root/test` OWNER TO user1;
```

Change database settings

Changes database settings. Only a database administrator can perform this operation.

Syntax

```
ALTER DATABASE path SET (key = value, ...)
```

Parameters

- `path` — path to the database.
- `key` — name of the setting to change:
  - `MAX_PATHS` — maximum number of paths (schema objects) in the database.
  - `MAX_SHARDS` — maximum number of tablets in the database.
  - `MAX_CHILDREN_IN_DIR` — maximum number of objects in a directory.
  - `MAX_SHARDS_IN_PATH` — maximum number of tablets associated with a single schema object. For example, the maximum number of partitions of one table.
- `value` — new value for the setting.

Examples

Change the limit on the maximum number of paths (schema objects) for database `/Root/test`:

```
ALTER DATABASE `/Root/test` SET (MAX_PATHS = 20000);
```

ALTER GROUP

Adds/removes the group to/from a specific user. You can list multiple users under one operator.

Syntax:

```
ALTER GROUP role_name ADD USER user_name [, ... ]
ALTER GROUP role_name DROP USER user_name [, ... ]
```

- `role_name`: The name of the group.
- `user_name`: The name of the user.

Built-in groups

The YDB cluster has built-in groups providing predefined role sets:

Group	Description
`ADMINS`	Unlimited rights over the entire cluster schema
`DATABASE-ADMINS`	Rights to create and delete databases (`CreateDatabase` , `DropDatabase`)
`ACCESS-ADMINS`	Rights to manage other users' permissions (`GrantAccessRights`)
`DDL-ADMINS`	Rights to alter database schemas (`CreateDirectory` , `CreateTable` , `WriteAttributes` , `AlterSchema` , `RemoveSchema`)
`DATA-WRITERS`	Rights to modify data (`UpdateRow` , `EraseRow`)
`DATA-READERS`	Rights to read data (`SelectRow`)
`METADATA-READERS`	Rights to read metadata, without access to data (`DescribeSchema` and `ReadAttributes`)
`USERS`	Rights to connect to databases (`ConnectDatabase`)

By default, all users are included in the `USERS` group, and the `root` user is included in the `ADMINS` group.

Below is a diagram demonstrating how groups inherit permissions from each other. For example, `DATA-WRITERS` includes all permissions of `DATA-READERS`:

ALTER TABLE

Using the `ALTER TABLE` command, you can change the column composition and additional parameters row and column tables. You can specify multiple actions in a single command. In general, the `ALTER TABLE` command looks like this:

```
ALTER TABLE table_name action1, action2, ..., actionN;
```

`action` is any table modification action from those described below:

- Renaming a table.
- Working with columns of row and column tables.
- Adding or removing a change stream.
- Working with indexes.
- Working with column groups of a row table.
- Changing additional table parameters.
- Running forced compaction.
- Changing the NOT NULL constraint.

Adding, deleting, and renaming an index

Adding an index

`ADD INDEX` — adds an index with the specified name and type for the given set of columns in row tables. Grammar:

```
ALTER TABLE `<table_name>`
  ADD INDEX `<index_name>`
    [GLOBAL|LOCAL]
    [UNIQUE]
    [SYNC|ASYNC]
    [USING <index_type>]
    ON ( <index_columns> )
    [COVER ( <cover_columns> )]
    [WITH ( <parameter_name> = <parameter_value>[, ...])]
  [,   ...]
```

- `GLOBAL/LOCAL` — global or local index, depending on the index type (`<index_type>`), only one of them may be available:
  - `GLOBAL` — an index implemented as a separate table or a set of tables. Synchronous update of such an index requires distributed transactions.
  - `LOCAL` — a local index within a shard of a columnar or row-based table, does not require distributed transactions during update, but does not provide pruning during search.
- `<index_name>` — unique index name by which data can be accessed.
- `SYNC/ASYNC` — indicator of index synchrony.
  - `SYNC` - synchronous index. Default value.
  - `ASYNC` - asynchronous index.
- `UNIQUE` — indicator of a unique secondary index. A unique index must be global synchronous (`GLOBAL UNIQUE SYNC`) and must not contain the `USING <index_type>` construct.
- `<index_type>` - index type, currently supported:
  - `secondary` — secondary index. Only the `GLOBAL` mode is available for secondary indexes. This is the default index type.
  - `vector_kmeans_tree` — vector index. More details are described in the Vector index section.
  - `fulltext_plain` — basic full-text index. More details are described in Fulltext index.
  - `fulltext_relevance` — full-text index with BM25 statistics for relevance calculation. More details are described in Fulltext index.
  - `json` — JSON index to speed up predicates `JSON_EXISTS` and `JSON_VALUE` on a column of type `Json` or `JsonDocument` . More details are described in JSON-index.
  - `bloom_filter` — local Bloom index. Only `LOCAL` is available. See ALTER TABLE ADD INDEX.
  - `bloom_ngram_filter` — local N-gram Bloom index. Only `LOCAL` is available. See ALTER TABLE ADD INDEX.
- `<index_columns>` — comma-separated list of column names of the table being created, which determines the composition and order of columns included in the index key. Must be specified. The index key will consist of these columns with the addition of the table's primary key columns.
- `<cover_columns>` — comma-separated list of column names of the table being created that will be stored in the index in addition to the index key columns, allowing you to get additional data without accessing the table. Empty by default.
- `<parameter_name>` and `<parameter_value>` are index parameters specific to a particular `<index_type>` .

Parameters for all index types:

- - maximum number of `parallel` handlers based on partitions involved in index building (an integer between `1` and `MaxBuildIndexShardsInFlight` from `SchemeShardConfig`).
- If the parameter is not specified, the default value `32` or `MaxBuildIndexShardsInFlight` is currently used, whichever is smaller. `MaxBuildIndexShardsInFlight` defaults to `1000` . In future versions, the default parallelism selection logic may change.
- You can set a lower limit to reduce the impact of index building on database performance.
- You can also set a higher limit to speed up index building if you have sufficient hardware resources.

Parameters specific to vector indexes:

- common parameters for all vector indexes:
  - `vector_dimension` - embedding vector dimensionality (should be between 1 and 16384)
  - `vector_type` - vector value type (`float` , `uint8` , or `int8`)
  - `distance` - distance function (`cosine` , `manhattan` , or `euclidean`), mutually exclusive with `similarity`
  - `similarity` - similarity function (`inner_product` or `cosine`), mutually exclusive with `distance`
- specific parameters for `vector_kmeans_tree` (read more about the index type):
  - `clusters` - number of centroids for k-means algorithm (should be between 2 and 2048)
  - `levels` - number of levels in the tree (should be between 1 and 16)
  - `overlap_clusters` - the number of nearest clusters to add each vector to (default 1)
  - the total number of nodes in the tree, calculated as `clusters` raised to the power of `levels` , should be no more than 1073741824
  - the product of `vector_dimension` and `clusters` should be no more than 4194304

> **Note**
>
> For vector indexes, the `vector_type` and `vector_dimension` parameters can be omitted if the table is not empty — they are determined automatically from the row contents. The `levels` and `clusters` parameters are also determined automatically, and for them the table can be empty, but doing so is strongly not recommended because the default values in this case are `levels` =1, `clusters` =2; it is much better to create the index on a table that already has data loaded, so that the values can be correctly determined.

Parameters specific to full-text indexes:

- common parameters for all fulltext indexes:
  - `tokenizer` - tokenizer type (`standard` , `whitespace` , or `keyword`)
  - `use_filter_lowercase` - lowercase filter (`true` or `false`)
  - `use_filter_length` - token length filter (`true` or `false`); when `true` , tokens shorter than `filter_length_min` or longer than `filter_length_max` are not indexed and are ignored during search
  - `filter_length_min` - minimum token length (positive integer); only applied when `use_filter_length=true`
  - `filter_length_max` - maximum token length (positive integer); only applied when `use_filter_length=true`
  - `use_filter_snowball` - Snowball stemmer filter (`true` or `false`)
  - `language` - language for the Snowball stemmer (for example, `english` , `russian`)
  - `use_filter_ngram` - n-gram filter (`true` or `false`)
  - `use_filter_edge_ngram` - edge n-gram filter (`true` or `false`)
  - `filter_ngram_min_length` - minimum n-gram length (positive integer)
  - `filter_ngram_max_length` - maximum n-gram length (positive integer)

Parameters of local bloom indexes

- `bloom_filter`
  - `false_positive_probability` : Target false-positive rate of the filter: the fraction of fragments that are not skipped even though the requested value is not there (range `(0, 1)`). A lower value reduces extra reads but increases index size.
    - If omitted, the default is `0.0001` for row-oriented tables and `0.1` for column-oriented tables. The stricter default on row-oriented tables matches OLTP point lookups; on column-oriented tables it reflects analytical scans, where a larger trade-off between index size and fragment skipping is acceptable.
  - Indexed columns: YQL types that support equality comparison, except `Yson` , `Json` , and `JsonDocument` (see comparison operators). One column in a column-oriented table; multiple columns in a row-oriented table. On row-oriented tables, the indexed columns must form a left prefix of the primary key.
- `bloom_ngram_filter` (`String` and `Utf8` columns; column-oriented tables only)
  - `ngram_size` : N-gram length, an integer from `3` to `8` (default `3`).
  - `false_positive_probability` : Target false-positive rate (range `(0, 1)` ; default `0.1`).
  - `case_sensitive` : Whether n-grams respect character case: `true` or `false` (default `true`).

Parameters of the local min_max index

You can also add a secondary index using the table index YDB CLI command.

Limitations

The `ADD INDEX` operation for creating global secondary (`GLOBAL` , `UNIQUE` , etc.) and vector indexes is supported only for row tables. For columnar tables, via `ADD INDEX` , only local bloom indexes are supported.

Features of local bloom indexes:

- The index is always local (`LOCAL`); there is no global variant.
- Queries do not use the `VIEW <index>` syntax (unlike, for example, fulltext indexes).
- The filter is applied on read only to data fragments where an index block was already stored during a write or portion merge, other fragments are not skipped by this index until merge.
- On row-oriented tables, `bloom_filter` is implemented as a **prefix bloom filter**: the indexed columns must form a left prefix of the primary key. The filter is built over that key prefix and accelerates point lookups and range scans that constrain the prefix. Multiple bloom indexes over the same prefix length are not allowed.

Limitations

- `COVER (...)` and extra index columns are not supported.
- Column-oriented tables allow only one indexed column. Row-oriented tables allow multiple indexed columns.
- `bloom_ngram_filter` is not supported on row-oriented tables.
- On row-oriented tables, the indexed columns of a `bloom_filter` must be a left prefix of the primary key. Non-prefix column sets are rejected.
- On row-oriented tables, two `bloom_filter` indexes cannot share the same prefix length (the same set of leading primary-key columns).

Examples

Secondary index:

```
ALTER TABLE `series`
  ADD INDEX `title_index`
  GLOBAL ON (`title`);
```

Vector index:

```
ALTER TABLE `series`
  ADD INDEX emb_cosine_idx GLOBAL SYNC USING vector_kmeans_tree
  ON (embedding) COVER (title)
  WITH (
    distance="cosine", vector_type="float", vector_dimension=512
  );
```

Full-text index:

```
ALTER TABLE `series`
  ADD INDEX ft_idx GLOBAL USING fulltext_plain
  ON (title)
  WITH (tokenizer=standard, use_filter_lowercase=true);
```

JSON index:

```
ALTER TABLE `series`
  ADD INDEX json_idx GLOBAL USING json
  ON (metadata);
```

Bloom index:

```
ALTER TABLE `/Root/Table`
  ADD INDEX idx_bloom LOCAL USING bloom_filter
  ON (resource_id)
  WITH (false_positive_probability = 0.01);
```

Bloom n-gram index:

```
ALTER TABLE `/Root/Table`
  ADD INDEX idx_ngram LOCAL USING bloom_ngram_filter
  ON (message)
  WITH (
    ngram_size = 3,
    false_positive_probability = 0.01,
    case_sensitive = true
  );
```

Changing index parameters

Индексы имеют параметры, зависящие от типа, которые можно настраивать. Глобальные индексы, синхронные или асинхронные, реализованы в виде скрытых таблиц, и их параметры автоматического партиционирования и реплик можно регулировать так же, как и настройки обычных таблиц.

Note

В настоящее время задание настроек партиционирования вторичных индексов при создании индекса не поддерживается ни в операторе `ALTER TABLE ADD INDEX`, ни в операторе `CREATE TABLE INDEX`.

```
ALTER TABLE <table_name> ALTER INDEX <index_name> SET <setting_name> <value>;
ALTER TABLE <table_name> ALTER INDEX <index_name> SET (<setting_name_1> = <value_1>, ...);
```

- `<table_name>` - name of the table whose index needs to be changed.
- `<index_name>` - name of the index to change.
- `<setting_name>` - name of the parameter to change. The set of allowed parameters depends on the index type:
  - for global secondary indexes:
    - AUTO_PARTITIONING_BY_SIZE
    - AUTO_PARTITIONING_BY_LOAD
    - AUTO_PARTITIONING_PARTITION_SIZE_MB
    - AUTO_PARTITIONING_MIN_PARTITIONS_COUNT
    - AUTO_PARTITIONING_MAX_PARTITIONS_COUNT
    - READ_REPLICAS_SETTINGS
  - for local bloom indexes (see Parameters of local bloom indexes):
    - `FALSE_POSITIVE_PROBABILITY`
    - `NGRAM_SIZE` and `CASE_SENSITIVE` (only for `bloom_ngram_filter`)

Note

The `RESET` operation for `ALTER INDEX` is not supported.

- `<value>` - new parameter value. Possible values include:
  - `ENABLED` or `DISABLED` for the `AUTO_PARTITIONING_BY_SIZE` and `AUTO_PARTITIONING_BY_LOAD` parameters
  - `"PER_AZ:<count>"` or `"ANY_AZ:<count>"` where `<count>` is the number of replicas for `READ_REPLICAS_SETTINGS`
  - for other parameters — an integer of type `Uint64`
  - for `FALSE_POSITIVE_PROBABILITY` — a floating-point number in the range `(0, 1)`; a smaller value usually reduces the number of false positives but increases the index size
  - for `NGRAM_SIZE` — an integer in the range from `3` to `8` (usually recommended to start with `3`)
  - for `CASE_SENSITIVE` — `true` or `false`

Example

The code in the following example enables automatic partitioning by load for the index named `title_index` in the table `series`, sets the minimum number of partitions to 5, and starts one replica in each availability zone (AZ) for each partition:

```
ALTER TABLE `series` ALTER INDEX `title_index` SET (
    AUTO_PARTITIONING_BY_LOAD = ENABLED,
    AUTO_PARTITIONING_MIN_PARTITIONS_COUNT = 5,
    READ_REPLICAS_SETTINGS = "PER_AZ:1"
);
```

For local bloom indexes, you can also change their specific parameters, for example:

```
ALTER TABLE `/Root/Table` ALTER INDEX idx_ngram SET (
    ngram_size = 4,
    false_positive_probability = 0.005,
    case_sensitive = false
);
```

Deleting an index

`DROP INDEX` — deletes the index with the specified name. The code below will delete the index named `title_index`.

```
ALTER TABLE `series` DROP INDEX `title_index`;
```

You can also delete an index using the table index YDB CLI command.

Renaming a secondary index

`RENAME INDEX` — renames the index with the specified name. If an index with the new name already exists, an error will be returned.

The ability to atomically replace an index under load is supported by the ydb table index rename YDB CLI command and specialized YDB SDK methods.

This applies to global secondary indexes (hidden index table and `--replace` mode). Local bloom indexes are not applicable to such atomic replacement under load.

Example of renaming an index:

```
ALTER TABLE `series` RENAME INDEX `title_index` TO `title_index_new`;
```

Changing columns

YDB supports adding columns to row and column tables, deleting non-key columns from tables, and changing properties of existing columns.

ADD COLUMN

Builds a new column with the specified name, type, and options for the specified table.

```
ALTER TABLE table_name ADD COLUMN column_name column_data_type [FAMILY <family_name>] [NULL | NOT NULL] [DEFA
ULT <default_value>] [COMPRESSION([algorithm=<algorithm_name>[, level=<value>]])] [ENCODING([OFF|DICT])];
```

When adding a `NOT NULL` column to a row-oriented table, you must also specify `DEFAULT` so that the new column can be populated in existing rows. Column-oriented tables do not support adding a `NOT NULL` column because they do not support `DEFAULT` values.

Request parameters

table_name

The path of the table to which you want to add a new column.

column_name

The name of the column to be created. When choosing a name for the column, consider the common column naming rules.

column_data_type

The data type of the column. The complete list of data types supported by YDB is available in the YQL data types section.

FAMILY <family_name> (column setting)

> **Warning**
>
> Supported only for row-oriented tables.

Specifies the belonging of this column to the specified group of columns. For more details, see the section Column groups.

DEFAULT <default_value>

> **Warning**
>
> The `DEFAULT` option is supported:
>
> - Only for row-oriented tables.
> - Only with literal values.

Allows you to set a default value for the column. If no value is specified for this column when inserting a row, the specified default value will be used. The default value must match the data type of the column.

The `DEFAULT false NOT NULL` construct is not allowed due to ambiguity of interpretation. In this case, you should use a comma-separated list or change the order of the options.

NULL

This column can contain `NULL` values (by default).

NOT NULL

This column does not accept `NULL` values.

COMPRESSION([algorithm=<algorithm_name>[, level=]])

> **Warning**
>
> Supported only for column-oriented tables.

The following compression parameters can be set for columns:

- `algorithm` — the data compression algorithm. Allowed values: `off` (disable compression), `lz4`, `zstd`.
- `level` — the compression level, supported only for the `zstd` algorithm (values from 0 to 22 are allowed).

If `COMPRESSION()` is specified without parameters, the default compression is used for the column. Currently, it is `lz4`; in future versions, it will be possible to configure the default compression at the cluster or table level.

ENCODING([OFF|DICT])

> **Warning**
>
> Supported only for column-oriented tables.

Allows you to set the data encoding method for the column.

Available options:

- `ENCODING(DICT)` — enables dictionary encoding. Repeating values are replaced with small integer identifiers, and the values themselves are stored in a dictionary. Dictionary encoding is effective for columns with low cardinality (a small number of unique

values). It reduces the amount of stored data and speeds up some operations. It is supported only for comparable data types, such as `String`, `Timestamp`, `UInt64`, and others. Using `ENCODING(DICT)` for incomparable types, such as `Json`, `JsonDocument`, or `Yson`, will result in an error.

- `ENCODING(OFF)` — disables special encoding. Data will be stored in the standard format without additional encoding.

If `ENCODING()` is set without parameters, the default encoding will be used for the column. Currently, it is `OFF`; in future versions, it will be possible to configure the default encoding at the database or table level.

Example

The code below will add a column named `views` with data type `Uint64` to the `episodes` table.

```
ALTER TABLE episodes ADD COLUMN views Uint64;
```

The code below will add a column named `rate` with data type `Double` and default value `5.0` to the `episodes` table.

```
ALTER TABLE episodes ADD COLUMN rate Double NOT NULL DEFAULT 5.0;
ALTER TABLE episodes ADD COLUMN rate Double (DEFAULT 5.0, NOT NULL); -- alternative syntax
```

ALTER COLUMN

Modifies properties of an existing column in the specified table. Property changes are applied without recreating the column. Some properties apply only to newly written data or during compaction (see the description of each property for details).

```
ALTER TABLE table_name ALTER COLUMN column_name SET [FAMILY <family_name>]{% if feature_flags.enable_set_colu
mn_constraint == true %} [NOT NULL]{% endif %} [DEFAULT <default_value>] [COMPRESSION([algorithm=<algorithm_n
ame>[, level=<value>]])] [ENCODING([OFF|DICT])];
ALTER TABLE table_name ALTER COLUMN column_name DROP [FAMILY] [NOT NULL] [DEFAULT] [COMPRESSION] [ENCODING];
```

Request parameters

table_name

The path of the table containing the column to change.

column_name

The name of the column to change in the specified table.

SET

Set a column property.

DROP

Remove a column property.

FAMILY <family_name> (column setting)

> **Warning**
>
> Supported only for row-oriented tables.

Specifies that this column belongs to the specified column group. For more information, see Column groups.

DEFAULT <default_value>

> **Warning**
>
> The `DEFAULT` option is supported:
>
> - Only for row tables.
> - Only with literal values.

Sets a default value for the column. If no value is specified for this column when inserting a row, the specified default value is used. The default value must match the column's data type.

NOT NULL

The following operations are available:

- `DROP NOT NULL` — removes the `NOT NULL` constraint from the column, again allowing `NULL` values.

For details, see Changing the `NOT NULL` constraint.

COMPRESSION([algorithm=<algorithm_name>[, level=]])

> **Warning**
>
> Supported only for column-oriented tables.

The following compression parameters can be set for columns:

- `algorithm` — data compression algorithm. Valid values: `off` (disable compression), `lz4`, `zstd`.
- `level` — compression level, supported only for the `zstd` algorithm (valid values from 0 to 22).

If `COMPRESSION()` is specified without parameters, the default compression is used for the column. Currently this is `lz4`; future versions will allow configuring default compression at the cluster or table level.

ENCODING([OFF|DICT])

> **Warning**
>
> Supported only for column-oriented tables.

Sets the encoding method for the column data.

Available options:

- `ENCODING(DICT)`: enables dictionary encoding. Duplicate values are replaced with small integer identifiers, and the values themselves are stored in a dictionary. Dictionary encoding is effective for columns with low cardinality (a small number of unique values). It reduces the amount of stored data and speeds up some operations. Supported only for comparable data types, such as `String`, `Timestamp`, `UInt64`, and others. For non-comparable types, such as `Json`, `JsonDocument`, or `Yson`, using `ENCODING(DICT)` will result in an error.
- `ENCODING(OFF)`: disables special encoding. Data will be stored in standard format without additional encoding.

If `ENCODING()` is specified without parameters, the default encoding will be used for the column. Currently it is `OFF`; future versions will allow configuring the default encoding at the database or table level.

A single `ALTER TABLE` statement can specify multiple `ALTER COLUMN` actions separated by commas.

Examples

The code below sets a default value for the `rate` column of the `episodes` table.

```
ALTER TABLE episodes ALTER COLUMN rate SET DEFAULT 5.0;
```

The code below changes default values for several columns of a table in a single statement — setting new defaults for `col_1` and `col_2` and clearing the default for `col_3`.

```
ALTER TABLE default_columns
    ALTER COLUMN col_1 SET DEFAULT "new_a"u,
    ALTER COLUMN col_2 SET DEFAULT 99,
    ALTER COLUMN col_3 DROP DEFAULT;
```

Reset column compression settings:

```
ALTER TABLE compressed_table ALTER COLUMN info SET COMPRESSION();
```

After the query runs, the column uses the default compression algorithm again (see the `COMPRESSION` option above).

Enable dictionary encoding on a column:

```
ALTER TABLE movies ALTER COLUMN genre SET ENCODING(DICT);
```

DROP COLUMN

Deletes a column with the specified name from the specified table.

```
ALTER TABLE table_name DROP COLUMN column_name;
```

Request parameters

table_name

The path of the table from which you want to delete a column.

column_name

The name of the column to be deleted.

Example

The code below will delete the column named `views` from the `episodes` table.

```
ALTER TABLE episodes DROP COLUMN views;
```

Changing column groups

> **Warning**
>
> Supported only for row-oriented tables.

The mechanism of column groups allows for improved performance of partial row read operations by dividing the storage of table columns into several groups. The most commonly used scenario is to organize the storage of infrequently used attributes into a separate column group.

Creating column groups

`ADD FAMILY`: Creates a new group of columns in the table. The code below creates the `family_small` column group in the `series_with_families` table.

```
ALTER TABLE series_with_families ADD FAMILY family_small (
    DATA = "ssd",
    COMPRESSION = "off"
);
```

Modifying column groups

Using the `ALTER COLUMN` command, you can change a column group for the specified column. The code below for the `release_date` column in the `series_with_families` table changes the column group to `family_small`.

```
ALTER TABLE series_with_families ALTER COLUMN release_date SET FAMILY family_small;
```

The two previous commands from listings 8 and 9 can be combined into one `ALTER TABLE` call. The code below creates the `family_small` column group and sets it for the `release_date` column in the `series_with_families` table.

```
ALTER TABLE series_with_families
    ADD FAMILY family_small (
        DATA = "ssd",
        COMPRESSION = "off"
    ),
    ALTER COLUMN release_date SET FAMILY family_small;
```

Using the `ALTER FAMILY` command, you can change the parameters of the column group.

Changing storage type

The code below changes the storage type to `rot` for the `default` column group in the `series_with_families` table:

```
ALTER TABLE series_with_families ALTER FAMILY default SET DATA "rot";
```

> **Note**
>
> Available types of storage devices depend on the YDB cluster configuration.

Changing compression codec

The code below changes the compression codec to `lz4` for the `default` column group in the `series_with_families` table:

```
ALTER TABLE series_with_families ALTER FAMILY default SET COMPRESSION "lz4";
```

Changing cache mode

When switching the cache mode to `in_memory` for an existing table with `ALTER TABLE`, the pages that are not yet in memory are loaded automatically.

If the table was previously in `in_memory` mode and `ALTER TABLE` then sets the cache mode to `regular`, the pages that are already in memory stay there, but they may later be evicted according to the general caching policy.

The code below changes the cache mode to `in_memory` for the `default` column group in the `series_with_families` table:

```
ALTER TABLE series_with_families ALTER FAMILY default SET CACHE_MODE "in_memory";
```

You can specify any column group parameters described in the `CREATE TABLE` command.

Changing the `NOT NULL` constraint

The `NOT NULL` constraint is a column-level data integrity constraint that prohibits writing `NULL` values. It ensures that the column always contains a valid value.

Dropping `NOT NULL`

`DROP NOT NULL` removes the `NOT NULL` constraint from the specified column.

For example, the following query will remove the `NOT NULL` constraint from column `column_name` in table `table_name`:

```
ALTER TABLE table_name ALTER COLUMN column_name DROP NOT NULL;
```

`DROP NOT NULL` can be applied to non-key columns in both row-oriented and column-oriented tables.

See also

- ALTER COLUMN

Modifying additional table parameters

Most parameters of row and column tables in YDB, listed on the table description page, can be modified using the `ALTER` command.

Generally, the command to modify any table parameter looks as follows:

```
ALTER TABLE table_name SET (key = value);
```

`key` — the name of the parameter, `value` — its new value.

Example of modifying the `TTL` parameter, which controls the time-to-live of records in a table:

```
ALTER TABLE series SET (TTL = Interval("PT0S") ON expire_at);
```

Resetting Additional Table Parameters

Some table parameters in YDB, listed on the table description page, can be reset using the `ALTER` command. The command to reset a table parameter looks as follows:

```
ALTER TABLE table_name RESET (key);
```

`key` — the name of the parameter.

For example, such a command will reset (remove) the `TTL` settings for row or column tables:

```
ALTER TABLE series RESET (TTL);
```

Adding or removing a changefeed

> **Warning**
>
> Supported only for row-oriented tables. Support for column-oriented tables is currently under development.

`ADD CHANGEFEED <name> WITH (<option> = <value>[, ...])`: Adds a changefeed with the specified name and options.

Changefeed options

- `MODE`: Operation mode. Specifies what to write to a changefeed each time table data is altered.
  - `KEYS_ONLY`: Only the primary key components and change flag are written.
  - `UPDATES`: Updated column values that result from updates are written.
  - `NEW_IMAGE`: Any column values resulting from updates are written.
  - `OLD_IMAGE`: Any column values before updates are written.
  - `NEW_AND_OLD_IMAGES`: A combination of `NEW_IMAGE` and `OLD_IMAGE` modes. Any column values *prior to* and *resulting from* updates are written.
- `FORMAT`: Data write format.
  - `JSON`: Write data in JSON format.
  - `DEBEZIUM_JSON`: Write data in the Debezium-like JSON format.
- `VIRTUAL_TIMESTAMPS`: Enabling/disabling virtual timestamps. Disabled by default.
- `USER_SIDS`: Enabling/disabling user SIDs. Disabled by default.
- `TRACE_IDS`: Enabling/disabling OpenTelemetry trace identifiers. Disabled by default.
- `BARRIERS_INTERVAL` — barrier emission interval. The value type is `Interval`. Disabled by default.
- `RETENTION_PERIOD`: Record retention period. The value type is `Interval` and the default value is 24 hours (`Interval('PT24H')`).
- `TOPIC_AUTO_PARTITIONING`: Topic autopartitioning mode:
  - `ENABLED` – An autopartitioned topic will be created for this changefeed. The number of partitions in such a topic increases automatically as the table update rate increases. Topic autopartitioning parameters can be configured.
  - `DISABLED` – A topic without autopartitioning will be created for this changefeed. This is the default value.
- `TOPIC_MIN_ACTIVE_PARTITIONS`: The initial number of topic partitions. By default, the initial number of topic partitions is equal to the number of table partitions. For autopartitioned topics, the number of partitions increases automatically as the table update rate increases.
- `INITIAL_SCAN`: Enables/disables initial table scan. Disabled by default.

The code below adds a changefeed named `updates_feed`, where the values of updated table columns will be exported in JSON format:

```
ALTER TABLE `series` ADD CHANGEFEED `updates_feed` WITH (
    FORMAT = 'JSON',
    MODE = 'UPDATES'
);
```

Records in this changefeed will be stored for 24 hours (default value). The code in the following example will create a changefeed with a record retention period of 12 hours:

```
ALTER TABLE `series` ADD CHANGEFEED `updates_feed` WITH (
    FORMAT = 'JSON',
    MODE = 'UPDATES',
    RETENTION_PERIOD = Interval('PT12H')
);
```

The example of creating a changefeed with enabled virtual timestamps:

```
ALTER TABLE `series` ADD CHANGEFEED `updates_feed` WITH (
    FORMAT = 'JSON',
    MODE = 'UPDATES',
    VIRTUAL_TIMESTAMPS = TRUE
);
```

The example of creating a changefeed with virtual timestamps and barriers every 10 seconds:

```
ALTER TABLE `series` ADD CHANGEFEED `updates_feed` WITH (
    FORMAT = 'JSON',
    MODE = 'UPDATES',
    VIRTUAL_TIMESTAMPS = TRUE,
    BARRIERS_INTERVAL = Interval('PT10S')
);
```

Example of creating a changefeed with initial scan:

```
ALTER TABLE `series` ADD CHANGEFEED `updates_feed` WITH (
    FORMAT = 'JSON',
    MODE = 'UPDATES',
    INITIAL_SCAN = TRUE
);
```

Example of creating a changefeed with autopartitioning:

```
ALTER TABLE `series` ADD CHANGEFEED `updates_feed` WITH (
    FORMAT = 'JSON',
    MODE = 'UPDATES',
    TOPIC_AUTO_PARTITIONING = 'ENABLED',
    TOPIC_MIN_ACTIVE_PARTITIONS = 2
);
```

`DROP CHANGEFEED` : Deletes the changefeed with the specified name. The code below deletes the `updates_feed` changefeed:

```
ALTER TABLE `series` DROP CHANGEFEED `updates_feed`;
```

Renaming a table

```
ALTER TABLE old_table_name RENAME TO new_table_name;
```

Note

When choosing a name for the table, consider the common schema object naming rules.

If a table with the new name already exists, an error will be returned. The ability to transactionally replace a table under load is supported by specialized methods in CLI and SDK.

Warning

If a YQL query contains multiple `ALTER TABLE ... RENAME TO ...` commands, each will be executed in auto-commit mode in a separate transaction. From the perspective of an external process, the tables will be renamed sequentially, one after another. To rename multiple tables in a single transaction, use specialized methods available in CLI and SDK.

Renaming can be used to move a table from one directory within the database to another, for example:

```
ALTER TABLE `table1` RENAME TO `/backup/table1`;
```

Running forced table compaction

```
ALTER TABLE table_name COMPACT [WITH (key = value [, ...])];
```

> **Warning**
>
> Supported only for row-oriented tables.

YDB automatically performs compaction of tables and usually does not require manual intervention. However, using the `ALTER TABLE ... COMPACT` command, you can explicitly start compaction of data in a given table without waiting for automatic compaction. The command is useful, for example, in the following scenarios:

- Bulk data deletion was performed and you want to free up the occupied space faster.
- Compression settings or column groups were changed, and you want to apply them to existing data faster.

The command creates a background operation and synchronously waits for its completion. The wait can be interrupted, and the operation will continue running in the background. Background compaction operations can be managed via the CLI and YDB UI.

Parameters

The following parameters can be specified in the `WITH` block:

- `CASCADE` — whether to compact the table together with its secondary indexes. Valid values: `TRUE` and `FALSE`. Default value: `FALSE` (only the table itself is compacted).
- `PARALLEL` — the maximum number of partitions that can be compacted simultaneously within this operation. Valid values are positive integers. Default value: 1. The overall limit on concurrently running manual compactions for the entire database is set separately in the YDB cluster configuration.

Behavior

- You can monitor the progress of running compaction operations using the CLI command `ydb operation list compaction`. Using the corresponding commands, you can get the status of a specific operation, cancel an operation, or delete the record of a completed operation.
- You can also view and manage operations using the YDB UI. To do this, go to the database page, open the `Operations` tab, and select the operation type `Compaction`.
- If a compaction operation is already running for the same table (or for one of its secondary indexes when `CASCADE = TRUE`), the launch will fail with an error. You need to either wait for the previous operation to complete or cancel it.
- Running the command requires the same permissions as other `ALTER TABLE` actions. Concurrent table schema changes are not blocked.
- Forced compaction also materializes borrowed data. As a result, the total data volume in the database may increase. The borrowing mechanism is used, for example, to implement CoW table copying, so when compacting copied tables, their volume may eventually increase by the size of the original table.

Examples

Run compaction of only the main table:

```
ALTER TABLE series COMPACT;
```

Run compaction of the table together with all its secondary indexes:

```
ALTER TABLE series COMPACT WITH (CASCADE = TRUE);
```

Run compaction of only the impl table of a specific secondary index:

```
ALTER TABLE `series/idx_release/indexImplTable` COMPACT;
```

Run compaction of the table, setting the number of simultaneously processed partitions:

```
ALTER TABLE series COMPACT WITH (PARALLEL = 5);
```

ALTER TRANSFER

The `ALTER TRANSFER` statement modifies the parameters and state of a transfer instance.

Syntax

```
ALTER TRANSFER <name> [SET USING lambda | SET (option = value [, ...])]
```

where:

- `name` — the name of the transfer instance.
- `lambda` — the lambda-function for message transformation.
- `SET (option = value [, ...])` — the transfer parameters.

Parameters

- `STATE` — the transfer state. Possible values:
- `PAUSED` — pauses the transfer.
- `ACTIVE` — resumes a paused transfer.
- Table write batching parameters let you balance the latency of records appearing in the table against the resources required by the transfer. Batching parameters affect the processing of each topic partition independently. Change batching parameters with caution, as this can either improve or degrade message stream processing speed, and may even lead to a denial of service if the parameters are misconfigured. For example, writing to the table in small batches can overload the table and degrade its performance, while an excessively large batch size can cause the server to run out of available memory.
  - `BATCH_SIZE_BYTES` — the batch size in bytes. Default: 8 MB.
  - `FLUSH_INTERVAL` — the table write interval. Default: 60 seconds. Data is written to the table at this interval, even if the batch has not reached the size specified in the `BATCH_SIZE_BYTES` parameter.
- Authentication settings for the topic database (one of the following):
  - Using a token:
    - `TOKEN_SECRET_PATH` — the secret that contains the token.
  - Using a username and password:
    - `USER` — the username.
    - `PASSWORD_SECRET_PATH` — the secret that contains the password.
  - Using a service agent:
    - `SERVICE_ACCOUNT_ID` — the identificator of the service account.
    - `INITIAL_TOKEN_SECRET_PATH` — the secret that contains the account's token. It is used for initial authentication.

Permissions

Modifying a transfer requires the `ALTER SCHEMA` permissions.

Examples

The following query modifies the message transformation lambda-function:

```
$new_lambda = ($msg) -> {
    return [
        <|
            partition: $msg._partition,
            offset: $msg._offset,
            message: CAST($msg._data || ' altered' AS Utf8)
        |>
    ];
};

ALTER TRANSFER my_transfer SET USING $new_lambda;
```

The following query pauses the transfer:

```
ALTER TRANSFER my_transfer SET (STATE = "PAUSED");
```

The following query modifies the batching parameters:

```
ALTER TRANSFER my_transfer SET (
    BATCH_SIZE_BYTES = 1048576,
    FLUSH_INTERVAL = Interval('PT60S')
);
```

The following query changes the secret:

```
ALTER TRANSFER my_transfer SET (
    TOKEN_SECRET_PATH = "my_token"
);
```

Lambda function

A message transformation lambda function takes a single structured parameter containing the message from the topic and returns a list of structures corresponding to the table rows for insertion.

Example:

```
$lambda = ($msg) -> {
  return [
    <|
      column_1: $msg._create_timestamp,
      column_2: $msg._data
    |>
  ];
};
```

In this example:

- `$msg` — the message received from the topic.
- `column_1` and `column_2` — the names of the table columns.
- `$msg._create_timestamp` and `$msg._data` — the values that will be written to the table. The value types must match the table column types. For example, if the `column_2` table column has the `String` type, the type of `$msg._data` must also be `String`.

The following fields are available in a topic message:

Attribute	Value type	Description
`_create_timestamp`	`Timestamp`	Message creation time
`_data`	`String`	Message body
`_offset`	`Uint64`	Message offset
`_partition`	`Uint32`	Message's partition number
`_producer_id`	`String`	Producer ID
`_seq_no`	`Uint64`	Message sequence number
`_write_timestamp`	`Timestamp`	Message write time

Testing lambda functions

To test a lambda function during development, you can simulate a topic message by passing a structure with the same fields that the transfer will provide. Example:

```
$lambda = ($msg) -> {
  return [
    <|
      offset: $msg._offset,
      data: $msg._data
    |>
  ];
};

$msg = <|
  _data: "value",
  _offset: CAST(1 AS Uint64),
  _partition: CAST(2 AS Uint32),
  _producer_id: "producer",
  _seq_no: CAST(3 AS Uint64)
|>;

SELECT $lambda($msg);
```

If a lambda function contains complex transformation logic, you can extract it into a separate lambda function to simplify testing.

```
$extract_value = ($data) -> {
  -- complex transformations
  return $data;
};

$lambda = ($msg) -> {
  return [
    <|
      column: $extract_value($msg._data)
    |>
  ];
};

-- You can test the extract_value lambda function like this

SELECT $extract_value('converted value');
```

ALTER SECRET

The `ALTER SECRET` statement modifies an existing secret.

Syntax

```
ALTER SECRET secret_name
WITH (option = value[, ...])
```

- `secret_name` — the name of the secret to modify.
- `option` — command option:
  - `value` — string with the secret value.

Permissions

Modifying a secret requires the right `ALTER SCHEMA`.

Examples

Change the value of secret `secret_name` to `secret_value_new`:

```
ALTER SECRET secret_name WITH (value = "secret_value_new");
```

See also

- CREATE SECRET
- DROP SECRET

ALTER VIEW

`ALTER VIEW` changes the definition of a view.

> **Warning**
>
> This feature is not supported yet.

Instead, you can redefine a view by dropping it and recreating it with a different query or options:

```
DROP VIEW redefined_view;
CREATE VIEW redefined_view ...;
```

Please note that the two statements are executed separately, unlike a single `ALTER VIEW` statement. If a view is recreated in this way, it might be possible to observe the view in a deleted state for a brief moment.

See also

- CREATE VIEW
- DROP VIEW

ALTER TOPIC

You can use the `ALTER TOPIC` command to change the topic settings, as well as add, update, or delete its consumers.

Here is the general format of the `ALTER TOPIC` command:

```
ALTER TOPIC topic_path action1, action2, ..., actionN;
```

`action` is one of the alter actions described below.

Updating a set of consumers

`ADD CONSUMER`: Adds a consumer to a topic.

The following example will add a consumer with default settings to the topic.

```
ALTER TOPIC `my_topic` ADD CONSUMER new_consumer;
```

When adding consumers, you can specify their settings, for example:

```
ALTER TOPIC `my_topic` ADD CONSUMER new_consumer2 WITH (important = false);
```

Full list of available topic consumer settings

- `important`: Defines an important consumer. No data will be deleted from the topic until all the important consumers read them. Value type: `boolean`, default value: `false`.
- `read_from`: Sets up the message write time starting from which the consumer will receive data. Data written before this time will not be read. Value type: `Datetime` OR `Timestamp` OR `integer` (unix-timestamp in the numeric format). Default value: `0` (read from the earliest available message).
- `supported_codecs`: List of codecs supported by the consumer.

`DROP CONSUMER`: Deletes the consumer from the topic.

```
ALTER TOPIC `my_topic` DROP CONSUMER old_consumer;
```

Updating consumer settings

`ALTER CONSUMER`: Adds a consumer for a topic.

Here is the general syntax for `ALTER CONSUMER`:

```
ALTER TOPIC `topic_name` ALTER CONSUMER consumer_name consumer_action;
```

Supports the following types of `consumer_action`:

- `SET`: Sets consumer settings

The following example will assign the `important` parameter to the consumer.

```
ALTER TOPIC `my_topic` ALTER CONSUMER my_consumer SET (important = true);
```

You can specify several `ALTER CONSUMER` statements for a consumer. However, the settings applied by them shouldn't repeat.

This is a valid statement:

```
ALTER TOPIC `my_topic`
    ALTER CONSUMER my_consumer SET (important = true)
    ALTER CONSUMER my_consumer SET (read_from = 0);
```

But this statement will raise an error.

```
ALTER TOPIC `my_topic`
    ALTER CONSUMER my_consumer SET (important = true)
    ALTER CONSUMER my_consumer SET (important = false);
```

Updating topic settings

Using the `SET (option = value[, ...])` action, you can update your topic settings.

The example below will change the retention period for the topic and the writing quota per partition:

```
ALTER TOPIC `my_topic` SET (
    retention_period = Interval('PT36H'),
    partition_write_speed_bytes_per_second = 3000000
);
```

Full list of available topic settings

- `min_active_partitions`: Minimum number of topic partitions. During automatic load balancing, the number of active partitions will not decrease below this value. Value type: `integer`, default value: `1`.

- `partition_count_limit`: Maximum number of active partitions in the topic. `0` is interpreted as unlimited. Value type: `integer`, default value: `0`.
- `retention_period`: Data retention period in the topic. Value type: `Interval`.
- `retention_storage_mb`: Limit on the maximum disk space occupied by the topic data. When this value is exceeded, the older data is cleared, like under a retention policy. The consumed space may exceed the set value when autopartitioning is enabled. Value type: `integer`, default value: `0` (no limit).
- `partition_write_speed_bytes_per_second`: Maximum allowed write speed per partition. If a write speed for a given partition exceeds this value, the write speed will be capped. Value type: `integer`, default value: `2097152` (2MB).
- `partition_write_burst_bytes`: Write quota allocated for write bursts. When set to zero, the actual write_burst value is equalled to the quota value (this allows write bursts of up to one second). Value type: `integer`, default value: `0`.
- `metering_mode`: Resource metering mode (`RESERVED_CAPACITY` - based on the allocated resources or `REQUEST_UNITS` - based on actual usage). This option applies to topics in serverless databases. Value type: `String`.
- `supported_codecs`: List of codecs supported by the topic. Value type: `String`.

Change autopartitioning strategies for the topic

The following command sets the autopartitioning strategy to `UP`:

```
ALTER TOPIC `my_topic` SET (
    min_active_partitions = 1,
    max_active_partitions = 5,
    auto_partitioning_strategy = 'scale_up'
);
```

The following command pauses the topic autopartitioning:

```
ALTER TOPIC `my_topic` SET (
    auto_partitioning_strategy = 'paused'
);
```

The following command unpauses the topic autopartitioning:

```
ALTER TOPIC `my_topic` SET (
    auto_partitioning_strategy = 'scale_up'
);
```

ALTER STREAMING QUERY

`ALTER STREAMING QUERY` changes settings of streaming queries and controls their lifecycle (start and stop).

Syntax

```
ALTER STREAMING QUERY [IF EXISTS] <query_name> SET (
    <key1> = <value1>,
    <key2> = <value2>,
    ...
)
```

Parameters

- `IF EXISTS` — do not fail if the streaming query does not exist.
- `query_name` — name of the streaming query to change.
- `SET (<key> = <value>)` — optional list of settings to update.

Changing query settings

Syntax:

```
ALTER STREAMING QUERY [IF EXISTS] <query_name> SET (<key> = <value>)
```

Available parameters:

- `RUN = (TRUE|FALSE)` — start or stop the query.
- `RESOURCE_POOL = <resource_pool_name>` — name of the resource pool where the query runs.

When you run `SET (RUN = TRUE)`, read offsets from topics and aggregation state are restored from a checkpoint. If there is no checkpoint, reading starts from the latest data.

Examples of changing settings are below.

Permissions

Streaming queries require permission `ALTER SCHEMA`. Example grant for `my_streaming_query`:

```
GRANT ALTER SCHEMA ON my_streaming_query TO `user@domain`
```

Examples

Changing settings

Stop `my_streaming_query`:

```
ALTER STREAMING QUERY my_streaming_query SET (
    RUN = FALSE
)
```

Start `my_streaming_query` in resource pool `my_resource_pool`:

```
ALTER STREAMING QUERY my_streaming_query SET (
    RUN = TRUE,
    RESOURCE_POOL = my_resource_pool
)
```

Query status

Current status is available in the `Status` column of the ⟦C2⟧ system view System database views:

```
SELECT
    Path,
    Status,
    Text,
    Run
FROM
    `.sys/streaming_queries`
```

Possible status values:

1. `CREATING` — query is being created after `CREATE STREAMING QUERY`.
2. `CREATED` — query exists but is not running (for example, `RUN = FALSE`).
3. `STARTING` — query is starting.
4. `RUNNING` — query is executing.
5. `SUSPENDED` — query paused due to internal errors; the system will retry.
6. `STOPPING` — query is stopping after `ALTER STREAMING QUERY ... SET (RUN = FALSE)`.
7. `STOPPED` — query is stopped.

After successful DDL for create or alter, status is guaranteed to be `CREATED`, `STARTING`, `RUNNING`, `STOPPED`, or `SUSPENDED` depending on `RUN = (TRUE|FALSE)` and whether startup succeeded.

More examples for other data formats: Data formats for reading/writing from topics. For capabilities and limitations of streaming queries, see Streaming queries.

See also

- Streaming queries
- CREATE STREAMING QUERY
- DROP STREAMING QUERY

ALTER USER

Changes the user password.

Syntax

```
ALTER USER user_name [ WITH ] option [ ... ]
```

- `user_name`: The name of the user.
- `option` — The command option:
  - `PASSWORD 'password'` — changes the password to `password`.
  - `PASSWORD NULL` — sets an empty password.
  - `NOLOGIN` - disallows user login (user lockout).
  - `LOGIN` - allows user login (user unlocking).

ALTER RESOURCE POOL

`ALTER RESOURCE POOL` changes the definition of a resource pool.

Syntax

Modifying parameters

The syntax for modifying any resource pool parameter is as follows:

```
ALTER RESOURCE POOL <name> SET (<key> = <value>);
```

`<key>` is the parameter name, `<value>` is its new value.

For example, the following command enables a limit of 100 concurrent queries:

```
ALTER RESOURCE POOL olap SET (CONCURRENT_QUERY_LIMIT = "100");
```

Resetting parameters

The command to reset a resource pool parameter is as follows:

```
ALTER RESOURCE POOL <name> RESET (<key>);
```

`<key>` is the parameter name.

For example, the following command resets the `TOTAL_CPU_LIMIT_PERCENT_PER_NODE` settings for a resource pool:

```
ALTER RESOURCE POOL olap RESET (TOTAL_CPU_LIMIT_PERCENT_PER_NODE);
```

Permissions

A permission `ALTER SCHEMA` on the resource pool in the `.metadata/workload_manager/pools` directory is required. Example of granting such a permission:

```
GRANT 'ALTER SCHEMA' ON `.metadata/workload_manager/pools/olap_pool` TO `user1@domain`;
```

Parameters

- `CONCURRENT_QUERY_LIMIT` (Int32) — an optional field that sets the number of concurrently executing queries in the resource pool. If the value is `-1`, there is no limit. Default value: `-1`. Valid values: .
- `QUEUE_SIZE` (Int32) — an optional field that defines the size of the waiting queue. The system can hold no more than queries at a time. If the value is `-1`, there is no limit. Default value: `-1`. Valid values: .
- `DATABASE_LOAD_CPU_THRESHOLD` (Int32) — an optional field that sets the CPU load threshold for the entire database, after which queries are not sent for execution and remain in the queue. If the value is `-1`, there is no limit. Default value: `-1`. Valid values: .
- `TOTAL_MEMORY_LIMIT_PERCENT_PER_NODE` (Double) — an optional field that defines the percentage of available memory on the node that all queries in this resource pool can use. If the value is `-1`, there is no limit. Default value: `-1`. Valid values: .
  If a limit is set and the total memory consumption by queries in the pool reaches this limit:
  - New queries that require memory will fail with error `OVERLOADED`.
  - Already running queries that need additional memory will also fail with error `OVERLOADED`.
- `TOTAL_CPU_LIMIT_PERCENT_PER_NODE` (Double) — an optional field that sets the percentage of available CPU that all queries on the node in this resource pool can use. If the value is `-1`, there is no limit. Default value: `-1`. Valid values: .
- `QUERY_CPU_LIMIT_PERCENT_PER_NODE` (Double) — an optional field that defines the percentage of available CPU on the node for a single query in the resource pool. If the value is `-1`, there is no limit. Default value: `-1`. Valid values: .
- `RESOURCE_WEIGHT` (Int32) — an optional field that sets weights for distributing resources among pools. If the value is `-1`, weights are not used. Default value: `-1`. Valid values: .

> **Warning**
>
> The `QUERY_MEMORY_LIMIT_PERCENT_PER_NODE` parameter is currently not supported. To limit the amount of memory allocated to a resource pool, use the `TOTAL_MEMORY_LIMIT_PERCENT_PER_NODE` parameter.

See also

- Workload Manager — resource consumption management
- CREATE RESOURCE POOL
- DROP RESOURCE POOL

ALTER RESOURCE POOL CLASSIFIER

`ALTER RESOURCE POOL CLASSIFIER` changes the definition of a resource pool classifier.

Syntax

Changing parameters

The syntax for changing any resource pool classifier parameter is as follows:

```
ALTER RESOURCE POOL CLASSIFIER <name> SET (<key> = <value>);
```

`<key>` is the parameter name, `<value>` is its new value.

For example, the following command changes the user to which the rule applies:

```
ALTER RESOURCE POOL CLASSIFIER olap_classifier SET (MEMBER_NAME = "user2@domain");
```

Resetting parameters

The command to reset a resource pool classifier parameter is as follows:

```
ALTER RESOURCE POOL CLASSIFIER <name> RESET (<key>);
```

`<key>` is the parameter name.

For example, the following command resets the `MEMBER_NAME` setting:

```
ALTER RESOURCE POOL CLASSIFIER olap_classifier RESET (MEMBER_NAME);
```

Permissions

The `ALL` permission on the database is required. Example of granting it:

```
GRANT 'ALL' ON `/my_db` TO `user1@domain`;
```

Parameters

- `RANK` (Int64) — Optional field that defines the order in which resource pool classifiers are chosen. If omitted, the maximum existing `RANK` is taken and 1000 is added. Allowed values: a unique number in the range .
- `RESOURCE_POOL` (String) — Required field: name of the resource pool to which queries matching the classifier criteria are sent.
- `MEMBER_NAME` (String) — Optional field specifying which user or group is routed to the given resource pool. If omitted, the classifier ignores `MEMBER_NAME` and classification uses other criteria.

See also

- Workload Manager — resource consumption management
- CREATE RESOURCE POOL CLASSIFIER
- DROP RESOURCE POOL CLASSIFIER

ANALYZE

`ANALYZE` forces the collection of statistics for YDB cost-based optimizer.

Syntax

```
ANALYZE <path_to_table> [ (<column_name> [, ...]) ]
```

This command forces the synchronous collection of table statistics and column statistics for the specified columns or for all columns if none are specified. `ANALYZE` returns once all the requested statistics have been collected and are up to date.

- `path_to_table` — the path to the table for which statistics should be collected.
- `column_name` — collect column statistics only for the specified columns of the table.

The current set of statistics is described in Statistics for the Cost-Based Optimizer.

Background operation

SQL operation `ANALYZE` executes synchronously and waits for completion. In addition a background operation is created for observability. Use the operation list command to monitor the progress of background `ANALYZE` operations.

BATCH DELETE FROM

> **Tip**
>
> Before diving into `BATCH DELETE FROM`, it is recommended to familiarize yourself with the standard DELETE FROM.

`BATCH DELETE FROM` allows to delete records in large tables while minimizing the risk of lock invalidation and transaction rollback by weakening guarantees. Specifically, data deletion is performed as a series of transactions for each partition of the specified table separately, processing 10 000 rows per iteration. Each query processes up to 10 partitions concurrently.

This query, like the standard `DELETE FROM`, executes synchronously and returns a status. If an error occurs or the client disconnects, data deletion stops, and applied changes are not rolled back.

The semantics are inherited from the standard `DELETE FROM` with the following restrictions:

- Supported only for row-oriented tables.
- Supported only for queries with implicit transaction control.
- The use of subqueries and multiple statements in a single query is prohibited.
- The `RETURNING` clause is unavailable.

Example

```
BATCH DELETE FROM my_table
WHERE Key1 > 1 AND Key2 >= "One";
```

BATCH UPDATE

> **Tip**
>
> Before diving into `BATCH UPDATE`, it is recommended to familiarize yourself with the standard UPDATE.

`BATCH UPDATE` allows to update records in large tables while minimizing the risk of lock invalidation and transaction rollback by weakening guarantees. Specifically, data updates are performed as a series of transactions for each partition of the specified table separately, processing 10 000 rows per iteration. Each query processes up to 10 partitions concurrently.

This query, like the standard `UPDATE`, executes synchronously and returns a status. If an error occurs or the client disconnects, the data update stops, and the applied changes are not rolled back.

The semantics are inherited from the standard `UPDATE` with the following restrictions:

- Supported only for row-oriented tables.
- Supported only for queries with implicit transaction control.
- Only idempotent updates are supported: expressions following `SET` should not depend on the current values of the columns being modified.
- The use of subqueries and multiple statements in a single query is prohibited.
- The `RETURNING` clause is unavailable.

Example

```
BATCH UPDATE my_table
SET Value1 = "foo", Value2 = 0
WHERE Key1 > 1;
```

BACKUP

The `BACKUP` statement creates a backup of tables in a backup collection.

```
BACKUP collection_name [INCREMENTAL];
```

Parameters

- `collection_name` — name of the backup collection.
- `INCREMENTAL` — create an incremental backup instead of a full backup.

Backup types

Full backup

A full backup creates a snapshot of all tables in the collection at a specific point in time. This serves as the baseline for subsequent incremental backups.

```
BACKUP production_backups;
```

Incremental backup

An incremental backup captures only the changes (inserts, updates, deletes) since the previous backup in the chain. The collection must have been created with `INCREMENTAL_BACKUP_ENABLED = 'true'`.

```
BACKUP production_backups INCREMENTAL;
```

> **Warning**
>
> Incremental backups require a previous full backup in the same collection. Always create a full backup first before taking incremental backups.

Examples

Creating an initial full backup:

```
-- First, create a collection
CREATE BACKUP COLLECTION daily_backups (
    TABLE orders
) WITH (
    STORAGE = 'cluster',
    INCREMENTAL_BACKUP_ENABLED = 'true'
);

-- Then create the full backup
BACKUP daily_backups;
```

Creating incremental backups:

```
-- After the initial full backup, create incremental backups
BACKUP daily_backups INCREMENTAL;
```

Monitoring backup operations

Backup operations run asynchronously in the background. You can monitor their progress using YDB CLI:

```
# List backup operations
ydb operation list incbackup

# Get operation details
ydb operation get <operation-id>
```

See also

- Backup collections.
- CREATE BACKUP COLLECTION.
- RESTORE.
- DROP BACKUP COLLECTION.
- Backup and recovery guide.

CREATE ASYNC REPLICATION

The `CREATE ASYNC REPLICATION` statement creates an asynchronous replication instance.

Syntax

```
CREATE ASYNC REPLICATION <name>
FOR <remote_path> AS <local_path> [, <another_remote_path> AS <another_local_path>]
WITH (option = value [, ...])
```

Parameters

- `name` — a name of the asynchronous replication instance.
- `remote_path` — a relative or absolute path to a table or directory in the source database.
- `local_path` — a relative or absolute path to a target table or directory in the local database.
- `WITH (option = value [, ...])` — asynchronous replication parameters:
  - `CONNECTION_STRING` — a connection string for the source database (mandatory).
  - `CA_CERT` — a root certificate for TLS. Optional parameter. Can be specified if the source database supports an encrypted data interchange protocol (`CONNECTION_STRING` starts with `grpcs://`).
  - `INITIAL_SCAN` : whether to perform an initial scan. An optional `Bool` parameter. If omitted, the server setting is used; the default is `TRUE` .
    - `TRUE` : source data is transferred through changefeeds, and replica objects are created automatically.
    - `FALSE` : replication is created in the `PAUSED` state and prepares changefeeds without an initial scan. Target tables are not created or attached to replication until it switches to `STANDBY` . First, back up the source and restore the data on the target, then start replication using ALTER ASYNC REPLICATION. When replication starts, target tables must exist and match the source schemas, subject to the restrictions. For the procedure, see the initial synchronization guide.
  - `AVAILABILITY_PERIOD` : the availability period for unacknowledged changes. An optional parameter: a positive value of type `Interval` or the string `'UNLIMITED'` . The default is `'UNLIMITED'` .
    - `'UNLIMITED'` : changes are retained until replication acknowledges their processing.
    - `Interval` , for example, `Interval('PT48H')` : unacknowledged changes are protected from deletion for the specified period. After it expires, they may be deleted.

    This parameter can only be set when replication is created. For help choosing a value, see the comparison of retention options.
  - Authentication details for the source database (mandatory) depending on the authentication method:
    - Access token:
      - `TOKEN_SECRET_PATH` — the secret that contains the token.
    - Login and password:
      - `USER` — a database user name.
      - `PASSWORD_SECRET_PATH` — the secret that contains the password for the source database user.
    - Delegated service account:
      - `SERVICE_ACCOUNT_ID` — identifier of the service account.
      - `INITIAL_TOKEN_SECRET_PATH` — the secret that contains the token for the service account. Used for initialization.
- `CONSISTENCY_LEVEL` — consistency level of replicated data:
  - `ROW` — row-level data consistency. Default mode.
  - `GLOBAL` — global data consistency. Additionally can be specified:
    - `COMMIT_INTERVAL` — change commit interval in ISO 8601 format. The default value is 10 seconds.

Examples

> **Tip**
>
> Before creating an asynchronous replication instance, you must create a secret with authentication credentials for the source database or ensure that you have access to an existing secret.

The following statement creates an asynchronous replication instance to synchronize the `original_table` source table in the `/Root/another_database` database to the `replica_table` target table in the local database:

```
CREATE ASYNC REPLICATION my_replication_for_single_table
FOR original_table AS replica_table
WITH (
    CONNECTION_STRING = 'grpcs://example.com:2135/?database=/Root/another_database',
    TOKEN_SECRET_PATH = 'my_secret'
);
```

The statement above uses the token from the `my_secret` secret for authentication and the `grpcs://example.com:2135` endpoint to connect to the `/Root/another_database` database.

The following statement creates an asynchronous replication instance to replicate the source tables `original_table_1` and `original_table_2` to the target tables `replica_table_1` and `replica_table_2` :

```
CREATE ASYNC REPLICATION my_replication_for_multiple_tables
FOR original_table_1 AS replica_table_1, original_table_2 AS replica_table_2
WITH (
    CONNECTION_STRING = 'grpcs://example.com:2135/?database=/Root/another_database',
    TOKEN_SECRET_PATH = 'my_secret'
);
```

The following statement creates an asynchronous replication instance for the objects in the `original_dir` directory:

```
CREATE ASYNC REPLICATION my_replication_for_dir
FOR original_dir AS replica_dir
WITH (
    CONNECTION_STRING = 'grpcs://example.com:2135/?database=/Root/another_database',
    TOKEN_SECRET_PATH = 'my_secret'
);
```

The following statement creates an asynchronous replication instance for the objects in the `/Root/another_database` database:

```
CREATE ASYNC REPLICATION my_replication_for_database
FOR `/Root/another_database` AS `/Root/my_database`
WITH (
    CONNECTION_STRING = 'grpcs://example.com:2135/?database=/Root/another_database',
    TOKEN_SECRET_PATH = 'my_secret'
);
```

The following statement creates an asynchronous replication instance with a TLS root certificate specified:

```
CREATE ASYNC REPLICATION my_consistent_replication
FOR original_table AS replica_table
WITH (
    CONNECTION_STRING = 'grpcs://example.com:2135/?database=/Root/another_database',
    TOKEN_SECRET_PATH = 'my_secret',
    CA_CERT = '-----BEGIN CERTIFICATE-----...'
);
```

The following statement creates an asynchronous replication instance in global data consistency mode (default change commit interval is 10 seconds):

```
CREATE ASYNC REPLICATION my_consistent_replication
FOR original_table AS replica_table
WITH (
    CONNECTION_STRING = 'grpcs://example.com:2135/?database=/Root/another_database',
    TOKEN_SECRET_PATH = 'my_secret',
    CONSISTENCY_LEVEL = 'GLOBAL'
);
```

The following statement creates an asynchronous replication instance in global data consistency mode with a one-minute change commit interval:

```
CREATE ASYNC REPLICATION my_consistent_replication_1min_commit_interval
FOR original_table AS replica_table
WITH (
    CONNECTION_STRING = 'grpcs://example.com:2135/?database=/Root/another_database',
    TOKEN_SECRET_PATH = 'my_secret',
    CONSISTENCY_LEVEL = 'GLOBAL',
    COMMIT_INTERVAL = Interval('PT1M')
);
```

The following statement creates replication with a 48-hour availability period for unacknowledged changes:

```
CREATE ASYNC REPLICATION my_replication_with_availability_period
FOR original_table AS replica_table
WITH (
    CONNECTION_STRING = 'grpcs://example.com:2135/?database=/Root/another_database',
    TOKEN_SECRET_PATH = 'my_secret',
    AVAILABILITY_PERIOD = Interval('PT48H')
);
```

The following statement creates replication for initial synchronization using backup and restore, retaining unacknowledged changes without an age limit:

```
CREATE ASYNC REPLICATION my_replication_without_initial_scan
FOR original_table AS replica_table
WITH (
    CONNECTION_STRING = 'grpcs://example.com:2135/?database=/Root/another_database',
    TOKEN_SECRET_PATH = 'my_secret',
    INITIAL_SCAN = FALSE,
    AVAILABILITY_PERIOD = 'UNLIMITED'
);
```

Replication prepares changefeeds in the `PAUSED` state. Wait until they are ready, perform the backup and restore, and then switch replication to `STANDBY` using ALTER ASYNC REPLICATION.

See also

- ALTER ASYNC REPLICATION
- DROP ASYNC REPLICATION

CREATE BACKUP COLLECTION

The `CREATE BACKUP COLLECTION` statement creates a backup collection.

```
CREATE BACKUP COLLECTION collection_name (
    TABLE table_name [, TABLE another_table_name ...]
) WITH (option = value [, ...]);
```

Parameters

- `collection_name` — name of the backup collection to create.
- `table_name` — full path to a table to include in the collection. Multiple tables can be specified.
- Options:
  - `STORAGE` — storage backend for backups. Supported values:
    - `'cluster'` — storage within the YDB cluster.
  - `INCREMENTAL_BACKUP_ENABLED` — enable incremental backup support. Set to `'true'` to enable incremental backups, `'false'` for full backups only.

> **Note**
>
> When choosing a name for the backup collection, please consider the common schema objects naming rules

Examples

Creating a backup collection with a single table:

```
CREATE BACKUP COLLECTION daily_backups (
    TABLE orders
) WITH (
    STORAGE = 'cluster',
    INCREMENTAL_BACKUP_ENABLED = 'true'
);
```

Creating a backup collection with multiple tables:

```
CREATE BACKUP COLLECTION production_backups (
    TABLE orders,
    TABLE products,
    TABLE customers
) WITH (
    STORAGE = 'cluster',
    INCREMENTAL_BACKUP_ENABLED = 'true'
);
```

See also

- Backup collections.
- BACKUP.
- RESTORE.
- DROP BACKUP COLLECTION.

CREATE GROUP

Creates a group with the specified name. Optionally, you can specify a list of users to add to the group.

Syntax

```
CREATE GROUP group_name [ WITH USER user_name [ , user_name [ ... ]] [ , ] ]
```

Parameters

- `group_name`: The name of the group. It may contain lowercase Latin letters and digits.
- `user_name`: The name of the user who will become a member of the group after its creation. It may contain lowercase Latin letters and digits.

Examples

```
CREATE GROUP group1;
```

```
CREATE GROUP group2 WITH USER user1;
```

```
CREATE GROUP group3 WITH USER user1, user2,;
```

```
CREATE GROUP group4 WITH USER user1, user3, user2;
```

CREATE EXTERNAL DATA SOURCE

The `CREATE EXTERNAL DATA SOURCE` statement creates an external data source.

```
CREATE EXTERNAL DATA SOURCE external_data_source WITH (
  SOURCE_TYPE="source_type",
  LOCATION="ip_address_or_fqdn:port",
  USE_TLS="use_tls",
  AUTH_METHOD="auth_method",
  LOGIN="login",
  PASSWORD_SECRET_PATH="password_secret_path"
)
```

Where:

- `external_data_source` — name of the external data source.
- `source_type` — type of the external data source. Possible values: `ClickHouse`, `PostgreSQL`, `ObjectStorage`.
- `ip_address_or_fqdn:port` — full network address of the external data source, including the port. The network address can be an IP address or FQDN.
- `use_tls` — flag indicating that the connection must use a secure (TLS) connection. Possible values: `TRUE`, `FALSE`.
- `auth_method` — authentication method for the external data source. For external sources of types `ClickHouse` and `PostgreSQL`, only the `BASIC` authentication type is supported. For the `ObjectStorage` external source, only the `NONE` authentication type is currently supported.
- `login` — login used to connect to the external data source.
- `password_secret_path` — secret containing the password for connecting to the external data source.

When using secure TLS channels, system certificates located on YDB servers are used.

Example

The query below creates an external data source named `TestDataSource` to a ClickHouse cluster with IP address `192.168.1.1` and port `8443`, with login `admin` and secret `test_secret`:

```
CREATE EXTERNAL DATA SOURCE TestDataSource WITH (
  SOURCE_TYPE="ClickHouse",
  LOCATION="192.168.1.1:8443",
  USE_TLS="TRUE",
  AUTH_METHOD="BASIC",
  LOGIN="admin",
  PASSWORD_SECRET_PATH="test_secret"
)
```

Connecting to ClickHouse

To create a connection to a ClickHouse cluster, create an external data source `EXTERNAL DATA SOURCE` and specify:

- in the `SOURCE_TYPE` field, the value `ClickHouse`;
- in the `LOCATION` field, the full network address of the ClickHouse cluster, including the port. The network address can be an IP address or FQDN. Connection to the ClickHouse cluster is currently always made over the HTTP protocol;
- in the `USE_TLS` field, the flag indicating that the connection to the ClickHouse cluster must use a secure (TLS) connection;
- in the `AUTH_METHOD` field, the value `BASIC`;
- in the `LOGIN` field, the login used to connect to the ClickHouse cluster;
- in the `PASSWORD_SECRET_PATH` field, the secret containing the password for connecting to the ClickHouse cluster.

When using secure TLS channels, system certificates located on YDB servers are used.

Example

The query below creates an external data source named `TestDataSource` to a ClickHouse cluster with IP address `192.168.1.1` and port `8443`, with login `admin` and secret `test_secret`:

```
CREATE EXTERNAL DATA SOURCE TestDataSource WITH (
  SOURCE_TYPE="ClickHouse",
  LOCATION="192.168.1.1:8443",
  USE_TLS="TRUE",
  AUTH_METHOD="BASIC",
  LOGIN="admin",
  PASSWORD_SECRET_PATH="test_secret"
)
```

Connecting to PostgreSQL

To create a connection to a PostgreSQL cluster, create an `EXTERNAL DATA SOURCE` object and specify in the fields:

- in the `SOURCE_TYPE` field, the value `PostgreSQL`;
- in the `LOCATION` field, the full network address of the PostgreSQL cluster, including the port. The network address can be an IP address or FQDN;
- in the `USE_TLS` field, the flag indicating that the connection to the PostgreSQL cluster must use a secure (TLS) connection;
- in the `AUTH_METHOD` field, the value `BASIC`;
- in the `LOGIN` field, the login used to connect to the PostgreSQL cluster;
- in the `PASSWORD_SECRET_PATH` field, the secret containing the password for connecting to the PostgreSQL cluster.

Connection to the PostgreSQL cluster is currently always made over the standard Frontend/Backend Protocol over TCP. When using secure TLS channels, system certificates located on YDB servers are used.

Example

The query below creates an external data source named `TestDataSource` to a PostgreSQL cluster with IP address `192.168.1.1` and port `5432`, with login `admin` and secret `test_secret`:

```
CREATE EXTERNAL DATA SOURCE TestDataSource WITH (
  SOURCE_TYPE="PostgreSQL",
  LOCATION="192.168.1.1:5432",
  USE_TLS="TRUE",
  AUTH_METHOD="BASIC",
  LOGIN="admin",
  PASSWORD_SECRET_PATH="test_secret"
)
```

Connecting to S3 (Object Storage)

To create an external data source pointing to a bucket with data in S3 (Object Storage), create an `EXTERNAL DATA SOURCE` object and specify in the fields:

- in the `SOURCE_TYPE` field, the value `ObjectStorage`;
- in the `LOCATION` field, the network path to the bucket;
- in the `AUTH_METHOD` field, the value `NONE`.

> **Note**
>
> Currently, only buckets that are not protected by authentication are supported.

Connection is possible to any data sources that support the AWS S3 access protocol. Any URLs to systems supporting this protocol can be specified.

Typical `LOCATION` field values when connecting to different systems for bucket `bucket`:

System name	URL
Object Storage	`https://storage.yandexcloud.net/bucket/`
AWS S3	`http://s3.amazonaws.com/bucket/`

Example

The query below creates an external data source named `TestDataSource` pointing to directory `folder` in bucket `bucket` in Object Storage:

```
CREATE EXTERNAL DATA SOURCE TestDataSource WITH (
  SOURCE_TYPE="ObjectStorage",
  LOCATION="http://s3.amazonaws.com/bucket/folder/",
  AUTH_METHOD="NONE"
)
```

CREATE STREAMING QUERY

`CREATE STREAMING QUERY` creates a streaming query.

Syntax

```
CREATE [OR REPLACE] STREAMING QUERY [IF NOT EXISTS] <query_name> [WITH (
    <key1> = <value1>,
    <key2> = <value2>,
    ...
)] AS
DO BEGIN
    <query_statement1>;
    <query_statement2>;
    ...
END DO
```

Parameters

- `OR REPLACE` — if a streaming query with this name already exists, it will be replaced with a new query while preserving the read offsets from the topic.
- `IF NOT EXISTS` — do not output an error if a streaming query with this name already exists; in this case, the existing query will remain unchanged.
- `query_name` — the name of the streaming query to create.
- `WITH (<key> = <value>)` — a list of settings for the new streaming query, optional.
- `AS DO BEGIN ... END DO` — the full text of the new streaming query, including all required SQL statements. Restrictions on the query text are given in Limitations, see below for query text examples.

The `OR REPLACE` and `IF NOT EXISTS` settings cannot be used simultaneously.

Available parameters of the `WITH` block:

- `RUN = (TRUE|FALSE)` — start the query after creation, default `TRUE`.
- `RESOURCE_POOL = <resource_pool_name>` — the name of the resource pool in which the query will run.

See below for examples of creating a streaming query.

Using a reader

A consumer is a named subscription to a topic that stores the current read position.

A consumer is created via the CLI or when creating a topic using CREATE TOPIC. The consumer name is specified in the query text with a pragma:

```
PRAGMA pq.Consumer="my_consumer";
```

If a consumer is not specified, reading from the topic is performed without one. Specifying a consumer allows tracking the read position and lag from the topic side, for example via the CLI.

Regardless of whether a reader exists, the read position of the streaming query is saved in a checkpoint.

Examples

Writing to a topic (JSON)

The query reads events from an input topic, forms a JSON object from individual fields, and writes the result to an output topic.

The `AsStruct` function creates a structure from the specified fields, `Yson::From` converts it to Yson, `Yson::SerializeJson` serializes it to a JSON string, and `ToBytes` converts it to the `String` type, which is required for writing to a topic.

> **Note**
>
> Streaming queries can work with local and external topics.
>
> In the example:
>
> - `ext_source` is a pre-created `external data source`.
> - `input_topic` and `output_topic` are local or external topics.

```
CREATE STREAMING QUERY my_streaming_query AS
DO BEGIN

    INSERT INTO output_topic -- or external topic ext_source.output_topic
    SELECT
        -- Formation of JSON from individual fields
        ToBytes(Unwrap(Yson::SerializeJson(Yson::From(
            AsStruct(Id AS id, Name AS name)
        ))))
    FROM
        ext_source.input_topic -- or local topic input_topic
    WITH (
        FORMAT = json_each_row,  -- Input data format
        SCHEMA = (               -- Input data schema
            Id Uint64 NOT NULL,
            Name Utf8 NOT NULL
        )
    );

END DO
```

Writing to a table

The query reads events from the topic and writes them to the `output_table` table. The table must be created in advance with a schema matching the selected columns.

> **Warning**
>
> Writing to tables in streaming queries is supported **only in UPSERT mode**. The `INSERT INTO` operation is not supported, because during reprocessing of events (the at-least-once guarantee) it would lead to duplicate rows. With `UPSERT`, if a row with such a primary key already exists, it will be updated; otherwise, a new row will be inserted, and `INSERT INTO` will fail with an error.

```
CREATE STREAMING QUERY my_streaming_query AS
DO BEGIN

    -- Write to table (only UPSERT, INSERT is not supported)
    UPSERT INTO output_table
    SELECT
        Id,
        Name
    FROM
        input_topic -- or external topic ext_source.input_topic
    WITH (
        FORMAT = json_each_row,  -- Input data format
        SCHEMA = (               -- Input data schema
            Id Uint64 NOT NULL,
            Name Utf8 NOT NULL
        )
    );

END DO
```

Running in a resource pool

The query is created in the specified resource pool but is not started automatically (`RUN = FALSE`). This allows you to check the configuration before starting or start the query later via ALTER STREAMING QUERY.

```
CREATE STREAMING QUERY my_streaming_query WITH (
    RUN = FALSE,                     -- Do not start automatically
    RESOURCE_POOL = my_resource_pool  -- Resource pool for execution
) AS
DO BEGIN

    INSERT INTO output_topic -- or external topic ext_source.output_topic
    SELECT
        ToBytes(Unwrap(Yson::SerializeJson(Yson::From(
            AsStruct(Id AS id, Name AS name)
        ))))
    FROM
        ext_source.input_topic -- or local topic input_topic
    WITH (
        FORMAT = json_each_row,
        SCHEMA = (
            Id Uint64 NOT NULL,
            Name Utf8 NOT NULL
        )
    );

END DO
```

CREATE OBJECT (TYPE SECRET)

> **Alert**
>
> **This command is deprecated** and will be removed in future versions of YDB. The recommended syntax for working with secrets is described in the Secrets section.

The following SQL statement creates a secret:

```
CREATE OBJECT <secret_name> (TYPE SECRET) WITH value = "<secret_value>";
```

Where:

- `secret_name` - the name of the secret.
- `secret_value` - the contents of the secret.

Example

The following statement creates a secret named `MySecretName` with `MySecretData` as a value.

```
CREATE OBJECT MySecretName (TYPE SECRET) WITH value = "MySecretData";
```

CREATE OBJECT (TYPE SECRET_ACCESS)

> **Alert**
>
> **This command is deprecated** and will be removed in future versions of YDB. The recommended syntax for working with secrets is described in the Secrets section.

All rights to use a secret belong to the secret's creator. The creator can grant another user read access to the secret through secret access management.

Access to secrets is managed using special `SECRET_ACCESS` objects. To grant permission to use the secret `secret_name` to the user `user_name`, create a `SECRET_ACCESS` object named `secret_name:user_name`.

```
CREATE OBJECT `secret_name:user_name` (TYPE SECRET_ACCESS);
```

Where:

- `secret_name` — the name of the secret.
- `user_name` — the name of the user who receives access.

Example

The following statement grants access to the secret `MySecretName` to the user `another_user`:

```
CREATE OBJECT `MySecretName:another_user` (TYPE SECRET_ACCESS);
```

CREATE EXTERNAL TABLE

The `CREATE EXTERNAL TABLE` statement creates an external table with the given schema.

```
CREATE EXTERNAL TABLE table_name (
  column1 type1,
  column2 type2 NOT NULL,
  ...
  columnN typeN NULL
) WITH (
  DATA_SOURCE="data_source_name",
  LOCATION="path",
  FORMAT="format_name",
  COMPRESSION="compression_name"
);
```

Where:

- `column1 type1`, `columnN typeN NULL` — column definitions and types;
- `data_source_name` — name of the connection to S3 (Object Storage).
- `path` — path inside the data bucket. The path must refer to an existing folder in the bucket.
- `format_name` — one of the supported storage formats.
- `compression_name` — one of the supported compression algorithms.

Only a limited subset of data types is allowed:

- `Bool`.
- `Int8`, `Uint8`, `Int16`, `Uint16`, `Int32`, `Uint32`, `Int64`, `Uint64`.
- `Float`, `Double`.
- `Date`, `DateTime`.
- `String`, `Utf8`.

Without extra modifiers, a column has an optional type and may contain `NULL`. Use `NOT NULL` for a non-optional column.

Example

The following creates an external table `s3_test_data` with string columns `key` and `value` in CSV format under `test_folder` in the bucket, using external data source `bucket`:

```
CREATE EXTERNAL TABLE s3_test_data (
  key Utf8 NOT NULL,
  value Utf8 NOT NULL
) WITH (
  DATA_SOURCE="bucket",
  LOCATION="folder",
  FORMAT="csv_with_names",
  COMPRESSION="gzip"
);
```

CREATE OBJECT (TYPE SECRET)

> **Alert**
>
> **This command is deprecated** and will be removed in future versions of YDB. The recommended syntax for working with secrets is described in the Secrets section.

The following SQL statement creates a secret:

```
CREATE OBJECT <secret_name> (TYPE SECRET) WITH value = "<secret_value>";
```

Where:

- `secret_name` - the name of the secret.
- `secret_value` - the contents of the secret.

Example

The following statement creates a secret named `MySecretName` with `MySecretData` as a value.

```
CREATE OBJECT MySecretName (TYPE SECRET) WITH value = "MySecretData";
```

CREATE RESOURCE POOL

`CREATE RESOURCE POOL` creates a resource pool.

Syntax

```
CREATE RESOURCE POOL <name>
WITH ( <parameter_name> [= <parameter_value>] [, ... ] )
```

- `name` is the name of the resource pool being created. It must be unique. Path notation is not allowed (i.e., it must not contain `/`).
- `WITH ( <parameter_name> [= <parameter_value>] [, ... ] )` allows setting parameter values that define the behavior of the resource pool.

Parameters

- `CONCURRENT_QUERY_LIMIT` (Int32) — an optional field that sets the number of concurrently executing queries in the resource pool. If the value is `-1`, there is no limit. Default value: `-1`. Valid values: .
- `QUEUE_SIZE` (Int32) — an optional field that defines the size of the waiting queue. The system can hold no more than queries at a time. If the value is `-1`, there is no limit. Default value: `-1`. Valid values: .
- `DATABASE_LOAD_CPU_THRESHOLD` (Int32) — an optional field that sets the CPU load threshold for the entire database, after which queries are not sent for execution and remain in the queue. If the value is `-1`, there is no limit. Default value: `-1`. Valid values: .
- `TOTAL_MEMORY_LIMIT_PERCENT_PER_NODE` (Double) is an optional field that defines the percentage of available memory on the node that all queries in this resource pool can use. If the value is `-1`, there are no limits. Default value: `-1`. Valid values: .

  If a limit is set and the total memory consumption by queries in the pool reaches this limit:

  - New queries that require memory will fail with error `OVERLOADED`.
  - Already running queries that need additional memory will also fail with error `OVERLOADED`.
- `TOTAL_CPU_LIMIT_PERCENT_PER_NODE` (Double) — an optional field that sets the percentage of available CPU that all queries on the node in this resource pool can use. If the value is `-1`, there is no limit. Default value: `-1`. Valid values: .
- `QUERY_CPU_LIMIT_PERCENT_PER_NODE` (Double) — an optional field that defines the percentage of available CPU on the node for a single query in the resource pool. If the value is `-1`, there is no limit. Default value: `-1`. Valid values: .
- `RESOURCE_WEIGHT` (Int32) — an optional field that sets weights for distributing resources among pools. If the value is `-1`, weights are not used. Default value: `-1`. Valid values: .

> **Warning**
>
> The `QUERY_MEMORY_LIMIT_PERCENT_PER_NODE` parameter is currently not supported. To limit the amount of memory allocated to a resource pool, use the `TOTAL_MEMORY_LIMIT_PERCENT_PER_NODE` parameter.

Notes

Queries are always executed in some resource pool. By default, all queries are sent to the resource pool `default`, which is created automatically and cannot be deleted — it is always present in the system.

If the value of parameter `CONCURRENT_QUERY_LIMIT` is set to 0, then all queries sent to this pool will be immediately terminated with status `PRECONDITION_FAILED`.

Permissions

Requires permission `CREATE TABLE` on the directory `.metadata/workload_manager/pools`, an example of granting such permission:

```
GRANT 'CREATE TABLE' ON `.metadata/workload_manager/pools` TO `user1@domain`;
```

```
CREATE RESOURCE POOL olap WITH (
    CONCURRENT_QUERY_LIMIT=20,
    QUEUE_SIZE=1000,
    DATABASE_LOAD_CPU_THRESHOLD=80,
    RESOURCE_WEIGHT=100,
    TOTAL_MEMORY_LIMIT_PERCENT_PER_NODE=80,
    TOTAL_CPU_LIMIT_PERCENT_PER_NODE=70
)
```

In the example above, a resource pool is created with the following limits:

- Maximum number of concurrent queries — 20.
- Maximum queue size — 1000.
- When the database load reaches 80%, queries stop running concurrently.
- All queries in the pool can consume no more than 80% of the available memory on the node.
- The total limit on available CPU for all queries in the pool on the node is 70%.
- The resource pool has a weight of 100, which only takes effect in case of oversubscription.

See also

- Workload Manager — resource consumption management
- ALTER RESOURCE POOL
- DROP RESOURCE POOL

CREATE RESOURCE POOL CLASSIFIER

`CREATE RESOURCE POOL CLASSIFIER` creates a resource pool classifier.

Syntax

```
CREATE RESOURCE POOL CLASSIFIER <name>
WITH ( <parameter_name> [= <parameter_value>] [, ... ] )
```

- `name` ТАФ the name of the resource pool classifier being created. It must be unique. The name must not contain characters prohibited for schema objects.
- `WITH ( <parameter_name> [= <parameter_value>] [, ... ] )` ТАФ allows you to set parameter values that define the behavior of the resource pool classifier.

Common parameters

- `RANK` (Int64) ТАФ an optional field that specifies the selection order of the resource pool classifier. If the value is not specified, the maximum existing `RANK` is taken and 1000 is added to it. Valid values: a unique number in the range .
- `RESOURCE_POOL` (String) ТАФ the name of the resource pool to which requests matching the classifier's predicates are directed.
- `ACTION` (Enum) ТАФ the action applied to a request when the classifier matches. Allowed value ТАФ `reject`: the request is rejected, and the user receives an error of the form `Request is rejected by classifier '<name>' (rank=<rank>)`.

> **Note**
>
> The `RESOURCE_POOL` and `ACTION` parameters are mutually exclusive: exactly one of them must be specified in a classifier.

Predicate parameters

A predicate is a condition checked for an incoming request. A classifier matches if **all** of its predicates are satisfied (logical **AND**). To express **OR** logic, create multiple classifiers with different `RANK` values. Classifiers are processed in ascending order of `RANK`; processing stops at the first match ТАФ the request has that classifier's `ACTION` applied or is directed to its `RESOURCE_POOL`.

Predicate parameters are optional. A classifier without any predicates matches any request ТАФ this is useful for a "catch-all" classifier with the maximum `RANK`, for example, to direct all unclassified traffic to a specific pool (`RESOURCE_POOL`) or to reject it (`ACTION='reject'`).

> **Warning**
>
> Be careful when creating a "catch-all" classifier: all classifiers following it by `RANK` will never fire ТАФ processing stops at the first match, and the "catch-all" always matches.

List of predicates:

- `MEMBER_NAME` (String) ТАФ the SID of the user or group on whose behalf the request was made. See below for details.
- `HAS_PATH` (String) ТАФ path to a YDB object accessed by the request; supports wildcards `*` and `?`. See below for details.
- `HAS_APP_NAME` (String) ТАФ client application identifier. See below for details.
- `HAS_FULL_SCAN` (String) ТАФ path to an object for which a full scan is expected; supports wildcards `*` and `?`. See below for details.
- `HAS_STREAM` (Bool) ТАФ indicates whether the request is streaming. See below for details.

MEMBER_NAME

`MEMBER_NAME` is compared character by character with the user's SID or any group SID from their authentication token. The SID format depends on how the user logged into the system.

- **Built-in YDB users (login/password)** ТАФ the SID matches the username, without a suffix. For example, `user1`. For more information, see Authenticating by username and password.
- **Cloud users (Access Service)** ТАФ the SID has the form `<subject_id>@as`, where `<subject_id>` is the user ID in IAM. The suffix is set by the `access_service_domain` parameter (default `as`). For example, `ajeb89hv69nujke769fa@as`. For more information, see Authentication through a third-party IAM provider.
- **LDAP** ТАФ the SID has the form `<login>@<domain>`, where the domain is set by the `ldap_authentication_domain` parameter (default `ldap`). For example, `user1@ldap`. For more information, see LDAP directory integration.
- **External identity providers (OIDC)** ТАФ the SID has the form `<login>@<domain>`, where the domain is set by the `external_idp_authentication_domain` parameter in the authentication configuration (default `sso`). For example, `user1@sso`.

You can specify either the SID of a specific user or the SID of a group. The `all-users@well-known` group is automatically added to all authenticated users ТАФ it is convenient when you need to direct queries from all authenticated clients to a pool.

Example. Direct requests from user `user1@ldap` to the `olap` pool:

```
CREATE RESOURCE POOL CLASSIFIER cl_user WITH (
    RANK=100,
    RESOURCE_POOL='olap',
    MEMBER_NAME='user1@ldap'
);
```

HAS_PATH

`HAS_PATH` compares the paths of YDB objects accessed by the request against the specified mask. The mask supports wildcards: `*` ТАФ any sequence of characters, `?` ТАФ any single character. The predicate matches if at least one object in the request plan matches the mask.

Example. Direct requests to archive tables to the `pool_archive` pool:

```
CREATE RESOURCE POOL CLASSIFIER cl_archive WITH (
    RANK=700,
    RESOURCE_POOL='pool_archive',
    HAS_PATH='/Root/db/archive/*'
);
```

HAS_APP_NAME

`HAS_APP_NAME` compares the value against the client application identifier. The value is passed by the client in gRPC request metadata via the `x-ydb-application-name` header; YDB SDKs provide a way to set it on the client side. Comparison is exact match (no wildcards).

> **Warning**
>
> The `HAS_APP_NAME` value is set by the client and is not authenticated by the server ТАФ do not use it as an access control mechanism. For effective isolation, combine it with `MEMBER_NAME` or direct unrecognized requests to a sandbox pool with strict limits.

Setting the application identifier on the client:

- **YDB UI** — fixed value `ydb-ui`, set by the viewer and not user-configurable.
- **YDB CLI** — not supported: the client application identifier is not sent in requests.
- **YDB C++ SDK** — per request via the `Header` parameter of `TRequestSettings`: `settings.Header({{ NYdb::YDB_APPLICATION_NAME, "my-app" }})`, where the `YDB_APPLICATION_NAME` constant equals `x-ydb-application-name`.
- **YDB Go SDK** — at the driver level via the `WithApplicationName` option in the `ydb.Open` call.
- **YDB Java SDK** — at the transport level via the `GrpcTransportBuilder.withApplicationName` method.
- **YDB Python SDK** — no dedicated parameter; the value is set per request via a generic header: `settings.with_header("x-ydb-application-name", "my-app")` (the `BaseRequestSettings.with_header` method).

Example. Direct requests from YDB UI to the `pool_adhoc` pool:

```
CREATE RESOURCE POOL CLASSIFIER cl_adhoc_ui WITH (
    RANK=200,
    RESOURCE_POOL='pool_adhoc',
    HAS_APP_NAME='ydb-ui'
);
```

HAS_FULL_SCAN

`HAS_FULL_SCAN` identifies requests that contain a full scan of the specified objects. A full scan is a table read without a key or key-range constraint. The argument is a path mask supporting wildcards `*` and `?`; the predicate matches if there is at least one such object in the request plan. Both row-oriented and column-oriented tables are supported. Objects to which the full-scan concept does not apply (for example, topics) are not considered.

Details of full-scan detection:

- **`LIMIT` does not cancel a full scan.** Without a key condition, the physical plan processes the entire table; `LIMIT` only limits the size of the result.
- **Secondary indexes.** A full scan of a secondary index's implementation table is counted against its own path. For example, for the table

  ```
  CREATE TABLE orders (
      Id Uint64 NOT NULL,
      Status Utf8,
      PRIMARY KEY (Id),
      INDEX by_status GLOBAL ON (Status)
  );
  ```

  the index table has path `/Root/orders/by_status/indexImplTable`. The query `SELECT * FROM orders VIEW by_status` performs a full scan of the index table ТАФ the main `/Root/orders` is not scanned. Therefore:

  - `HAS_FULL_SCAN='/Root/orders'` ТАФ **will not match**;
  - `HAS_FULL_SCAN='/Root/orders/by_status/indexImplTable'` or `HAS_FULL_SCAN='/Root/orders/*'` ТАФ **will match**.

Example. Reject requests that cause a full scan of the orders archive:

```
CREATE RESOURCE POOL CLASSIFIER cl_fullscan_reject WITH (
    RANK=100,
    ACTION='reject',
    HAS_FULL_SCAN='/Root/db/orders_archive/*'
);
```

HAS_STREAM

`HAS_STREAM` determines whether a request is streaming ТАФ that is, performs a long-running continuous read and/or write over data streams. Allowed values:

- `true` ТАФ the classifier matches streaming requests;
- `false` ТАФ the classifier matches non-streaming requests.

Example. Direct streaming requests to the `pool_stream` pool:

```
CREATE RESOURCE POOL CLASSIFIER cl_stream WITH (
    RANK=500,
    RESOURCE_POOL='pool_stream',
    HAS_STREAM=true
);
```

Notes

If `RANK` is not specified in the DDL for creating a resource pool classifier, it will be assigned the default value . All `RANK` values must be unique to ensure a strictly deterministic order of resource pool selection in case of conflicting conditions. This behavior is chosen to allow adding new resource pool classifiers between existing ones.

It is also possible to have a classifier that references a non-existent resource pool or one to which the user does not have access. In that case, it is skipped.

For limitations on the number of classifiers, see the limitations page.

Permissions

The permission `USE` on the database is required.

Example of granting such a permission:

```
GRANT 'USE' ON `/my_db` TO `user1@domain`;
```

Examples

Below is a combined example that composes several classifiers and predicates: rejecting full scans of archive tables, isolating streaming requests, and dedicating a pool for interactive admin queries from YDB UI.

Creating resource pools:

```
CREATE RESOURCE POOL pool_stream WITH (
    TOTAL_CPU_LIMIT_PERCENT_PER_NODE=20
);

CREATE RESOURCE POOL pool_adhoc_admin WITH (
    TOTAL_CPU_LIMIT_PERCENT_PER_NODE=10
);
```

Creating classifiers:

```
-- Reject full scans of archive tables.
CREATE RESOURCE POOL CLASSIFIER cl_fullscan_reject WITH (
    RANK=100,
    ACTION='reject',
    HAS_FULL_SCAN='/Root/db/orders_archive/*'
);

-- Direct streaming requests to a dedicated pool.
CREATE RESOURCE POOL CLASSIFIER cl_stream WITH (
    RANK=200,
    RESOURCE_POOL='pool_stream',
    HAS_STREAM=true
);

-- Admin requests from YDB UI — into the interactive-queries pool.
-- AND condition: both MEMBER_NAME and HAS_APP_NAME must match.
CREATE RESOURCE POOL CLASSIFIER cl_adhoc_admin WITH (
    RANK=300,
    RESOURCE_POOL='pool_adhoc_admin',
    MEMBER_NAME='admin',
    HAS_APP_NAME='ydb-ui'
);
```

Classifiers are processed in ascending order of `RANK`; the first matching classifier is applied to the request. A request that does not match any classifier is directed to the `default` pool.

- ALTER RESOURCE POOL CLASSIFIER
- DROP RESOURCE POOL CLASSIFIER

CREATE SECRET

The `CREATE SECRET` statement creates a secret.

Syntax

```
CREATE SECRET secret_name
WITH (option = value[, ...])
```

- `secret_name` — the name of the secret to create.
- `option` — command option:
  - `value` — string with the secret value.
  - `inherit_permissions` — when enabled, rights on the secret are inherited from the directory where the secret is created. When disabled, only the right `DESCRIBE SCHEMA` is inherited from the directory. The secret owner gets all possible rights on it in any case. Default is `False`.

Permissions

Creating a secret requires the right `CREATE TABLE`.

Examples

Create a secret in the database root named `secret_name` with value `secret_value`:

```
CREATE SECRET secret_name WITH (value = "secret_value");
```

Create a secret in directory `dir` in the database root named `secret_name` with value `secret_value`. If directory `dir` does not exist, it will be created:

```
CREATE SECRET `dir/secret_name` WITH (value = "secret_value");
```

Create a secret in the database root named `secret_name` with value `secret_value` with the same rights as the secret's parent directory:

```
CREATE SECRET secret_name WITH (value = "secret_value", inherit_permissions = True);
```

See also

- ALTER SECRET
- DROP SECRET

CREATE TABLE

The `CREATE TABLE` call creates a table with the specified data schema and key columns (`PRIMARY KEY`). It allows defining secondary indexes on the created table.

```
CREATE TABLE [IF NOT EXISTS] <table_name> (
  [<column_name> <column_data_type>] [FAMILY <family_name>] [NULL | NOT NULL] [DEFAULT <default_value>]
  [COMPRESSION([algorithm=<algorithm_name>[, level=<value>]])]
  [ENCODING([OFF|DICT])]
  [, ...],
    INDEX <index_name>
      [GLOBAL|LOCAL]
      [UNIQUE]
      [SYNC|ASYNC]
      [USING <index_type>]
      ON ( <index_columns> )
      [COVER ( <cover_columns> )]
      [WITH ( <parameter_name> = <parameter_value>[, ...])]
    [, ...]
  PRIMARY KEY ( <column>[, ...]),
  [FAMILY <column_family> ( family_options[, ...])]
)
[PARTITION BY HASH ( <column>[, ...])]
[WITH (<setting_name> = <setting_value>[, ...])]

[AS SELECT ...]
```

Query parameters

table_name

Path of the table being created.

When choosing a table name, follow the general naming rules for schema objects.

IF NOT EXISTS

If a table with the specified name already exists, the statement execution is completely skipped — no checks or schema comparison are performed, and no error occurs. Note that the existing table may differ in structure from the one you intended to create with this query — no comparison or equivalence check is performed.

column_name

Name of the column being created in the new table.

When choosing a column name, follow the general column naming rules.

column_data_type

Data type of the column. The full list of data types supported by YDB is available in the YQL data types section.

FAMILY <family_name> (column setting)

> **Warning**
>
> Supported only for row-oriented tables.

Specifies the belonging of this column to the specified group of columns. For more details, see the section Column groups.

DEFAULT <default_value>

> **Warning**
>
> The `DEFAULT` option is supported:
>
> - Only for row-oriented tables.
> - Only with literal values.

Allows you to set a default value for the column. If no value is specified for this column when inserting a row, the specified default value will be used. The default value must match the data type of the column.

The `DEFAULT false NOT NULL` construct is not allowed due to ambiguity of interpretation. In this case, you should use a comma-separated list or change the order of the options.

NULL

This column can contain `NULL` values (by default).

NOT NULL

This column does not accept `NULL` values.

COMPRESSION([algorithm=<algorithm_name>[, level=]])

> **Warning**
>
> Supported only for column-oriented tables.

The following compression parameters can be set for columns:

- `algorithm` — the data compression algorithm. Allowed values: `off` (disable compression), `lz4`, `zstd`.
- `level` — the compression level, supported only for the `zstd` algorithm (values from 0 to 22 are allowed).

If `COMPRESSION()` is specified without parameters, the default compression is used for the column. Currently, it is `lz4`; in future versions, it will be possible to configure the default compression at the cluster or table level.

ENCODING([OFF|DICT])

Warning

Supported only for column-oriented tables.

Allows you to set the data encoding method for the column.

Available options:

- `ENCODING(DICT)` — enables dictionary encoding. Repeating values are replaced with small integer identifiers, and the values themselves are stored in a dictionary. Dictionary encoding is effective for columns with low cardinality (a small number of unique values). It reduces the amount of stored data and speeds up some operations. It is supported only for comparable data types, such as `String`, `Timestamp`, `UInt64`, and others. Using `ENCODING(DICT)` for incomparable types, such as `Json`, `JsonDocument`, or `Yson`, will result in an error.
- `ENCODING(OFF)` — disables special encoding. Data will be stored in the standard format without additional encoding.

If `ENCODING()` is set without parameters, the default encoding will be used for the column. Currently, it is `OFF`; in future versions, it will be possible to configure the default encoding at the database or table level.

INDEX

Defining an index on the table. Supported types:

- secondary indexes,
- vector indexes,
- full-text indexes,
- Bloom indexes,
- JSON indexes.

PRIMARY KEY

Defining the table's primary key. Specifies the columns that make up the primary key in the order listed. For more details on choosing a primary key, see the Choosing a primary key section.

PARTITION BY HASH

Defining partitioning keys for **column-oriented** tables. Specifies the columns by whose hash the data partitioning is performed. The columns must be part of the primary key. However, the columns do not necessarily have to be a prefix or suffix — the requirement is to be part of the primary key.

If the parameter is not specified, the table will be split into partitions by the same columns that are part of the primary key. For guidance on how to choose partitioning keys for column-oriented tables, see the article Choosing keys for maximum column-oriented table performance.

For more details on partitioning column-oriented tables, see the Partitioning Column-Oriented Tables section.

FAMILY <column_family> (column group settings)

Defining a column group with specified parameters. For more details, see the Column groups section.

WITH

Additional table creation parameters. For more details, see the Additional parameters (WITH) section.

Note

YDB supports two types of tables:

- Row-oriented.
- Column-oriented.

The table type when created is specified by the `STORE` parameter in the `WITH` block, where `ROW` means row-oriented table and `COLUMN` means column-oriented table:

```
CREATE <table_name> (
  columns
  ...
)

WITH (
  STORE = COLUMN -- Default value ROW
)
```

By default, if the `STORE` parameter is not specified, a row-oriented table is created.

Note

When choosing a table name, follow the general naming rules for schema objects.

AS SELECT

Creating and populating a table based on the results of the `SELECT` query. For more details, see the Creating a table filled with query results section.

Table creation examples

Creating a row-oriented table

```
  CREATE TABLE <table_name> (
    a Uint64,
    b Uint64,
    c Float,
    PRIMARY KEY (a, b)
  );
```

Example of creating a table using a default value (DEFAULT):

```
  CREATE TABLE table_with_default (
  id Uint64,
  name String DEFAULT "unknown",
  score Double NOT NULL DEFAULT 0.0,
  PRIMARY KEY (id)
);
```

For key columns, only primitive and serial data types are allowed; for non-key columns, only primitive data types are allowed.

Without additional modifiers, the column acquires an optional type and allows `NULL` to be written as values. To obtain a non-optional type, use `NOT NULL`.

It is mandatory to specify `PRIMARY KEY` with a non-empty list of columns. These columns become part of the key in the order they are listed.

Example of creating a row table with partitioning options:

```
CREATE TABLE <table_name> (
  a Uint64,
  b Uint64,
  c Float,
  PRIMARY KEY (a, b)
)
WITH (
  AUTO_PARTITIONING_BY_SIZE = ENABLED,
  AUTO_PARTITIONING_PARTITION_SIZE_MB = 512
);
```

This code will create a row table with automatic partitioning enabled by partition size (`AUTO_PARTITIONING_BY_SIZE`) and a preferred partition size (`AUTO_PARTITIONING_PARTITION_SIZE_MB`) of 512 megabytes. The full list of row table partitioning options is in the Row table partitioning section of the Table article.

Creating a column table

```
CREATE TABLE table_name (
  a Uint64 NOT NULL,
  b Timestamp NOT NULL,
  c Float,
  PRIMARY KEY (a, b)
)
PARTITION BY HASH(b)
WITH (
  STORE = COLUMN
);
```

For column tables, you can explicitly specify which columns will be used for partitioning using the `PARTITION BY HASH` construct. Typically, primary key columns with a large number of unique values are chosen for this, for example, `Timestamp`. If `PARTITION BY HASH` is not specified, partitioning will occur automatically across all columns that are part of the primary key. For more details on selecting and working with partitioning keys in column tables, see the Choosing keys for maximum column-oriented table performance article.

Currently, column tables do not support automatic repartitioning, so it is important to specify the correct number of partitions when creating a table using the `AUTO_PARTITIONING_MIN_PARTITIONS_COUNT` parameter:

```
CREATE TABLE table_name (
  a Uint64 NOT NULL,
  b Timestamp NOT NULL,
  c Float,
  PRIMARY KEY (a, b)
)
PARTITION BY HASH(b)
WITH (
  STORE = COLUMN,
  AUTO_PARTITIONING_MIN_PARTITIONS_COUNT = 10
);
```

This code will create a column table with 10 partitions. For a full list of column table partitioning options, see the Partitioning Column-Oriented Tables section of the Table article.

When creating row tables, you can specify:

- Secondary index.
- Vector index.
- Full-text index.
- JSON index.
- Bloom index.
- Column groups.
- Additional parameters.
- Creating and populating a table based on query results.

For column tables, when creating them, you can specify:

- Bloom index.
- Column groups.
- Additional parameters.
- Creating and populating a table based on query results.

INDEX

The INDEX construct is used to define a secondary index in a row-oriented table:

```
CREATE TABLE `<table_name>` (
  ...
    INDEX `<index_name>`
    [GLOBAL|LOCAL]
    [UNIQUE]
    [SYNC|ASYNC]
    [USING <index_type>]
    ON ( <index_columns> )
    [COVER ( <cover_columns> )]
    [WITH ( <parameter_name> = <parameter_value>[, ...])]
  [,   ...]
)
```

where:

- `GLOBAL/LOCAL` — global or local index, depending on the index type (`<index_type>`), only one of them may be available:
  - `GLOBAL` — an index implemented as a separate table or a set of tables. Synchronous update of such an index requires distributed transactions.
  - `LOCAL` — a local index within a shard of a columnar or row-based table, does not require distributed transactions during update, but does not provide pruning during search.
- `<index_name>` — unique index name by which data can be accessed.
- `SYNC/ASYNC` — indicator of index synchrony.
  - `SYNC` - synchronous index. Default value.
  - `ASYNC` - asynchronous index.
- `UNIQUE` — indicator of a unique secondary index. A unique index must be global synchronous (`GLOBAL UNIQUE SYNC`) and must not contain the `USING <index_type>` construct.
- `<index_type>` - index type, currently supported:
  - `secondary` — secondary index. Only the `GLOBAL` mode is available for secondary indexes. This is the default index type.
  - `vector_kmeans_tree` — vector index. More details are described in the Vector index section.
  - `fulltext_plain` — basic full-text index. More details are described in Fulltext index.
  - `fulltext_relevance` — full-text index with BM25 statistics for relevance calculation. More details are described in Fulltext index.
  - `json` — JSON index to speed up predicates `JSON_EXISTS` and `JSON_VALUE` on a column of type `Json` or `JsonDocument`. More details are described in JSON-index.
  - `bloom_filter` — local Bloom index. Only `LOCAL` is available. See ALTER TABLE ADD INDEX.
  - `bloom_ngram_filter` — local N-gram Bloom index. Only `LOCAL` is available. See ALTER TABLE ADD INDEX.
- `<index_columns>` — comma-separated list of column names of the table being created, which determines the composition and order of columns included in the index key. Must be specified. The index key will consist of these columns with the addition of the table's primary key columns.
- `<cover_columns>` — comma-separated list of column names of the table being created that will be stored in the index in addition to the index key columns, allowing you to get additional data without accessing the table. Empty by default.
- `<parameter_name>` and `<parameter_value>` are index parameters specific to a particular `<index_type>` .

> **Warning**
>
> Supported only for row-oriented tables. Support for column-oriented tables is currently under development.

Example

```
CREATE TABLE my_table (
    a Uint64,
    b Bool,
    c Utf8,
    d Date,
    INDEX idx_d GLOBAL ON (d),
    INDEX idx_ba GLOBAL ASYNC ON (b, a) COVER (c),
    INDEX idx_uniq GLOBAL UNIQUE SYNC ON (c),
    PRIMARY KEY (a)
)
```

Vector index

Vector index in row-oriented tables is created using the same syntax as secondary indexes, by specifying `vector_kmeans_tree` as the index type. Subset of syntax available for vector indexes:

```
CREATE TABLE `<table_name>` (
    ...
    INDEX `<index_name>`
        GLOBAL
        [SYNC]
        USING vector_kmeans_tree
        ON ( <index_columns> )
        [COVER ( <cover_columns> )]
        [WITH ( <parameter_name> = <parameter_value>[, ...])]
    [,   ...]
)
```

Where:

- `<index_name>` - unique index name for data access
- `SYNC` - indicates synchronous data writing to the index. This is the only currently available option, and it is used by default.
- `<index_columns>` - comma-separated list of table columns used for index searches (the last column is used as embedding, others as filtering columns)
- `<cover_columns>` - list of additional table columns stored in the index to enable retrieval without accessing the main table
- `<parameter_name>` and `<parameter_value>` - list of key-value parameters:

- common parameters for all vector indexes:
  - `vector_dimension` - embedding vector dimensionality (should be between 1 and 16384)
  - `vector_type` - vector value type (`float` , `uint8` , or `int8`)
  - `distance` - distance function (`cosine` , `manhattan` , or `euclidean`), mutually exclusive with `similarity`
  - `similarity` - similarity function (`inner_product` or `cosine`), mutually exclusive with `distance`
- specific parameters for `vector_kmeans_tree` (read more about the index type):
  - `clusters` - number of centroids for k-means algorithm (should be between 2 and 2048)
  - `levels` - number of levels in the tree (should be between 1 and 16)
  - `overlap_clusters` - the number of nearest clusters to add each vector to (default 1)
  - the total number of nodes in the tree, calculated as `clusters` raised to the power of `levels` , should be no more than 1073741824
  - the product of `vector_dimension` and `clusters` should be no more than 4194304

Warning

It is recommended to create a vector index after loading data into the table, as an index created on an empty table will have only one cluster and will not speed up the search at all. For more details, see Updating Vector Indexes.

Warning

Supported only for row-oriented tables. Support for column-oriented tables is currently under development.

Example

```
CREATE TABLE user_articles (
    article_id Uint64,
    user String,
    title String,
    text String,
    embedding String,
    INDEX emb_cosine_idx GLOBAL SYNC USING vector_kmeans_tree
    ON (user, embedding) COVER (title, text)
    WITH (
        distance="cosine",
        vector_type="float",
        vector_dimension=512,
        clusters=128,
        levels=2,
        overlap_clusters=3
    ),
    PRIMARY KEY (article_id)
)
```

Fulltext index

Fulltext indexes in row-oriented tables are created using the same syntax as secondary indexes, by specifying `fulltext_plain` or `fulltext_relevance` as the index type. Subset of syntax available for fulltext indexes:

```
CREATE TABLE `<table_name>` (
    ...
    INDEX `<index_name>`
        GLOBAL
        [SYNC]
        USING fulltext_plain | fulltext_relevance
        ON ( <text_column> )
        [COVER ( <cover_columns> )]
        [WITH ( <parameter_name> = <parameter_value>[, ...])]
    [,   ...]
)
```

Where:

- `<index_name>` - unique index name for data access
- `SYNC` - indicates synchronous data writing to the index. This is the only currently available option, and it is used by default.
- `<text_column>` - a single table column with text content (currently only one indexed column is supported)
- `<cover_columns>` - list of additional table columns stored in the index to enable retrieval without accessing the main table
- `<parameter_name>` and `<parameter_value>` - list of key-value parameters:

- common parameters for all fulltext indexes:
  - `tokenizer` - tokenizer type (`standard` , `whitespace` , or `keyword`)
  - `use_filter_lowercase` - lowercase filter (`true` or `false`)
  - `use_filter_length` - token length filter (`true` or `false`); when `true` , tokens shorter than `filter_length_min` or longer than `filter_length_max` are not indexed and are ignored during search
  - `filter_length_min` - minimum token length (positive integer); only applied when `use_filter_length=true`
  - `filter_length_max` - maximum token length (positive integer); only applied when `use_filter_length=true`
  - `use_filter_snowball` - Snowball stemmer filter (`true` or `false`)
  - `language` - language for the Snowball stemmer (for example, `english` , `russian`)
  - `use_filter_ngram` - n-gram filter (`true` or `false`)
  - `use_filter_edge_ngram` - edge n-gram filter (`true` or `false`)
  - `filter_ngram_min_length` - minimum n-gram length (positive integer)
  - `filter_ngram_max_length` - maximum n-gram length (positive integer)

Warning

Supported only for row-oriented tables. Support for column-oriented tables is currently under development.

Examples

Basic example

```
CREATE TABLE articles (
    id Uint64,
    title String,
    body String,
    INDEX ft_idx GLOBAL USING fulltext_relevance
    ON (body) COVER (title)
    WITH (
        tokenizer=standard,
        use_filter_lowercase=true
    ),
    PRIMARY KEY (id)
)
```

Example with n-grams

N-grams allow finding substrings within words. When using the n-gram filter, each word is split into all possible substrings of specified length. For example, the word "search" with parameters `filter_ngram_min_length=3` and `filter_ngram_max_length=5` will be split into: "sea", "ear", "arc", "rch" (3-grams), "sear", "earc", "arch" (4-grams), "searc", "earch" (5-grams). This enables finding documents by partial matches anywhere within a word.

```
CREATE TABLE products (
    id Uint64,
    name String,
    description String,
    INDEX ft_ngram_idx GLOBAL USING fulltext_plain
    ON (name)
    WITH (
        tokenizer=standard,
        use_filter_lowercase=true,
        use_filter_ngram=true,
        filter_ngram_min_length=3,
        filter_ngram_max_length=5
    ),
    PRIMARY KEY (id)
)
```

Example with edge n-grams

Edge n-grams create substrings only from the beginning of a word. For example, the word "search" with parameters `filter_ngram_min_length=2` and `filter_ngram_max_length=10` will be split into: "se", "sea", "sear", "searc", "search". This is particularly useful for implementing autocomplete functionality, when you need to find words that start with a user-entered prefix.

```
CREATE TABLE users (
    id Uint64,
    username String,
    email String,
    INDEX ft_edge_ngram_idx GLOBAL USING fulltext_plain
    ON (username)
    WITH (
        tokenizer=standard,
        use_filter_lowercase=true,
        use_filter_edge_ngram=true,
        filter_ngram_min_length=2,
        filter_ngram_max_length=10
    ),
    PRIMARY KEY (id)
)
```

JSON-index

JSON indexes in row tables are created using the same syntax as secondary indexes, by specifying `json` as the index type. A subset of the syntax available for JSON indexes:

```
CREATE TABLE `<table_name>` (
    ...
    INDEX `<index_name>`
        GLOBAL
        [SYNC]
        USING json
        ON ( <json_column> )
    [,   ...]
)
```

Where:

- `<index_name>` — unique index name for data access.
- `SYNC` — specifies synchronous index update. This is the only mode available for JSON indexes; explicit specification is not required.
- `<json_column>` — table column of type `Json` or `JsonDocument`. A JSON index is built on a single column only.

A JSON index does not support the `COVER` expression — attempting to specify it will result in an error.

> **Warning**
>
> Supported only for row-oriented tables. Support for column-oriented tables is currently under development.

Example

```
CREATE TABLE documents (
    id Uint64 NOT NULL,
    payload JsonDocument NOT NULL,
    INDEX json_idx GLOBAL USING json ON (payload),
    PRIMARY KEY (id)
)
```

In this example, a table `documents` is created with a JSON index `json_idx` on column `payload`. The index will be used by queries whose `WHERE` predicate contains calls to `JSON_EXISTS` or `JSON_VALUE` on column `payload`.

Bloom skip index

Bloom skip indexes are local indexes and must be declared with `LOCAL`. In the `INDEX` clause use `bloom_filter` or `bloom_ngram_filter` (similar to a secondary index, but with `LOCAL` and the matching `USING` type). See also local indexes.

```
CREATE TABLE `<table_name>` (
    ...
    INDEX `<index_name>`
        LOCAL
        USING bloom_filter | bloom_ngram_filter
        ON ( <index_columns> )
        [WITH ( <parameter_name> = <parameter_value>[, ...])]
    [,   ...]
)
```

Where:

- `<index_name>`: Index name.
- `LOCAL`: Required keyword for Bloom skip indexes.
- `<index_columns>`: List of columns used to build the index; the number of columns depends on the table type and index type. On row-oriented tables, the indexed columns of a `bloom_filter` must be a left prefix of the primary key.
- `COVER (...)` and data columns are not supported for Bloom skip indexes.

`WITH (...)` parameters:

- `bloom_filter`
  - `false_positive_probability`: Target false-positive rate of the filter: the fraction of fragments that are not skipped even though the requested value is not there (range `(0, 1)`). A lower value reduces extra reads but increases index size.
    - If omitted, the default is `0.0001` for row-oriented tables and `0.1` for column-oriented tables. The stricter default on row-oriented tables matches OLTP point lookups; on column-oriented tables it reflects analytical scans, where a larger trade-off between index size and fragment skipping is acceptable.
  - Indexed columns: YQL types that support equality comparison, except `Yson`, `Json`, and `JsonDocument` (see comparison operators). One column in a column-oriented table; multiple columns in a row-oriented table. On row-oriented tables, the indexed columns must form a left prefix of the primary key.
- `bloom_ngram_filter` (`String` and `Utf8` columns; column-oriented tables only)
  - `ngram_size`: N-gram length, an integer from `3` to `8` (default `3`).
  - `false_positive_probability`: Target false-positive rate (range `(0, 1)`; default `0.1`).
  - `case_sensitive`: Whether n-grams respect character case: `true` or `false` (default `true`).

Creating and altering these indexes on an existing table is described in `ALTER TABLE ADD INDEX`.

Examples

`bloom_filter` index

```
CREATE TABLE events (
    id Uint64,
    resource_id Utf8,
    PRIMARY KEY (id),
    INDEX idx_bloom LOCAL USING bloom_filter
        ON (resource_id)
        WITH (false_positive_probability = 0.01)
);
```

`bloom_ngram_filter` index

```
CREATE TABLE events (
    id Uint64,
    message Utf8,
    PRIMARY KEY (id),
    INDEX idx_ngram LOCAL USING bloom_ngram_filter
        ON (message)
        WITH (
            ngram_size = 3,
            false_positive_probability = 0.01,
            case_sensitive = true
        )
);
```

min_max index

min-max index is a local index that can only be specified with the `LOCAL` keyword. When creating a table, the `min_max` type is used in the `INDEX` section (similar to a secondary index, but with a mandatory `LOCAL` and corresponding `USING`). See also local indexes.

```
CREATE TABLE `<table_name>` (
    ...
    INDEX `<index_name>`
        LOCAL
        USING min_max
        ON ( <index_column> )
    [,   ...]
)
```

Where:

- `<index_name>` — index name.
- `LOCAL` — required keyword for the min_max index.
- `<index_column>` — the column on which the index is built. You must specify exactly one column.
- For the min_max index, covering columns (`COVER (...)`) and additional data columns are not supported.

`WITH (...)` parameters:

The min_max index has no specific parameters `WITH (...)`.

Creating a min_max index for an existing table is described in the `ALTER TABLE ADD INDEX` section.

Example

```
CREATE TABLE events (
    id Uint64,
    created_at Timestamp,
    level Int32,
    PRIMARY KEY (id),
    INDEX idx_created_at LOCAL USING min_max
        ON (created_at),
    INDEX idx_level LOCAL USING min_max
        ON (level)
)
WITH (
    STORE = COLUMN
);
```

Column groups

> **Warning**
>
> Supported only for row-oriented tables.

Columns of the same table can be grouped to set the following parameters:

- `DATA`: A storage device type for the data in this column group. Acceptable values: `"ssd"`, `"rot"`.
- `COMPRESSION`: A data compression codec. Acceptable values: `"off"`, `"lz4"`.
- `CACHE_MODE`: Caching mode. Acceptable values: `"in_memory"`, `"regular"`.

By default, all columns are in the same group named `default`. If necessary, the parameters of this group can also be redefined, if they are not redefined, then predefined values are applied.

Example

In the example below, for the created table, the `family_large` group of columns is added and set for the `series_info` column, and the parameters for the default group, which is set by `default` for all other columns, are also redefined.

```
CREATE TABLE series_with_families (
    series_id Uint64,
    title Utf8,
    series_info Utf8 FAMILY family_large,
    release_date Uint64,
    PRIMARY KEY (series_id),
    FAMILY default (
        DATA = "ssd",
        COMPRESSION = "off",
        CACHE_MODE = "in_memory"
    ),
    FAMILY family_large (
        DATA = "rot",
        COMPRESSION = "lz4",
        CACHE_MODE = "regular"
    )
);
```

> **Note**
>
> Available types of storage devices depend on the YDB cluster configuration.

Additional parameters (WITH)

You can also specify a number of YDB-specific parameters for the table. When you create a table, those parameters are listed in the `WITH` clause:

```
CREATE TABLE table_name (...)
WITH (
    key1 = value1,
    key2 = value2,
    ...
)
```

Here, `key` is the name of the parameter and `value` is its value.

The list of allowable parameter names and their values is provided on the table description page YDB.

For example, such a query will create a string table with automatic partitioning enabled based on partition size and a preferred size of each partition being 512 megabytes:

```
CREATE TABLE my_table (
    id Uint64,
    title Utf8,
    PRIMARY KEY (id)
)
WITH (
    AUTO_PARTITIONING_BY_SIZE = ENABLED,
    AUTO_PARTITIONING_PARTITION_SIZE_MB = 512
);
```

A colum-oriented table is created by specifying the parameter `STORE = COLUMN` in the `WITH` clause:

```
 CREATE TABLE table_name (
    a Uint64 NOT NULL,
    b Timestamp NOT NULL,
    c Float,
    PRIMARY KEY (a, b)
  )
  PARTITION BY HASH(b)
  WITH (
    STORE = COLUMN
  );
```

The properties and capabilities of columnar tables are described in the article Table, and the specifics of their creation through YQL are described on the page CREATE TABLE.

Time to Live (TTL)

The TTL (Time to Live) — the lifespan of a row — can be specified in the WITH clause for row-based and columnar tables. TTL automatically deletes rows or evicts them to external storage when the specified number of seconds has passed since the time recorded in the TTL column. TTL can be specified when creating row-based and columnar tables or added later using the `ALTER TABLE` command only for row-based tables.

The short form of the TTL value for specifying the time to delete rows:

```
Interval("<literal>") ON column [AS <unit>]
```

The general form of the TTL value:

```
Interval("<literal1>") action1, ..., Interval("<literalN>") actionN ON column [AS <unit>]
```

- `action` — the action performed when the TTL expression triggers. Allowed values:
  - `DELETE` — delete the row;
  - `TO EXTERNAL DATA SOURCE <path>` — evict the row to external storage specified by the external data source at the path `<path>`.
- `<unit>` — the unit of measurement, specified only for columns with a numeric type:
  - `SECONDS`;
  - `MILLISECONDS`;
  - `MICROSECONDS`;
  - `NANOSECONDS`.

Example of creating a row-oriented and column-oriented tables with TTL:

Creating row-oriented table with TTL

```
CREATE TABLE my_table (
    id Uint64,
    title Utf8,
    expire_at Timestamp,
    PRIMARY KEY (id)
)
WITH (
    TTL = Interval("PT0S") ON expire_at
);
```

Creating column-oriented table with TTL

```
CREATE TABLE table_name (
    a Uint64 NOT NULL,
    b Timestamp NOT NULL,
    c Float,
    PRIMARY KEY (a, b)
)
PARTITION BY HASH(b)
WITH (
    STORE = COLUMN,
    TTL = Interval("PT0S") ON b
);
```

Example of creating a column-oriented table with eviction to external storage:

> **Warning**
>
> Supported only for column-oriented tables. Support for row-oriented tables is currently under development.

```
CREATE TABLE table_name (
    a Uint64 NOT NULL,
    b Timestamp NOT NULL,
    c Float,
    PRIMARY KEY (a, b)
)
PARTITION BY HASH(b)
WITH (
    STORE = COLUMN,
    TTL =
        Interval("PT1D") TO EXTERNAL DATA SOURCE `/Root/s3`,
        Interval("P2D") DELETE
    ON b
);
```

Creating a table filled with query results

> **Warning**
>
> Supported only for column-oriented tables. Support for row-oriented tables is currently under development.

`CREATE TABLE AS` creates a new table table filled with data from query results.

```
CREATE TABLE table_name (
    PRIMARY KEY ( column, ... )
)
WITH ( key = value, ... )
AS SELECT ...
```

Names and types of columns will correspond to the `SELECT` results.
Non-optional columns will also have the `NOT NULL` constraint.

The `CREATE TABLE AS` syntax allows you to specify only the primary key and `WITH` parameters, so when creating a table, specifying column names, secondary indexes, vector indexes, full-text indexes, local bloom indexes, local min_max indexes, and column groups is not supported. The column names and data types of the new table are automatically inherited from the result set of the SELECT query. You can change all of the above using `ALTER TABLE` after creating the table. Additionally, additional parameters are supported.

Considerations

> **Warning**
>
> Rows are overwritten, similar to using `REPLACE INTO`, but the order in which rows are written is unpredictable.
>
> If `SELECT` returns two or more rows with the same primary key value, after the `CREATE TABLE AS` is executed, there will only be one row with that primary key value in the created table. Which record from the `SELECT` was written to the table is undetermined.

- `CREATE TABLE AS` is supported only in the implicit transaction control mode. The table will appear at the specified path already populated.
- `CREATE TABLE AS` can only be a single DML/DDL statement in a query. It's possible to use PRAGMA, DECLARE or named expressions in the same query.
- `CREATE TABLE AS` doesn't cause lock conflicts with other transactions. It doesn't use locks. Reads use a consistent snapshot. Moving or splitting tablets doesn't cause errors.
- `CREATE TABLE AS` allows using column-oriented tables and row-oriented tables in the same query.
- `CREATE TABLE AS` creates a table in the temporary directory `.tmp/sessions`, and after successful data write moves it to the specified location. If the operation is interrupted due to an error, the temporary table is not deleted immediately but remains in the system for some time.

Examples

- Creating a columnar table from query results

```
CREATE TABLE my_table (
    PRIMARY KEY (key1, key2)
) WITH (
    STORE=COLUMN
) AS SELECT
    key AS key1,
    Unwrap(other_key) AS key2,
    value,
    String::Contains(value, "test") AS has_test
FROM other_table;
```

CREATE TRANSFER

Creates a transfer from a topic to a table.

Syntax:

```
CREATE TRANSFER transfer_name
FROM topic_name TO table_name USING lambda
WITH (option = value[, ...])
```

- `transfer_name` — the name of the transfer to be created.
- `topic_name` — the name of the topic containing the source messages for transformation and writing to the table.
- `table_name` — the name of the table where the data will be written.
- `lambda` — lambda-function for message transformation.
- `option` — a command option:
  - `CONNECTION_STRING` — the connection string to the database containing the topic. This is only specified if the topic is located in a different YDB database.
  - Authentication settings for the topic's database (required if the topic is in another database), using one of the following methods:
    - Using a token:
      - `TOKEN_SECRET_PATH` — the secret that contains the token.
    - Using a username and password:
      - `USER` — the username.
      - `PASSWORD_SECRET_PATH` — the secret that contains the password.
    - Using a service agent:
      - `SERVICE_ACCOUNT_ID` — the identificator of the service account.
      - `INITIAL_TOKEN_SECRET_PATH` — the secret that contains the account's token. It is used for initial authentication.
  - `CONSUMER` — the name of the source topic consumer. If a name is specified, a consumer with that name must already exist in the topic, and the transfer will start processing messages from the first uncommitted message in the topic. If no name is specified, a consumer will be added to the topic automatically, and the transfer will start processing messages from the first message stored in the topic. The name of the automatically created consumer can be obtained from the description of the transfer instance.
  - Table write batching parameters let you balance the latency of records appearing in the table against the resources required by the transfer. Batching parameters affect the processing of each topic partition independently. Change batching parameters with caution, as this can either improve or degrade message stream processing speed, and may even lead to a denial of service if the parameters are misconfigured. For example, writing to the table in small batches can overload the table and degrade its performance, while an excessively large batch size can cause the server to run out of available memory.
    - `BATCH_SIZE_BYTES` — the batch size in bytes. Default: 8 MB.
    - `FLUSH_INTERVAL` — the table write interval. Default: 60 seconds. Data is written to the table at this interval, even if the batch has not reached the size specified in the `BATCH_SIZE_BYTES` parameter.

Permissions

The following permissions are required to create a transfer:

- `CREATE TABLE` — to create a transfer instance;
- `ALTER SCHEMA` — to automatically create a topic consumer (if applicable);
- `SELECT ROW` — to read messages from the source topic;
- `UPDATE ROW` — to update rows in the destination table.

Examples

Creating a transfer instance from the `example_topic` topic to the `example_table` table in the current database:

```
CREATE TABLE example_table (
    partition Uint32 NOT NULL,
    offset Uint64 NOT NULL,
    message Utf8,
    PRIMARY KEY (partition, offset)
);

CREATE TOPIC example_topic;

$transformation_lambda = ($msg) -> {
    return [
        <|
            partition: $msg._partition,
            offset: $msg._offset,
            message: CAST($msg._data AS Utf8)
        |>
    ];
};

CREATE TRANSFER example_transfer
    FROM example_topic TO example_table USING $transformation_lambda;
```

Creating a transfer instance from the `example_topic` topic in the `/Root/another_database` database to the `example_table` table in the current database. Before creating the transfer, you need to create the destination table in the current database and create the source topic in the `/Root/another_database` database:

> **Tip**
>
> Before performing the operation, create a secret with authentication credentials to connect, or make sure it exists and you have access to it.

```
$transformation_lambda = ($msg) -> {
    return [
        <|
            partition: $msg._partition,
            offset: $msg._offset,
            message: CAST($msg._data AS Utf8)
        |>
    ];
};

CREATE TRANSFER example_transfer
    FROM example_topic TO example_table USING $transformation_lambda
WITH (
    CONNECTION_STRING = 'grpcs://example.com:2135/?database=/Root/another_database',
    TOKEN_SECRET_PATH = 'my_secret'
);
```

Creating a transfer instance and explicitly specifying the consumer `existing_consumer_of_topic`:

```
$transformation_lambda = ($msg) -> {
    return [
        <|
            partition: $msg._partition,
            offset: $msg._offset,
            message: CAST($msg._data AS Utf8)
        |>
    ];
};
CREATE TRANSFER example_transfer
    FROM example_topic TO example_table USING $transformation_lambda
WITH (
    CONSUMER = 'existing_consumer_of_topic'
);
```

Example of processing a message in JSON format:

```
// example message:
// {
//   "update": {
//     "operation":"value_1"
//   },
//   "key": [
//     "id_1",
//     "2019-01-01T15:30:00.000000Z"
//   ]
// }

$transformation_lambda = ($msg) -> {
    $json = CAST($msg._data AS JSON);
    return [
        <|
            timestamp: CAST(Yson::ConvertToString($json.key[1]) AS Timestamp),
            object_id: CAST(Yson::ConvertToString($json.key[0]) AS Utf8),
            operation: CAST(Yson::ConvertToString($json.update.operation) AS Utf8)
        |>
    ];
};

CREATE TRANSFER example_transfer
    FROM example_topic TO example_table USING $transformation_lambda;
```

Creating a transfer instance and explicitly specifying the batching option:

```
$transformation_lambda = ($msg) -> {
    return [
        <|
            partition: $msg._partition,
            offset: $msg._offset,
            message: CAST($msg._data AS Utf8)
        |>
    ];
};
CREATE TRANSFER example_transfer
